- 25 Circuit Construction
- 26 Test Procedures and Projects
- 27 Troubleshooting and Repair

## **Operating Practices**

- 28 Electromagnetic Interference (EMI)
- 29 Regulations
- 30 References

## **Index**

# Foreword

If you have a '95 *Handbook*, you know it's a tough act to follow. Well, this '96 edition does a great job! This year we set our sights on projects and brought home some real prizes: a 2-m brick amplifier, a multiband QRP transceiver, new keyers and many others. Whether your interest is Power Supplies, Amplifiers, 2-m HTs, Satellites, QRP or Contesting, it's covered here! Let's look at a few highlights:

**Amplifiers**—'96 is the year for 2-m amplifiers: A new "brick" boosts an HT to 25 or 50 W (builder's choice), and a 3CX1200Z7 provides 1.2 kW after only 10 seconds of warm up. Now that's talk power!

**Station Accessories**—An audio break-out box feeds several accessories from a single source. 12-V distribution boxes simplify power hook ups for station (and mobile) accessories. Use the RF Sniffer to help track down sources of RF. Build an audio meter display for both vision impaired and sighted hams. Tips tell how to transport HTs conveniently. Keyers for all! There's an updated Uncle Al's keyer that reads CW too, two more based on the Curtis 8044ABM IC, and a CW send and receive system for IBM compatible computers.

**Satellites**—Learn more about plans for the new Phase 3D bird. Build a "Junk Box" Satellite Receiver or a Mode-S Receive Converter.

**Transceivers**—Check out the new multiband QRP transceiver from Wayne Burdick, N6KR, and the NorCal QRP club: The Sierra can operate from 160 through 10 m with plug-in band modules. There's also a VLF transceiver (no license required!) and a QRP transmitter built from a single IC.

**Filters**—A new DSP filter from Dave Hershberger, W9GR, provides 18 different modes, including DTMF and CTCSS tone decoding.

I hope you enjoy this newest *Handbook*. Planning is already underway for the 1997 edition, so please let us know what you would like to see in future *Handbooks*. It's our goal to produce *Handbooks* that appeal to hams like you!

David Sumner, K1ZZ  
Executive Vice President

Newington, Connecticut  
October 1995

# Preface

A lot of things changed in 1995. If you don't already have that edition, it may take a while to become familiar with the new layout. Here are answers to some questions that may arise:

*Where are the etching patterns?*

They are no longer in the book. When you wish to build a project, simply write, phone, fax or e-mail a request to the Technical Department Secretary at ARRL HQ. We will send you the pattern by mail. This provides you with better quality patterns and all available updates and corrections when you set out to build a project. It tells us which projects are most popular, so we can bring you more projects of that sort.

*Why so **bold**?*

First references to figures and tables appear in boldface type. When you see a figure or table that interests you, scan the text for the bold reference and you can quickly spot the discussion you seek.

*What is in **References**?*

The **References** chapter is a central location for much of the *Handbook* information that is used regularly: filter design tables, schematic symbols, abbreviations, international call-sign prefixes, frequency charts and so on. The **Component Data** chapter retains information that relates directly to components, but some elements (SWR tables, aluminum alloy table, Parts Suppliers List) that do not relate directly to parts have moved to **References**.

The new Address List will be particularly helpful. There you will find contact information for all suppliers (not only parts suppliers) mentioned in this book.

*What if I find a mistake?*

Please let us know about updates and corrections. The feedback form at the back of this book is a convenient way to do this—or just drop a note to the Handbook Editor at ARRL Headquarters.

73,

Robert Schetgen, KU7G  
ARRL Handbook Editor

# **The Amateur's Code**

## **The Radio Amateur is:**

**CONSIDERATE**...never knowingly operates in such a way as to lessen the pleasure of others.

**LOYAL**...offers loyalty, encouragement and support to other amateurs, local clubs, and the American Radio Relay League, through which Amateur Radio in the United States is represented nationally and internationally.

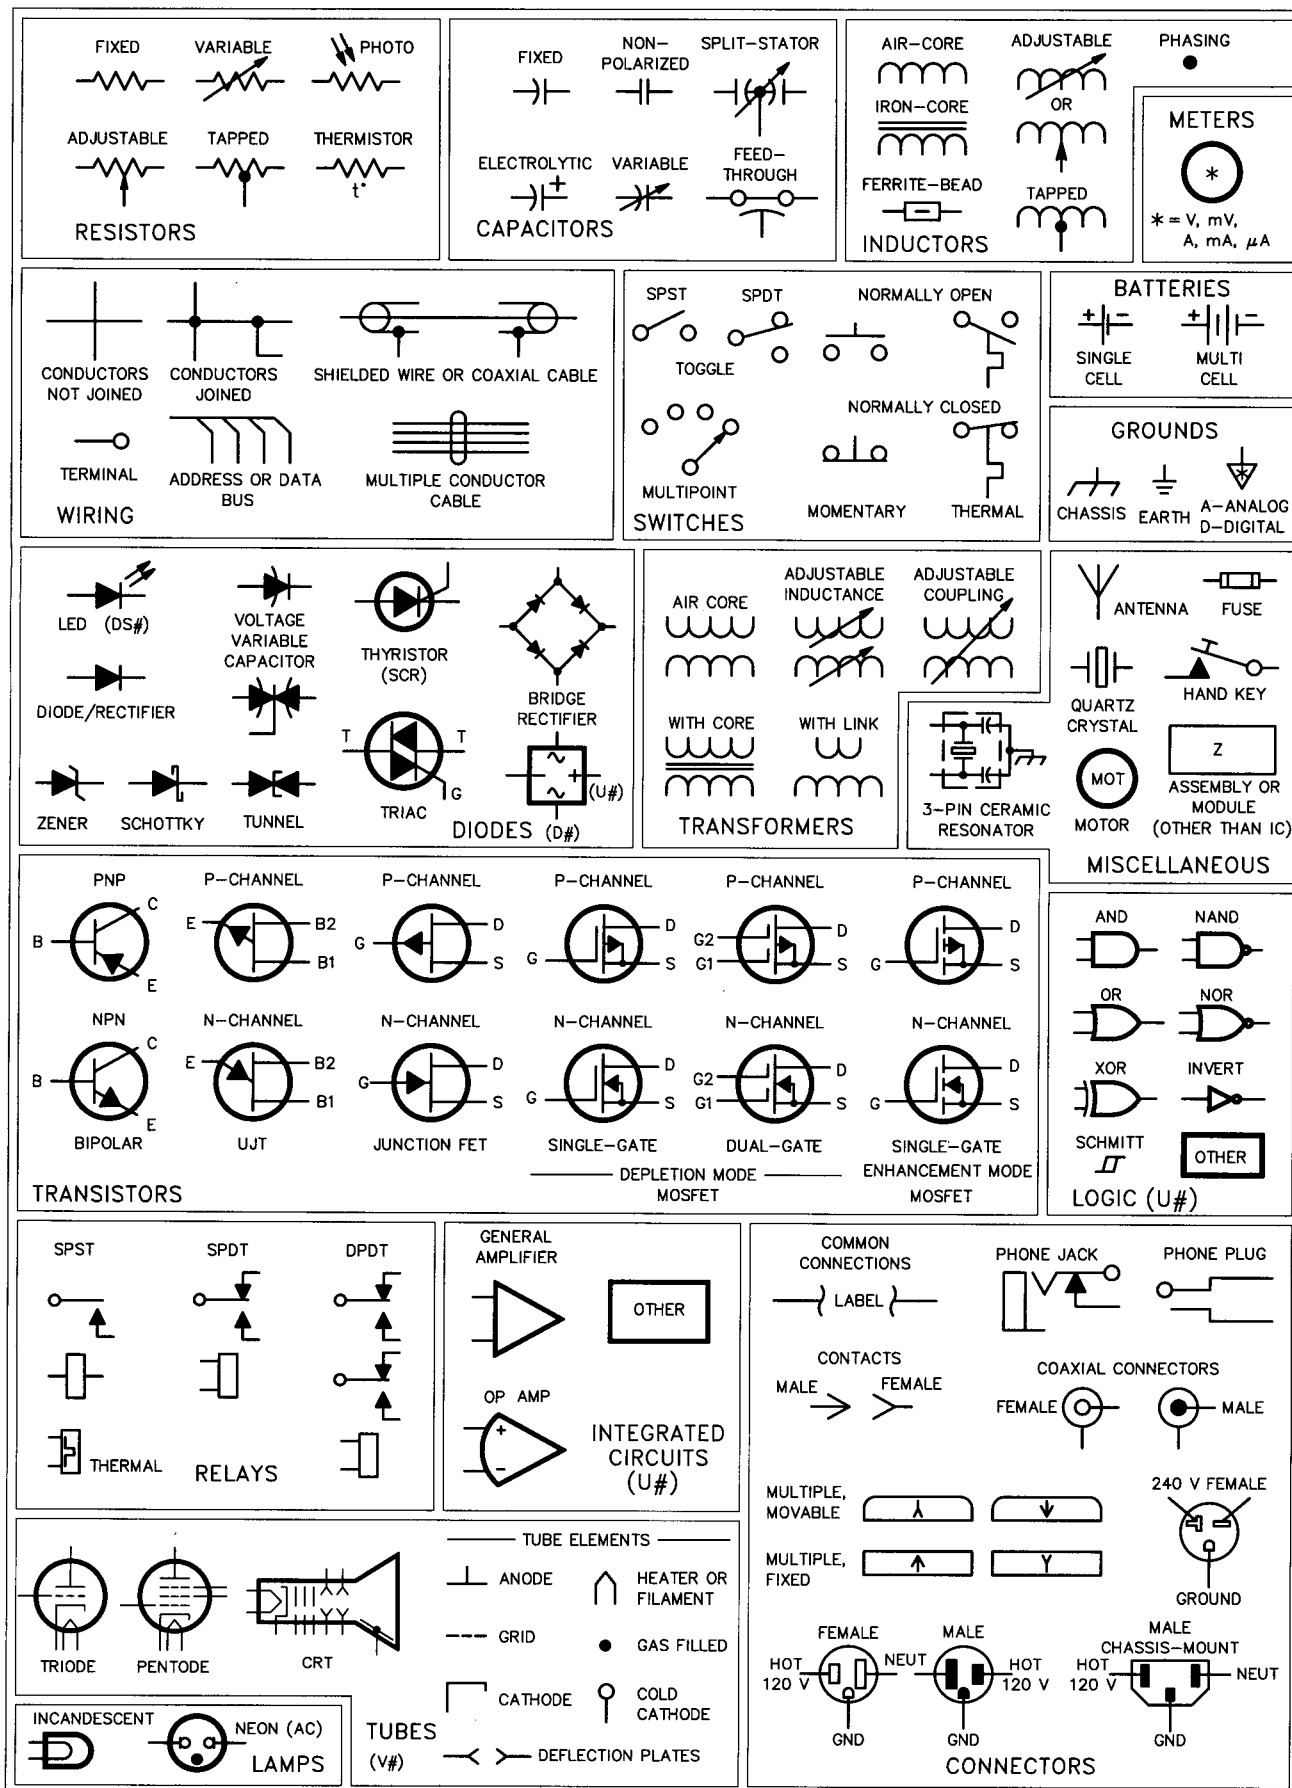

**PROGRESSIVE**...with knowledge abreast of science, a well-built and efficient station and operation above reproach.

**FRIENDLY**...slow and patient operating when requested; friendly advice and counsel to the beginner; kindly assistance, cooperation and consideration for the interests of others. These are the hallmarks of the amateur spirit.

**BALANCED**...radio is an avocation, never interfering with duties owed to family, job, school or community.

**PATRIOTIC**...station and skill always ready for service to country and community.

**—The original Amateur's Code was written by Paul M. Segal, W9EEA, in 1928.**

# What is Amateur Radio?

## 1

**P**eople who pursue the hobby of using a personal radio station to communicate, purely for non-commercial purposes, with other radio hobbyists call it *ham radio* or *Amateur Radio*. They call themselves Amateur Radio operators, ham radio operators or just plain "hams."

You already know a little about the hobby—hams communicate with other

hams, around the block, on a distant continent—or from an orbiting space station! Some talk via computers, others prefer to use regular voice communications, and some use the efficient and enjoyable 19th century technology known as Morse code. Some hams help save people's lives by handling emergency communications following a natural disaster or other emergency. Some become close friends with

the people they talk to on the other side of the globe—then make it a point to meet one or more of them in person. Some can take a bag full of electrical parts and turn it into a station accessory that improves their station's reception of distant radio signals.

This chapter, by Rosalie White, WA1STO, covers the basics—what hams do, and how they do it.

**A** Youngsters enjoy putting together a simple but effective dipole antenna for the amateur high-frequency (HF) bands. Beams and verticals are the most popular types of antennas for the very-high frequency (VHF) and ultra-high frequency (UHF) bands. (photo courtesy L. Marks)

**B** Many hams can repair and modify their own equipment. (photo courtesy N4PDY)

**C** Computers and ham radio: an unbeatable combination. Hams use computers to enhance their operating enjoyment in any number of ways. (photo courtesy W0AIH)

**D** A young scout enjoys his first taste of ham radio. (photo courtesy W3FTG)

## HOBBY OF DIVERSITIES

You can't imagine all of the unusual, interesting things you can do as an Amateur Radio operator. What types of people will you meet as a ham? If you walk down a city street, you'll pass men and women, girls and boys, and people of all ages, ethnic backgrounds and physical abilities. They're office workers and students, nurses and mail carriers, engineers and truck drivers, housewives and bankers. Any of them might be a ham you will meet tonight on your radio.

If you drive your car on the interstate this weekend, you'll see people on their way to a state park, a scout camp, a convention, an airport or a computer show. The young couple going to the park to hike for the day have their hand-held ham radio transceivers in their backpacks. When they stop on a scenic hilltop for a rest, they'll pull out their radios and see how far away they can communicate with the radio's 3 watts of power. And, the radios will be handy just in case they break down on the road or lose the hiking trail.

The father and son on their way to scout camp will soon be canoeing with their scout troop. After setting up camp, they'll get out a portable radio, throw a wire antenna over a branch, and get on the air. Aside from the enjoyment of talking with other hams from their campsite, their radios give them the security of having reliable communications with the outside world, in case of emergency.

The family driving to the ham radio convention will spend the day talking

with their ham friends, including two they've never met but know quite well from talking to them on the air every week. They will also look at new and used radio equipment, listen to a speaker talk about the latest ways computers can be used to operate on the Amateur Radio bands, and enjoy a banquet talk by a NASA astronaut who is also a ham radio operator.

The couple on the way to the airport to take a pleasure flight in their small plane have packed their hand-held ham radios in their flight bags. Once they're airborne, they'll contact hams on the ground all along their flight path. Up at 5,000 feet, they can receive and transmit over much greater distances than they can from the ground. Those they contact will enjoy the novelty of talking to hams in a plane. The radios are an ideal means of backup communications, too.

The two friends on their way to the computer show are discussing the best interface to use between their computers and their ham radios for a mode of operating called packet radio. They're looking forward to seeing a number of their ham friends who are also into computers.

What other exciting things can you look forward to on the ham bands? You might catch yourself excitedly calling (along with 50 other hams) a Russian cosmonaut in space or a sailor on the Coast Guard's tall ship *Eagle*. You could be linked via packet radio with an Alaskan sled-dog driver, a rock star, a US legislator, a major league baseball player, a ham operating the Amateur Radio station aboard the

ocean liner *Queen Mary*, an active-duty soldier, a king—or someone who is building the same power supply that you are from a design in this *ARRL Handbook*.

On the other hand, a relaxing evening at home could find you in a friendly radio conversation with a ham in Frankfort, Kentucky, or Frankfurt, Germany. Unlike any other hobby, Amateur Radio knows no country boundaries and brings the world together as good friends.

### All Types of Physical Abilities

People who don't get around as much as they'd like to, find the world of Amateur Radio a rewarding place to make friends — around the block

or around the globe. Many hams with and without certain physical abilities belong to the HANDI-HAM System, an international organization of radio amateurs who bring ham radio to all individuals. HANDI-HAM members live in every state and many countries around the world, and are ready to help in whatever manner they can. The HANDI-HAM System provides study materials and aids for persons with physical disabilities. Local HANDI-HAMs will assist you with studies at home. Once you receive your license, the Courage HANDI-HAM System may lend you basic radio equipment to get you started on the air.

This QSL card (a postcard that serves as a confirmation of a ham radio contact) is from the ham station aboard a tourist attraction in Long Beach harbor — the ocean liner *Queen Mary*.

Although talking with astronauts isn't exactly an everyday ham radio occurrence, more and more hams are doing just that, as many NASA astronauts are ham radio operators. And the Russian space station *Mir* almost always has a cosmonaut-ham onboard who enjoys chatting with ground-based hams.

## TECH OR NOVICE: IT'S YOUR CHOICE

When you're ready to start, you can choose whether or not you want to earn an Amateur Radio license that requires knowledge of the Morse code. Most beginners start with either the *Novice* or the *Technician* license.

The one with a Morse code requirement, the Novice, offers communications with the world, some using voice modes but the majority via Morse code. You'll also be able to talk on some ham frequencies that cover short distances.

With a Technician license, you have use of many frequency bands, including the popular VHF 2-meter band. Technicians can also use the nationwide network of Amateur Radio *repeaters* that extend the distances covered by hand-held and mobile VHF and UHF radios. Technicians also communicate through *satellites* or *packet radio* networks.

To earn the Novice license, you'll pass an examination that covers rules and regulations that govern the airwaves, operating procedures and basic electricity plus a Morse code test at 5 words per minute. You can study all of the questions that could possibly be on the written examination from available study guides such as those offered by the American Radio Relay League.

To earn the Technician license, you'll pass the Novice written exam plus an exam that covers rules and regulations, operating procedures and a bit more electrical theory. There is no Morse code exam for the Technician license. The Technician Plus license, earned by passing the Novice and Technician written tests as well as the 5-wpm Morse code test, allows operation on the VHF and UHF bands as well as the Novice HF bands.

## WHAT'S IN A CALL SIGN?

When you earn your Amateur Radio license, you receive a unique *call sign*. Many hams are known by their call signs (and not necessarily by their names!). All hams get a call sign, a set of letters and numbers, assigned to them by the Federal Communications Commission (FCC). No one else "owns" your call sign—it's unique. Your Amateur Radio license with your unique call sign gives you permis-

sion to operate your Amateur Radio station on the air. US call signs begin with W, K, N or A, with some combination of letters and numbers that follow. You can tell what country issued a ham's call sign by the *prefix*—the letters before the number. In addition, the number in the middle of the call sign indicates the location within the country. In the US, for example, call signs that have a 9 in them indicate that the ham lived in the Midwest when the license was issued, and call signs with the number 1 indicate New England.

## HAM RADIO ACTION

Amateur Radio and public service go together. On a warm early-summer weekend, hams can be found directing radio communications in the aftermath of a train derailment—a simulated one, that is—to help prepare for a real emergency. Others provide radio communications for a walk-a-thon. Still others hone their communications skills by setting up a station outdoors, away from electrical power. This largest public-service-related ham activity is called *Field Day*.

## Biking and Cruising

Hams even operate their radios while riding on bicycle treks. They easily carry their lightweight hand-held radios in their packs, and can pull them out quickly, if needed. Or if they're really serious they pull along a small trailer with a sleeping bag, food and water supplies and a ham radio that they can set up in the evenings.

Ham radio manufacturers have begun offering hams adventures on ships that sail in the picturesque Caribbean. They set

## Field Day: Ham Radio Alfresco

If you know any hams, they've probably talked about Field Day. On the fourth full weekend each June, amateurs from all over the US and Canada, and in other parts of the world as well, take their equipment into the great outdoors to operate away from power mains. The idea is to practice setting up and operating under emergency conditions. Participants set up efficient temporary stations and contact as many other Field Day participants as possible. Although it is a practice effort for future serious situations, Field Day is, above all, fun; you can't help but enjoy the challenge of working cooperatively with your group to compete against perhaps 100,000 other hams who are also braving the elements to attain the same goal!

Field Day is a disaster-preparedness exercise that's fun for all ages. (photo courtesy KD1AP)

Hand-held radios are ideal for all outdoor activities. This one is so small it's almost hidden in the operator's hand. (photo courtesy KB9HKB)

This ham operated a contest while on a family vacation in the Bahamas. Hams often enjoy operating while on vacations or business trips.

up radio stations for you to operate at various exotic ports on these expeditions. You get to operate the radios, relax luxuriously on the open seas, meet new friends from all over the globe and see new places. Although not all trips to exotic locales to operate ham radio stations, which hams call *DXpeditions*, are this glamorous, many hams enjoy activating a rare country to provide contacts for their fellow hams around the world.

### Nets: Scheduled Get-Togethers

If you'd like to find other hams with vocational or avocational interests like yours (such as chess, gardening, rock climbing, railroads, computer programming or teaching), you'll soon learn about *nets*. A net forms when hams with similar interests get together on the air on a regular schedule. You can find your special interest—from the Armenian Amateur Radio and Traffic Net to the Zenith National Net—listed in *The ARRL Net Directory* published annually.

### Awards and Contests: Competitive Fun

If you're competitive by nature, you'll want to explore ham radio awards and contests. These activities recognize your ability to contact other hams under published guidelines. In the ARRL DX Contest, for example, you'll try to contact as many DX (foreign) stations as possible over a weekend. Experienced hams with top-notch stations have worked more than 100 different countries during a single DX Contest weekend!

These Japanese hams are operating a contest. Ham radio contests provide a chance to test your station's efficiency and your operating skill against those of other participants.

Awards you can earn include *Worked All States*, earned by communicating with a ham in every US state, *Worked All VE*, earned by contacting hams in every Canadian province and the *DX Century Club*, for working stations in 100 or more different countries.

In an outdoor orienteering competition, "fox-hunters" (also called "bunny-hunters") track and locate hidden transmitters by car or on foot. This activity also has its

### Support for Expeditions

The first ham radio operator to cooperate in an expedition was League member Don Mix, 1TS.

With his radio equipment in tow, he accompanied Donald B. MacMillan to the Arctic on the schooner *Bowdoin* in 1923. In subsequent years, hams assisted with perhaps 200 other voyages and expeditions.

This tradition continues to this day. In 1988, members of a joint Soviet/Canadian expedition crossed the North Pole on skis. Amateur Radio operators provided daily communications, and the OSCAR 11 satellite's "talking" computer relayed position information to the expedition every 100 minutes. In 1993, hams tracked the progress and breakdowns of solar vehicles in "Sunrayce '93," during which solar-powered cars raced from Texas to Minnesota.

serious side: Skills learned in tracking the "fox" come in handy when there's a suspected pirate (unlicensed station) in the neighborhood.

### QRP: Talk to the World with 5 Watts of Power

For a real challenge, try operating *QRP* — using low-power. Some enjoy operating with only 1 watt, or even less. It's certainly a challenge, but with decent antennas and skillful operating, QRP enthusiasts can be heard around the world. One of the best reasons for operating QRP is that equipment is lightweight, inexpensive and easy to build. Some hams use nothing but "home-brew" equipment.

### Unusual Modes

If computers are your favorite aspect of today's technology, you'll soon discover that you can connect your computer and ham radio equipment and operate on such digital modes as *packet radio* and *AMTOR*. With packet, you can leave messages that other packet enthusiasts will pick up and answer later. One popular packet activity is the *DX PacketCluster*, which allows hams to get real-time information about where and when rare foreign stations can be found on the bands. Another is satellites: A series of packet radio satellites provides long-distance computer-based communications with low power. AMTOR is a popular digital mode used on the amateur high-frequency (HF) bands.

Computers also can help you practice taking ham radio license examinations or improve your Morse code abilities. ARRL, and others, offer software especially designed to help you pass ham radio exams. As you become more experienced, you'll discover software for any number of ham radio applications, from keeping track of the stations you've contacted during a contest to designing the best antenna for your location. Hams also use software to download pictures transmitted by weather satellites.

### Enhancing Radio Signals

Radio signals normally travel in straight lines, which limits their range. But hams have found some ingenious ways of extending the distance and improving the quality of the signals they transmit. High-frequency (HF) radio waves can be refracted or bent by a layer of the atmosphere called the ionosphere. In this way, signals are returned to Earth, often after several "hops." This *ionospheric propagation* of radio signals allows worldwide communication on the HF bands. Hams have also learned how to bounce signals

Joanne, KA1SIP, of West Hartford, Connecticut, operates a mode called packet radio through a Japanese ham radio satellite. (photo courtesy K1CE)

## Hams at the Forefront

Over the years, the military and the electronics industry have often drawn on ham ingenuity to improve designs or solve problems. Hams provided the keystone for the development of modern military communications equipment, for example. In the 1950s, the Air Force needed to convert its long-range communications from Morse code to voice, and jet bombers had no room for skilled radio operators. At the time, hams communicated by voice at great distance with both home-built and commercial single-sideband (SSB) equipment. Air Force Generals LeMay and Griswold, both radio amateurs, hatched an experiment that used ham equipment at the Strategic Air Command headquarters in Omaha and an airplane traveling around the world. They found that the equipment would need only slight modification to meet Air Force needs. By applying ham radio technology to a military problem, the two generals saved the government millions of dollars in research and development costs.

communications even when power is knocked out. If need be, hams can make and install antennas "on the spot" from whatever materials and supports they find available.

Working with emergency personnel such as police and fire departments, the Red Cross and medical personnel, ham volunteers provide any communications necessary. Hams can handle communications between agencies whose normal radios are incompatible with one another, for example. The ability of radio amateurs to help the public in emergencies is one of the reasons Amateur Radio has survived and prospered since the early days of the 20th century.

## Community Events

To keep their emergency-preparedness skills honed, and to help their community, hams enjoy assisting with communications to aid the public at any number of events and activities. Hams volunteer to provide communications for walk-a-thons, bike races, parades and other community events. In fact, it's rare to see a large community event that doesn't make use of public-spirited ham radio operators.

off the moon, airplanes and even meteor trails! Repeaters, located on hilltops or on tall buildings, strengthen signals and transmit them much farther than would be possible without repeaters.

## Helping out in Emergencies

When commercial communications services are disrupted by power failures or damage that accompanies natural disasters such as earthquakes, floods and hurricanes, Amateur Radio operators are often first at the scene. Battery-powered equipment allows hams to provide essential

**Ham equipment can be any size and complexity. This home-built transceiver puts out a whopping 1/2 watt of power. (photo courtesy KA0NDS)**

## Build It Yourself

Another favorite activity hams enjoy is building their own radio equipment. Hams proudly stay at the forefront of technology, continually being challenged to keep up with advances that could be applied to the hobby. Many have an incessant curiosity and an eagerness to try new techniques. They also are constantly driven to find ways to allow the radio frequency bands to support more users, since some portions of certain bands are very popular and can be crowded.

The projects you'll find in this book

**Hams of all ages and backgrounds enjoy learning the skill of soldering, especially when the result is a useful ham radio accessory. (photo courtesy Raiche Photography, Manchester, NH)**

provide a wide variety of equipment and accessories that make ham radio more convenient and enjoyable. Many manufacturers provide parts kits and etched circuit boards to make building even easier.

## Hams in Space

In 1983, the first ham/astronaut made history by communicating with ground-based hams from the Space Shuttle *Columbia*. On that mission, Payload Specialist Owen Garriott, whose Amateur Radio call sign is W5LFL, took along a hand-held amateur transceiver and placed a specially designed antenna in an orbiter window. It was the first time ham radio operators throughout the world were to experience the thrill of working an astronaut aboard an orbiting spacecraft. In 1985, Mission Specialist Tony England, W0ORE, transmitted slow-scan television (SSTV) via Amateur Radio while orbiting the Earth from the Shuttle *Challenger*. He named the payload SAREX, for Shuttle Amateur Radio Experiment.

It wasn't long before NASA was routinely scheduling SAREX missions. In 1991, each of the five members of a shuttle crew had earned an Amateur Radio license. NASA promotes ham radio activity aboard shuttle spacecraft because of its proven public relations and educational value. It's also a reliable means of backup communication. During 1995, five shuttle crews requested that NASA include a SAREX payload on their flights. As for the future, hams are making plans for a ham radio station aboard a manned space station.

## GETTING STARTED

Now that you have an idea of what hams do, you're probably asking, "Okay, how do I get started?" The first step is to earn a license.

**Ham radio has saved many lives over the years. Rescue workers can use their hand-held radios to relay messages from even the most remote locations. (photo courtesy N0CQW)**

## OSCARs: The Ham Satellites

You can experience the thrill of hearing your own signal returned from space by an orbiting "repeater in the sky" — a ham radio satellite. Or marvel at the clear pictures of the Earth you receive from the camera aboard another ham satellite. Hams regularly use Amateur Radio satellites, called OSCARs (for *Orbiting Satellites Carrying Amateur Radio*). VHF and UHF signals from a ham radio transceiver normally don't travel much beyond the horizon. But if you route your signal through an orbiting satellite, you can make global radio contacts on VHF and UHF.

In 1990, a series of small Amateur Radio satellites, called Microsats, were launched. One, called WEBERSAT, transmits image data that you can process into pictures using your personal computer and special software. Another is a packet radio satellite that allows messages from Earth to be stored and forwarded back down to Earth when the spacecraft is within range of the designated station.

Hams are experimenting with low-orbit global communication satellites that can store their real-time radio messages for delivery at a later time. This would allow hams to communicate with other hams in developing countries that can't afford expensive channels on geostationary satellites. Hams from around the globe are working together to design, build and launch an exciting new satellite that is the most ambitious amateur satellite project ever conceived. It will use the latest electronics technology to provide thousands of hams with reliable and pleasurable worldwide communications on several radio frequencies up through the microwave bands.

Does all of this sound futuristic or beyond your skills? It shouldn't. All it takes is a Technician license to enjoy this exciting ham radio technology.

These California high school students learned how to operate through, and built models of, orbiting Amateur Radio satellites. (photo courtesy KF6PJ)

Astronaut Mike Foale, KB5UAC, operated a ham radio transceiver aboard the Space Shuttle *Discovery* in 1995. (photo courtesy NASA)

The crew of the Space Shuttle *Endeavour* sent this QSL card to those they contacted during their 1994 mission.

There are six classes of license, each with increased privileges, issued by the Federal Communications Commission (FCC). In this way, the hams are encouraged to improve their knowledge and skill. Exams are given by local ham volunteer examiners. Questions that appear on written exams are published in study guides. The exams consist of a certain number of questions from this question pool.

### Study Guides

You can prepare for the exams on your own or in a class. Help is available at

every step. The ARRL publishes complete study materials for all classes of Amateur Radio licenses. Contact the ARRL Educational Activities Department (the address and phone number are at the end of this chapter) for a free package of information. It contains everything you need to get started: a list of nearby Amateur Radio clubs, Amateur Radio instructors who have registered with ARRL, and local volunteer examiners. The package also includes a description of what frequencies Novices and Technicians can operate on, and the most popular activities to take part

Study guides such as ARRL's *Now You're Talking!* make it easy to prepare for the exam leading to a ham radio license. ARRL and other publishers offer study guides for all classes of amateur license. (photo courtesy L. Marks)

in. It also has information about the latest versions of ARRL study guides and videotape licensing courses.

ARRL's book for beginners, *Now You're Talking!*, includes the complete, up-to-date question pool with the correct answers, as well as clear explanations. You'll also find tips for how to choose your equipment and put together your ham radio station, how to build and install simple, inexpensive antennas and much more.

ARRL's *Technician Class Video Course* is five hours of interesting videotape. The three tapes come with a study guide and optional exam review software. ARRL licensing videotapes come with a money-back guarantee: pass your Technician exam within a year or get a full refund.

All ARRL study guides assume no prior electronics background. Children as young as six years old have passed ham radio exams!

## Elmers

Many ham radio operators learn how to get on the air through the buddy system. An experienced ham, called an "Elmer," teaches one or more newcomers about Amateur Radio on a one-to-one basis.

Elmering became a ham tradition many years ago. It was first documented in ARRL's monthly magazine, *QST*, in a story that was meant to be a public thank you from an appreciative student whose mentor's name was Elmer. Elmers are there for you as you study for your exam, buy your first radio and set up your station. Many watch with pride as their newly licensed friends make their first on-the-air contacts.

## Putting Together a Station

As with any other hobby, you can have fun with ham radio no matter how large (or small) your budget. You can start with a hand-held transceiver that fits in your pocket or purse, and take it along when you hike, canoe or aviate. Or you can fill your "radio shack" with the latest and fanciest radios technology offers and money can buy, and talk to people in all corners of the world. You can build a simple, inexpensive wire antenna to string between two trees in your backyard, or install giant towers, with arrays of phased beam antennas on top.

Accessories and equipment for your ham radio station come in all price ranges. *QST* contains display advertisements for new ham gear plus columns of classified ads for previously

held transceivers and used HF radios for less than \$300. Many hams start with a radio that costs between \$300 and \$600. Antennas and other gear can add appreciably to the cost, but less-expensive alternatives, such as putting together your own antenna or low-power transceiver, are available.

## HAMS AS WORLD CITIZENS

When you become an Amateur Radio operator, you become a "world citizen"—you join a group of people who have

Ham radio fosters international understanding in countless ways. Gaynell, an American ham, enjoyed her visit to the ham radio station of an on-the-air friend in the Ukraine. (photo courtesy KK4WW)

Resourceful hams have found that a ham station can fit comfortably in a corner of a room. If space is available, setting up your radio shack in a place that is separated from others in the household usually works best.

owned items. The ARRL Educational Activities Department can provide you with information about where to find ham radio equipment.

## Used Versus New

Hams are continually upgrading their stations, so you can always find a ready supply of good previously owned Amateur Radio gear. You can find new hand-

earned the privilege of talking to other hams around the corner or around the world. Hams have a long tradition of spreading international goodwill. One way hams do this is to assist with getting needed medical advice or medicine to developing countries. Another is by learning about the lives and cultures of those they contact. On the other hand, it's a good idea to avoid sensitive political or ethical issues.

Although English is the standard language on the ham bands, English-speakers will make a good impression on hams in foreign countries if they can speak a few words of the other person's language—even if it's as simple as *danke* or *sayonara*.

## International Amateur Radio

Hams in other countries have formed national organizations, just as US hams

organized the American Radio Relay League. These sister societies work together to have a united voice in international radio affairs, such as when governments get together to decide how radio frequencies will be divided among its various users. The International Amateur Radio Union (IARU), composed of more than 100 national Amateur Radio societies, works to advance the cause of Amateur Radio at the international level. ARRL works closely with other IARU societies to help protect the amateur frequencies.

## THE ADMINISTRATORS: ITU AND FCC

The laws of physics allow for a limited spectrum of radio frequencies. These radio frequencies must be shared by many competing radio services: broadcasters, land mobile, aeronautical and marine, to name a few.

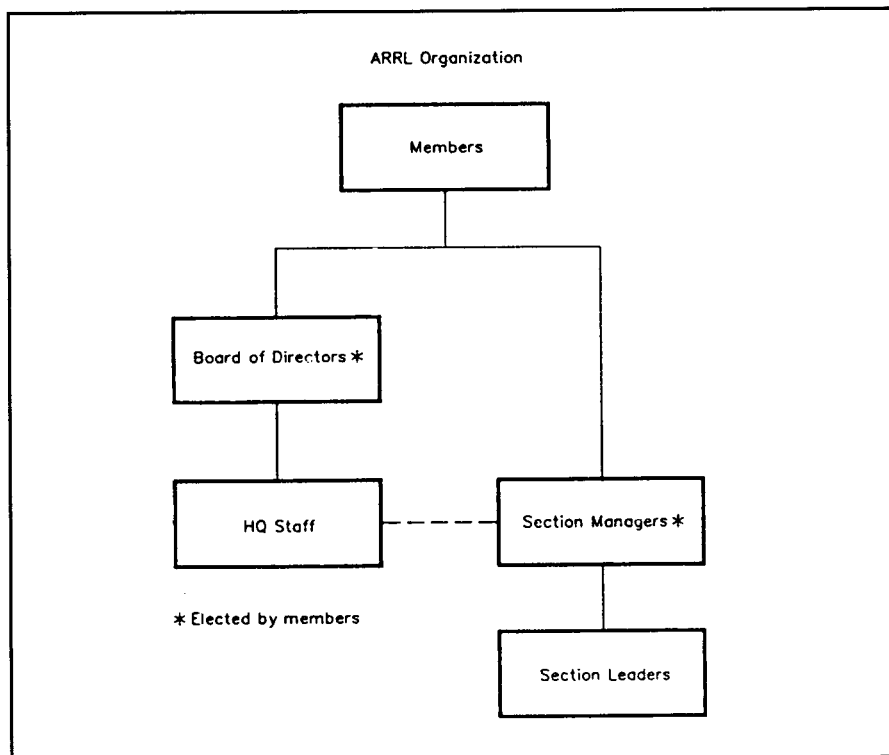

The International Telecommunication Union (ITU), an agency of the United Nations, allocates these frequencies among the many services that use them. With its long tradition of public service and technological savvy, ham radio enjoys the use of many different frequency bands.

In the US, a government agency, the FCC, regulates the radio services, including Amateur Radio. The section of the FCC Rules that deals with Amateur Radio is Part 97. Hams are expected to know the important sections of Part 97, as serious violations (such as causing malicious interference or operating without the appropriate license) can lead to fines and even imprisonment! Aside from writing and enforcing the rules governing Amateur Radio, the FCC also assigns call signs and issues licenses to those who have earned them.

## THE ARRL

Since it was founded, in 1914, the League has grown and evolved along with Amateur Radio. The ARRL Headquarters building and Maxim Memorial Station, W1AW, are in Newington, Connecticut, near Hartford. Through its network of dedicated volunteers and a professional staff, the ARRL promotes the advancement of the amateur service in the US and around the world.

The League operates as a nonprofit, educational and scientific organization dedicated to the promotion and protection of the many privileges that ham radio operators enjoy today. Of, by and for the radio amateur, ARRL numbers within its ranks the vast majority of active amateurs in North America. Around 170,000 licensed ham radio operators and unlicensed persons with an interest in ham

**Fig 1 – Full Members of the ARRL control it through an elected Board of Directors. Volunteers (all positions except for HQ staff) accomplish much of the work.**

**The ARRL Maxim Memorial Station in Newington, Connecticut, is considered the most famous Amateur Radio station in the world. (photo courtesy W2ABE)**

# The Amateur's Code

## THE RADIO AMATEUR IS:

**CONSIDERATE**...never knowingly operates in such a way as to lessen the pleasure of others.

**LOYAL**...offers loyalty, encouragement, and support to other amateurs, local clubs, and the American Radio Relay League, through which Amateur Radio in the United States is represented nationally and internationally.

**PROGRESSIVE**...with knowledge abreast of science, a well-built and efficient station and operation above reproach.

**FRIENDLY**...slow and patient operating when requested; friendly advice and counsel to the beginner; kindly assistance, cooperation and consideration for the interests of others. These are the hallmarks of the amateur spirit.

**BALANCED**...radio is an avocation, never interfering with duties owed to family, job, school, or community.

**PATRIOTIC**...station and skill always ready for service to country and community.

—The original Amateur's Code was written by Paul M. Segal, W9EEA, in 1928.

**Hams have adopted many special radio traditions over the years. In 1928, Paul M. Segal, W9EEA, composed an Amateur's Code. Ham radio operators proudly uphold The Amateur's Code today, just as in the past.**

radio are members. Licensed hams join as Full Members, while unlicensed persons become Associate Members who have all membership privileges except for voting in ARRL elections. Anyone who has an interest in Amateur Radio has a place in the League.

The ARRL volunteer corps is called the Field Organization. Working at the state and local level, these volunteers carry out the League's work of furthering Amateur Radio. They organize emergency communications in times of disaster and work with agencies such as the Red Cross, the National Weather Service and Civil Air Patrol. Other field volunteers keep state and local government officials abreast of the good that ham volunteers are doing at the state and local level.

## Membership Services

When you join ARRL, you add your

voice to those who are most involved with ham radio. The most prominent benefit of League membership is *QST*, the premiere Amateur Radio magazine. *QST* has Amateur Radio news you'll want to know and need to hear. You'll also find a wide range of articles, columns and features—projects to build, announcements of upcoming ham radio activities, reviews of the latest equipment, reports on the role hams are playing in emergencies, and much more.

But being an ARRL member is far more than a subscription to *QST*. The League represents your interests to the FCC and Congress, sponsors contests and other operating events, and offers membership services at a personal level. These include

- the QSL bureau (which lets you exchange postcards with hams in foreign countries as a confirmation of your contacts with them)

- the volunteer examiner program
- the Technical Information Service (which provides answers to your questions about any technical subject in Amateur Radio)
- low-cost equipment insurance and much more.

## School Teachers and Volunteer Instructors

The Educational Activities Department (EAD) at ARRL provides teachers with materials for using Amateur Radio in their schools. Thousands of teachers have found that Amateur Radio is an ideal way to provide hands-on, intercurricular learning, while enticing students to become interested in science and technology. EAD also has materials, including newsletters and instructor guides, to help hams who wish to start teaching Amateur Radio licensing classes.

## WELCOME!

For answers to any questions you may have about Amateur Radio, write or call ARRL Headquarters. See Resources, below, for contact information.

**A ham teacher can influence students toward a career in electronics, or a great hobby—or both. (photo courtesy Susan Houghtaling)**

# Glossary

*Note:* Words in **boldface italics** have separate entries in the Glossary.

- Amateur Radio**—A radiocommunication service for the purpose of self-training, intercommunication and technical investigations carried out by amateurs, that is, duly authorized persons interested in radio technique solely with a personal aim and without pecuniary interest. (*Pecuniary* means payment of any type, whether money or other goods.) Also called ham radio.
- Amateur Radio operator** — A person holding a license to operate an amateur station.
- Amateur Radio station** — A station licensed in the amateur service, including necessary equipment, used for amateur communication.
- Amateur service** — Another name for *Amateur Radio*; one of the radiocommunication services regulated in the US by the Federal Communications Commission (*FCC*).
- Amateur television (ATV)** — A mode of operation that Amateur Radio operators can use to exchange pictures from their radio stations.
- American Radio Relay League (ARRL)** — The membership organization for Amateur Radio operators in the US.
- AMSAT** — An abbreviation for the *Radio Amateur Satellite Corporation*.
- Band** — A range of frequencies. Hams are authorized to transmit on several different bands.
- Beam antenna** — A type of ham radio antenna that can be pointed in different directions.
- Bunny hunt** — Another name for *fox hunt*.
- Call sign** — A series of unique letters and numbers assigned to a person who has earned an Amateur Radio license.
- Contact** — A two-way communication between Amateur Radio operators.
- Contest** — An Amateur Radio activity in which hams and their stations compete against others to try to contact the most stations within the designated time period.
- Courage HANDI-HAM System** — A membership organization for Amateur Radio enthusiasts with various physical abilities.
- CW** — Abbreviation for *continuous wave*; another name for *Morse code* telegraphy.
- Digital communications** — Computer-based communications modes, such as *packet radio*.
- Digital signal processing (DSP)** — A recently developed technology that allows software to replace electronic circuitry.
- Dipole antenna** — A popular type of wire antenna often used on the high-frequency amateur bands.
- DX** — A ham radio abbreviation for *distance* or *foreign countries*.
- DXCC** — A popular ARRL award earned for contacting Amateur Radio operators in 100 different countries.
- DX PacketCluster** — A method of informing hams, via their computers, about the activities of stations operating from unusual locations.
- DXpedition** — A trip to an unusual location, such as an uninhabited island, where hams operate for a designated period of time. DXpeditions provide sought-after contacts for hams who are anxious to contact that rare location.
- Educational Activities Department (EAD)** — A department at ARRL Headquarters that helps newcomers get started in ham radio and provides materials to hams who want to help newcomers.
- Elmer** — A traditional term for someone who enjoys helping newcomers get started in ham radio on a one-to-one basis.
- Emergency communications** — Amateur Radio communications that take place during a situation where there is danger to lives or property.
- Fast-scan television (FSTV)** — A mode of operation that Amateur Radio operators can use to exchange live TV images from their stations.
- Federal Communications Commission (FCC)** — The government agency that regulates Amateur Radio in the US.
- Field Day** — A popular Amateur Radio activity during which hams set up radio stations outdoors and away from electrical service to simulate emergency conditions.
- Field Organization** — A cadre of ARRL volunteers who perform various services for the Amateur Radio community at the local level.
- FM (frequency modulation)** — An operating *mode* commonly used on ham radio *repeaters*.
- Fox hunt** — A competitive ham radio activity in which ham radio operators track down a transmitted signal. Also called *bunny hunt*.
- Ham band** — A range of frequencies on which amateur communications are authorized.
- Ham radio** — Another name for *Amateur Radio*.
- Ham radio operator** — A person holding a written authorization to operate an amateur station. An *Amateur Radio operator*.
- High frequencies (HF)** — The radio frequencies from 3 to 30 MHz.
- International Amateur Radio Union (IARU)** — The international organization made up of national Amateur Radio organizations such as the ARRL.
- International Telecommunication Union (ITU)** — An agency of the United Nations that allocates the radio spectrum among the various radio services.
- Microsat** — A series of small Amateur Radio satellites.
- Mode** — A type of ham radio communication; examples are *frequency modulation (FM)*, *slow-scan television (SSTV)* and *packet radio*.
- Morse code**—A communications mode transmitted by on/off keying of a radio-frequency signal. Hams use the *international Morse code*, which differs from American (telegraph) Morse.
- Net** — An on-the-air meeting of Amateur Radio operators at a particular time, day and radio frequency.
- Novice license** — One of the two entry-level Amateur Radio licenses. Allows the licensee to use Morse code on four HF (long-distance) bands, code and voice on one HF band, plus all authorized modes on a VHF and a UHF band.
- OSCAR** — An acronym for *Orbiting Satellite Carrying Amateur Radio*, a series of Amateur Radio satellites designed and built by the international ham radio community. Also see *AMSAT*.
- Packet radio** — A computer-to-computer communications mode in which information is broken into short bursts. The bursts (packets) also contain addressing and error-detection information.
- Payload** — A package taken onboard a space shuttle, such as the Shuttle Amateur Radio Experiment (*SAREX*), which allows shuttle astronaut/hams to communicate with other hams from space.
- Public service** — Activities involving Amateur Radio that hams perform to benefit their communities.
- QRP** — An abbreviation for low power.
- QSL bureau** — A system of forwarding *QSL cards* to and from ham radio operators.
- QSL cards** — Postcards that serve as a confirmation of communication between two hams.

**QST** — The premiere Amateur Radio monthly magazine, published by the *American Radio Relay League*. *QST* means "calling all radio amateurs."

**Radio Amateur Satellite Corporation (AMSAT)** — An international membership organization that designs, builds and promotes the use of Amateur Radio satellites.

**Radio frequencies (RF)** — The range of frequencies that can travel through space in the form of electromagnetic radiation.

**Radio shack** — The room where Amateur Radio operators keep their station.

**Radiotelegraphy** — See *Morse code*.

**Receiver** — A device that converts radio signals into a form that can be heard.

**Repeater** — An amateur station, usually located on a mountaintop, hilltop or tall building, that receives a signal and retransmits it for greater range.

**SAREX** — An abbreviation for *Shuttle Amateur Radio Experiment*.

**Shortwave listener (SWL)** — A person who enjoys listening to radio broadcasts or Amateur Radio conversations.

**Shuttle Amateur Radio Experiment** — A payload of Amateur Radio equipment flown aboard the space shuttle and operated by astronauts who are licensed Amateur Radio operators.

**Single sideband (SSB)** — A common *mode* of voice operation on the amateur bands.

**Slow-scan television (SSTV)** — A *mode* of operation in which Amateur Radio operators exchange still pictures from their radio stations.

**Technical Information Service** — A service of the *American Radio Relay League* that helps hams solve technical problems.

**Technician license** — One of two entry-level classes of Amateur Radio licenses. Those who hold this license can use *all* the amateur bands above 30 MHz. In addition, Technicians who have passed a 5-word-per-minute Morse code test can use the four HF Novice bands.

**Transceiver** — A radio transmitter and receiver combined in one unit.

**Transmitter** — A device that produces radio-frequency signals.

**Ultra-high frequencies (UHF)** — The radio frequencies from 300 to 3000 MHz.

**Very-high frequencies (VHF)** — The radio frequencies from 30 to 300 MHz.

**Volunteer Examiners (VEs)** — Amateur Radio operators who give Amateur Radio licensing examinations.

**Wavelength** — A means of designating a frequency *band*, such as the 80-meter band.

**WEBERSAT** — An Amateur Radio satellite that transmits image data that can be processed into pictures using unique software and a personal computer.

**Worked All States (WAS)** — An *ARRL* award that is earned when an Amateur Radio operator talks to a ham in each of the 50 states in the US.

**Worked All VE (WAVE)** — An award that is earned when an Amateur Radio operator talks to a ham in each of the Canadian provinces.

**Work** — To contact another ham.

Prospective hams call 1-800-32 NEW HAM (1-800-326-3942)

Membership organization of US ham radio operators and those interested in ham radio. Publishes study guides for all Amateur Radio license classes, a monthly journal, *QST*, and many books on Amateur Radio and electronics.

**AMSAT NA (The Radio Amateur Satellite Corporation, Inc)**  
PO Box 27  
Washington, DC 20044  
301-589-6062

Membership organization for those interested in Amateur Radio satellites. Publishes *The AMSAT Journal*, monthly.

**Courage HANDI-HAM System**  
3915 Golden Valley Rd  
Golden Valley, MN 55422  
612-520-0515

Provides assistance to persons with disabilities who want to earn a ham radio license or set up a station.

*Now You're Talking! All You Need to Get Your First Ham Radio License*  
(Newington, CT: ARRL)

Complete introduction to Amateur Radio, including the Novice and Technician question pools, complete explanations of the subjects covered on the exams. Tips on buying equipment, setting up a station and learning Morse code, and more.

*Your Introduction to Morse Code*  
(Newington, CT: ARRL)

A set of audio cassettes that makes learning Morse code fun. Teaches all letters and numbers, and provides practice text.

*ARRL Technician Class Video Course*  
(Newington, CT: ARRL)

Five hours of lively, interesting preparation for the Novice and Technician written exams. Includes 164-page course book with practice exams, plus optional exam-review software.

*Morse Tutor/Morse Tutor Gold*

Software for IBM PCs and compatibles that teaches the code and provides plenty of practice at user-selected speeds from 1 to 100 words per minute.

# Activities

## 2

One of the best things about this hobby we call Amateur Radio is its *flexibility*. In other words, Amateur Radio can be whatever *you* want it to be. Whether you are looking for relaxation, excitement, or a way to stretch your mental (and physical) horizons, Amateur Radio can provide it. This chapter was written by Larry Kollar, KC4WZK. Let's take a brief tour through the following topic areas:

**Awards**—the individual and competitive pursuits that make up the tradition we call “paper chasing.”

**Contests**—the challenge of on-the-air competition.

**Nets**—both traffic nets, where amateurs pass messages on behalf of hams and nonhams, and the casual nets, where groups of people with common interests often meet on the air to swap equipment, anecdotes and information.

**Ragchewing**—meeting new friends on the air.

**Amateur Radio Education**—Educating current and future hams brings in new blood (and revitalizes old blood!); educating our neighbors about ham radio is good for public relations and awareness.

**ARRL Field Organization**—Amateur Radio in general, and the ARRL in particular, depend on the volunteer spirit. As part of the Field Organization, you can exercise your administrative, speaking and diplomatic skills in service of the amateur community.

**Emergency Communications**—When disaster strikes, hams often have the only reliable means to communicate with the outside world. Practice and preparation are key to fulfilling this mission.

**DF (Direction Finding)**—If you've ever wanted to know where a transmitter (hidden or otherwise) is located, you'll

find DFing is an enjoyable and useful skill.

**Satellite Operation**—You may be surprised to learn that hams have their own communications satellites! Satellite operation can be great fun and a technical challenge for those who want to operate on the “final frontier.”

**Repeaters**—Using and operating repeaters is one of the most popular activities for both new and old hams.

**Image Communications**—Although it's fun to talk to other amateurs, it's even more fun to *see* them.

**Digital Communications**—Use your computer to communicate with stations around your town or around the world.

**VHF, UHF and Microwave Weak-Signal Operating**—Explore the challenging, quirky and surprising world above 50 MHz.

**EME (Earth-Moon-Earth), Meteor Scatter and Aurora**—Making contacts by bouncing your signals off the moon, the fiery trails of meteors and auroras.

### AWARDS

Winning awards, or “paper chasing,” is a time-honored amateur tradition. For

those who enjoy individual pursuits or friendly competition, the ARRL and other organizations offer awards ranging from the coveted to the humorous.

### DX Awards

The two most popular DX awards are DXCC (DX Century Club), sponsored by the ARRL and WAC (Worked All Continents), sponsored by the International Amateur Radio Union (IARU). The WAC award is quite simple: all you have to do is work one station on each of six continents. The DXCC is more challenging: you must work at least one station in each of 100 countries! QSL cards from each continent or country are required as proof of contact.

### How-to's of DXCC—Direct QSLs and DX Bureaus

Since DX stations are often inundated with QSL cards (and QSL requests) from US hams, it is financially impossible for most of them to pay for the return postage. Hams have hit upon several ways to lighten the load on popular DX stations.

The fastest, but most expensive, way to get QSL cards is the *direct* approach. You send your QSL card, with one or two International Reply Coupons—IRCs—(or one or two dollars) and a self-addressed air-mail envelope to the DX station. International Reply Coupons are available from your local post office and can be used nearly anywhere in the world for return postage. Some DX hams prefer that you send one or two “green stamps” (dollar bills) because they can be used to defray posting, printing and other expenses. However, it is illegal in some countries to possess foreign currency. If you're not sure, ask the DX station or check DX bulletins available on packet radio and BBSs.

One of the most prized awards in Amateur Radio: the DX Century Club.

Many DX hams have recruited *QSL managers*, hams who handle the QSL chores of one or more DX stations. QSL managers are convenient for everyone. The DX station need only send batches of blank cards and a copy of the logs; hams wanting that station's card need only send a First Class stamp for US return postage and can expect a prompt reply. (In the case of QSL managers located outside the United States, you must still send IRCs [or dollars] and a self-addressed return envelope.)

The easiest (and slowest) way to send and receive large batches of QSL cards is through the incoming and outgoing QSL bureaus. The outgoing bureau is available to ARRL members. The incoming bureaus are available to all amateurs. Bureau instructions and addresses are printed periodically in *QST*; they appear in the *ARRL Operating Manual*, and they are available from ARRL Headquarters for an SASE.

### DXpeditions

What does the avid DXer who has worked them all (or almost all of them) do for an encore? Answer: *become* the DX! DXpeditions journey to countries with few or no hams, often making thousands of contacts in the space of a few days.

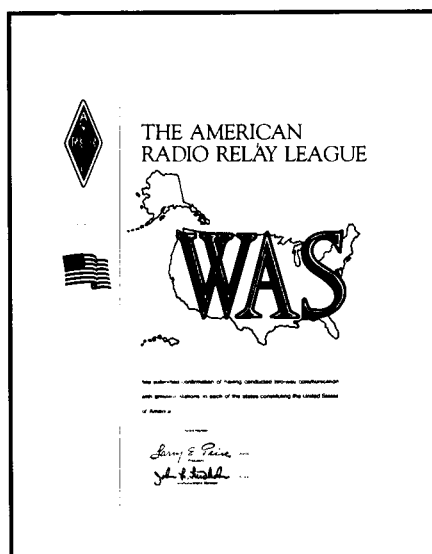

In 1991, Albania opened its borders and legalized Amateur Radio for the first time in many years. To train the first new generation of Albanian hams and to relieve the pileups that were sure to happen, a contingent of European and American hams organized a DXpedition to Albania. The DXpedition made over 10,000 contacts and changed Albania from one of the rarest and most-desired countries to an "easy one."

### DX Nets

The beginning DXer can get a good jump on DXCC by frequenting DX nets. On DX nets, a net control station keeps track of which DX stations have checked into the net. He or she then allows a small group of operators (usually 10) to check in and work one of the DX stations. This permits weaker stations to be heard instead of being buried in a pileup. Since the net control station does not tolerate net members making contacts out-of-turn, beginning operators have a better chance of snagging a new country. Nets and frequencies on which they operate vary. For the latest information on DX nets, check with local DXers and DX bulletins.

### Efficient DX Operation

The best DXers will tell you the best equipment you have is "the equipment be-

**Work one station in each of the 50 states and you're eligible for the ARRL's Worked All States (WAS) award.**

tween your ears." Good operators can make contacts with modest power. The details of efficient DX operating cannot be covered in such a brief space. The ARRL sells two publications that are excellent references for new DX enthusiasts: *The Complete DXer* and *The DXCC Companion*.

### WAS (Worked All States)

The WAS certificate is awarded to amateurs who have QSL cards from at least one operator in each of the 50 United States. Chasing WAS is often a casual affair, although there are also nets dedicated to operators who are looking for particular states.

### Endorsements

The initial DXCC or WAS award does not mean the end. There are over 300 DXCC countries. As you reach certain levels in your country count, you qualify for endorsements. Endorsements arrive in the form of stickers that you attach to your DXCC certificate.

Both WAS and DXCC offer endorsements for single-band or single-mode operation. For example, if you work all 50 United States on the 15-m band, your certificate has an endorsement for 15 m. The most difficult endorsement is the 5-band (5B) endorsement. Rare indeed is the operator who can display a 5BDXCC certificate!

### Other Awards

The ARRL and other organizations offer a variety of awards for both serious and fun achievements. You can qualify for some awards, like the ARRL's RCC

(Rag Chewers' Club, for long contacts), on your very first contact! Other awards are sponsored by local clubs.

The ARRL Friendship Award is available to any ARRL member who can prove contact with 26 stations whose call signs end with each of the 26 letters of the alphabet. (For example, N1MZA, K0ORB, W3ABC...K1ZZ.) Any frequency or mode qualifies. Most consider the Friendship Award to be the next step up from the Rag Chewers' Club. It's more difficult to earn, but just as much fun.

One of the most coveted awards is the A-1 Operator Club. Qualifying for this award is as simple as cultivating spotless operating habits and always operating by the Amateur's Code (found near the front of this *Handbook*). To receive this award, you must be recommended by two A-1 members.

### CONTESTS

Some people enjoy the thrill of competition, and Amateur Radio provides challenges at all levels in the form of operating contests. Besides the competitive outlet, contests have provided many hams with a means to hone their operating skills under less-than-optimum conditions. On the VHF and higher bands, contests are one way to stimulate activity on little-used segments of the amateur spectrum.

This section briefly discusses a few ARRL-sponsored contests. The Contest Corral section of *QST* provides up-to-date information on these and other contests. The ARRL also publishes the *National Contest Journal (NCJ)*, which is good reading for any serious (or semi-serious) contester.

### Field Day

Every year on the fourth full weekend in

**Elaine Larson, KD6DUT, takes a turn at logging as Fred Martin, KI6YN, works the paddles during the Conejo Valley Amateur Radio Club's Field Day operation.**

June, thousands of hams take to the hills, forests, campsites and parking lots to participate in Field Day. The object of Field Day is not only to make contacts, but to make contacts under conditions that simulate the aftermath of a disaster. Most stations are set up outdoors and use emergency power sources.

Many clubs and individuals have built elaborate Field Day equipment, and that is all to the best—if a real disaster were to strike, those stations could be set up quickly, wherever needed, and need not depend on potentially unreliable commercial power!

### Other Contests

Other popular contests include:

**QSO Parties.** These are fairly relaxed contests—good for beginners. There are many state QSO parties, and others for special interests, such as the QRP ARCI Spring QSO Party.

**Sweepstakes.** This is a high-energy contest that brings thousands of operators out of the woodwork each year.

**Various DX contests.** DX contests offer good opportunities for amateurs to pursue their DXCC award contacts. A good operator can work over 100 countries in a weekend!

**VHF, UHF and microwave contests.** These contests are designed to stimulate activity on the weak-signal portions of our highest-frequency bands. The ARRL VHF/UHF contests are held during the spring and fall. There is also a contest for 10-GHz operators, and another one for EME (moonbounce) enthusiasts.

Each issue of *QST* lists the contests to be held during the next two months.

### NETS

A net is simply a group of hams who meet on a particular frequency at a particular time. Nets come in three classes: public service, traffic and special interest.

#### Public Service/Traffic Nets

Public service and traffic nets are part of a tradition that dates back almost to the dawn of Amateur Radio. The ARRL, in fact, was formed to coordinate and promote the formation of traffic nets. In those early days, nets were needed to communicate over distances longer than a few miles. (Thus the word “Relay” in “American Radio Relay League.”)

Public service and traffic nets benefit hams and nonhams alike. Any noncommercial message—birthday and holiday greetings, personal information or a friendly hello—may be sent anywhere in the US and to foreign countries that have third-party agreements with the United

### Keeping a Logbook

At one time, keeping a log of your contacts was an FCC requirement. The FCC has dropped this requirement in recent years, but many amateurs, both new and old, still keep logs.

#### Why Keep a Log?

If keeping a log is optional, why do it? Some of the more important reasons for keeping a log include:

**Legal protection.**—If you can show a complete log of your activity, it can help you deal with interference complaints. Good recordkeeping can help you protect yourself if you are ever accused of intentional interference, or have a problem with unauthorized use of your call sign.

**Awards tracking.**—A log helps you keep track of contacts required for DXCC, WAS, or other awards. Keeping a log lets you quickly see how well you are progressing toward your goal.

**An operating diary.**—A logbook is a good place for recording general information about your station. You may be able to tell just how well that new antenna is working compared to the old one by comparing recent QSOs with older contacts. The logbook is also a logical place to record new acquisitions (complete with serial numbers in case your gear is ever stolen). You can also record other events, such as the names and calls of visiting operators, license upgrades, or contests, in your log.

#### Paper and Computer Logs

Many hams, even those with computers, choose to keep their logs on paper. Paper logs still offer several advantages (such as flexibility) and do not require power. Paper logs also survive hard-drive crashes!

Preprinted logsheets are available, or you can create your own. Computers with word processing and publishing software let you create customized logsheets in no time.

On the other hand, computer logs offer many advantages to the serious contester or DXer. For example, the computer can search a log and instantly tell you whether you need a particular station for DXCC. Contesters use computer logs in place of *dupe sheets* to weed out duplicate contacts before they happen, saving valuable time. Computer logs can also tell you at a glance how far along you are toward certain awards.

Computer logging programs are available from commercial vendors. Some programs may be available as shareware (you can download it from a BBS and pay for the program if you like the way it works). If you can program your computer, you can also create your own custom logging program—and then give it to your friends or even sell it!

States. Many missionaries in South America, for example, keep in touch with stateside families and sponsors via Amateur Radio.

The ARRL National Traffic System (NTS) oversees many of the existing traffic nets. Most nets are local or regional. They use many modes, from slow-speed CW nets in the Novice HF bands, to FM repeater nets on 2 m.

Since the amateur packet-radio network now covers much of the US and the world, many messages travel over packet links. Amateurs use the packet radio network not only for personal or third-party traffic, but for lively conferences, discussions and for trading equipment.

#### HF and Repeater Nets

HF nets usually cover a region, although some span the entire country. This has obvious advantages for amateurs sending traffic over long distances. Repeater nets

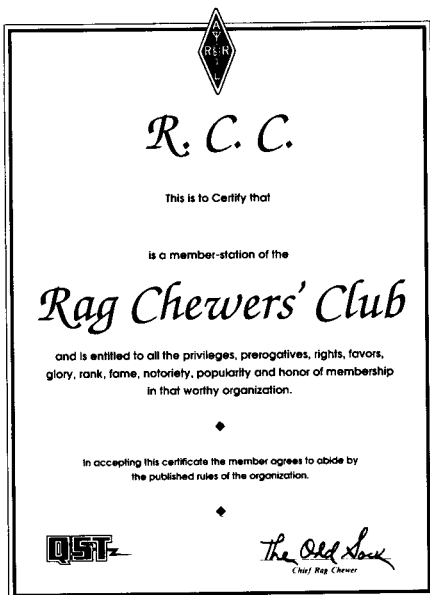

usually cover only a local area, but some linked repeater nets can cover several states.

Both types of nets work together to speed traffic to its destination. For example, think of the HF nets as a “trunk” or highway that carries traffic quickly and reliably toward its *approximate* destination. From there, the local and regional nets take over and pass the traffic directly to the city or town. Finally, a local amateur delivers the message to the recipient.

Routine traffic handling keeps the National Traffic System (NTS) prepared for emergencies. In the wake of Hurricane Andrew in 1992, hams carried thousands of messages in and out of the stricken south Florida region. The work that hams do during crisis situations ensures good relations with neighbors and local governments.

#### Other Nets

Many nets exist for hams with common

The Rag Chewers' Club award is one of the easiest to earn. You probably qualify already!

interests inside and outside of Amateur Radio. Some examples include computers, owners of Collins radio equipment, religious groups and scattered friends and families. Most nets meet on the 80- and 20-m phone bands, where propagation is fairly predictable and there are no short-wave broadcast stations to dodge.

## RAGCHEWING

Ragchewing is the fine art of the long contact. Old friends often get together on the air to catch up on current events. Family members use ham radio to keep in touch. And, of course, new acquaintances get to know each other!

In many cases, friends scattered across the country get together to create ragchewing nets. These nets are very informal and may not make much sense to the outsider listening in. The "serious" ragchewer's shack decoration is not complete without the Rag Chewers' Club (RCC) certificate. The RCC, the Friendship Award and other certificates are discussed earlier in this chapter.

## AMATEUR RADIO EDUCATION

*Elmering* (helping new and prospective operators) is a traditional amateur activity. Much of an amateurs' educational efforts go toward licensing (original and upgrading), but there are other opportunities for education, including public relations.

Dave Hanson, KBØEVM (r), is congratulated by Volunteer Examiner (VE) Len Buonaiuto, KE2LE, after passing his exam. (photo courtesy of KE2LE)

Dry run just before the shuttle pass. Keilah Meuser is practicing with others looking on.

## License Classes

Anyone can set up license classes. Many Amateur Radio clubs hold periodic classes, usually for the Novice and Technician elements with CW practice sessions. The ARRL supports Registered Amateur Radio Instructors, but registration is not necessary to conduct a class.

If you are looking for a class to attend, and do not have an "Elmer" to answer your questions, write the ARRL Educational Activities Department for a list and schedule of classes in your area. If you want to become an instructor, you can request the same list of classes from the Educational Activities Department—most classes will welcome another helping hand.

## Volunteer Examiners (VEs)

To become a VE, you must hold a General or higher amateur license and be certified by one of the VE Coordinators (VECs). The ARRL supports the largest VE program in the nation; other organizations run VE programs on a national or regional basis. General and Advanced licensees on a VE team must be supervised by at least one Extra Class licensee.

## School Presentations

Amateur Radio complements any school program. Schoolchildren suddenly find that Amateur Radio gives them a chance to apply their studies immediately. The math and science used in Amateur Radio applies equally to the classroom. Even geography takes on a new meaning when a student works a new country!

Unfortunately, many schools do not have an active Amateur Radio presence—and that is why local volunteers are important. An HF or satellite station, or even a 2-m hand-held transceiver tuned to the local repeater, can prove an exciting and educational experience for both the volunteer and the students.

Thanks to NASA's SAREX (Shuttle Amateur Radio Experiment) program, amateurs all over the nation have put schoolchildren in direct contact with shuttle astronauts. Who knows how many future scientists received their inspiration while sitting behind an amateur's microphone?

## ARRL FIELD ORGANIZATION

ARRL members elect the Board of Directors and the Section Managers. Each Section Manager appoints volunteers to posts that promote Amateur Radio within that Section. (The United States is divided into 15 ARRL Divisions. These Divisions are further broken down into 69 Sections.) A few of the posts include:

**Assistant Section Managers—ASMs** are appointed as necessary by the SM to assist the SM in responding to membership needs within the Section.

**Official Observers (OO) / Amateur Auxiliary**—Official Observers are authorized by the FCC to monitor the amateur bands for rules discrepancies or violations. The Amateur Auxiliary is administered by Section Managers and OO Coordinators, with support from ARRL Headquarters.

**Technical Coordinators (TC) and Technical Specialists (TS)**—Technical Coordinators and Technical Specialists assist hams with technical questions and interference problems. They also represent the ARRL at technical symposiums, serve on cable TV advisory committees and advise municipal governments on technical matters.

## EMERGENCY COMMUNICATIONS

The FCC Rules list emergency communications as one of the purposes of the Amateur Radio Service—and in reality, the ability to provide emergency communications justifies Amateur Radio's existence. The FCC has recognized Amateur Radio as being among the most reliable

**Chuck, N1SI (left), and Rick, WB5TJV, were two of the many hams who provided communications in the wake of a devastating earthquake in Mexico City. (photos courtesy of WB5TJV)**

means of medium- and long-distance communication in disaster areas.

Amateur Radio operators have a long tradition of operating from backup power sources. Through events such as Field Day, hams have cultivated the ability to set up communication posts wherever they are needed. Moreover, Amateur Radio can provide computer networks (with over-the-air links where needed) and provide other services such as video (ATV) and store-and-forward satellite links that no other service can deploy on a wide scale. One can argue, therefore, that widespread technology makes Amateur Radio even more crucial in a disaster situation.

If you are interested in participating in this important public service, you should contact your local EC (Emergency Coordinator). Plan to participate in preparedness drills and a yearly SET (Simulated Emergency Test).

### **ARES and RACES**

The Amateur Radio Emergency Service (ARES) and the Radio Amateur Civil Emergency Service (RACES) are the umbrella organizations of Amateur Radio emergency communications. The ARES is sponsored by ARRL (although ARRL membership is not required for ARES participation) and handles many different kinds of public-service activities. On the other hand, RACES is administered by the Federal Emergency Management Agency (FEMA) and operates only for civil preparedness and in times of civil emergency. RACES is activated at the request of a state or federal official.

Amateurs serious about emergency communication should carry dual RACES/ARES membership. RACES rules now make it possible for ARES and RACES to use the same frequencies, so that an ARES group also enrolled in RACES can work in either organization as required by the situation.

### **MILITARY AFFILIATE RADIO SERVICE (MARS)**

MARS is administered by the US armed forces, and exists for the purpose of transmitting communications between those serving in the armed forces and their families. This service has existed in one form or another since 1925.

There are three branches of MARS: Army MARS, Navy/Marine Corps MARS and Air Force MARS. Each branch has its own requirements for membership, although all three branches require members to hold a valid US Amateur Radio license and to be 18 years of age or older (amateurs from 14 to 18 years of age may join with the signature of a parent or legal guardian).

MARS operation takes place on frequencies adjoining the amateur bands and usually consists of nets. Nets are usually scheduled to handle traffic or to handle administrative tasks. Various MARS branches may also maintain repeaters or packet systems.

MARS demonstrated its importance during the 1991 Desert Storm conflict, when MARS members handled thousands of messages between the forces on the front lines and their friends and families at home. While MARS usually handles rou-

**Dave Pingree, N1NAS, hunts down a transmitter on 2-m FM. (photo by Kirk Kleinschmidt, NT0Z)**

tine traffic, the organization is set up to handle official and emergency traffic if needed.

### **DIRECTION FINDING (DF)**

If you've ever wanted to learn a skill that's both fun *and* useful, then you'll enjoy direction finding, or DFing. DFing is the art of locating a signal or noise source by tracking it with portable receivers and directional antennas. Direction finding is not only fun, it has a practical side as well. Hams have been instrumental in hunting down signals from aircraft ELTs (emergency locator transmitters), saving lives and property in the process.

Dick Esneault, W4IJC, a member of the original Project OSCAR team, looks over a model of the Phase 3D satellite. The body of the actual satellite will be well over 7 feet wide. This advanced Amateur Radio satellite is scheduled for launch in 1996. (photo courtesy AMSAT-NA)

We will just scratch the surface of DF activities in this section. There is much more in the **Repeaters, Satellites, EME and DF** chapter.

### Fox Hunting

Fox hunting, also called *T-hunting* or sometimes *bunny hunting*, is ham radio's answer to hide-and-seek. One player is designated the fox; he or she hides a transmitter and the other player attempts to find it. Rules change from place to place, but the fox must generally locate the transmitter within certain boundaries and transmit at specific intervals.

Fox hunts vary around the world. American fox hunts often employ teams of fox hunters cruising in their cars over a wide area. European and other fox hunters employ a smaller area and conduct fox hunts on foot. *Radiosport* competitions are usually European style.

### Locating Interference

Imagine trying to check into your favorite repeater or HF net one day, only to find reception totally destroyed by noise or a rogue signal. If you can track down the interference, then you can figure out how to eliminate it.

Finding interference sources, accidental or otherwise, has both direct and indirect benefits. Touch lamps are a notorious noise source, especially on 80 m. If you can find one, the owner is legally obligated to eliminate the interference. Even

Assembling a 2.4-GHz Mode-S downlink dish is easier than you think. Ed Krome, KA9LNV, put together this portable home-brew dish in less than 15 minutes. It's made of wood dowels, wire mesh and Dacron string. The helical feed and reflector plate are mounted at the focal point. (photo by WB8IMY)

better, if you can show your neighbors that something other than your station is interfering with their TV reception, you might gain an ally next time you petition the local government to let you have a higher tower!

### SATELLITE OPERATION

Amateur Radio has maintained a presence in space since 1961, with the launch of OSCAR 1 (OSCAR is an acronym for Orbiting Satellite Carrying Amateur Radio). Since then, amateurs have launched over two dozen satellites, with

over a dozen still in orbit today.

Amateurs have pioneered several developments in the satellite industry, including low-orbit communication "birds" and PACSATs—orbiting packet bulletin board systems.

### What Does It Take?

When someone mentions satellite operation, many people conjure up an image of large dishes and incredibly complex equipment. Actually, you can probably work several OSCARs with the equipment you have in your shack right now!

The entire collection of OSCARs—and their operating modes—can be broken down into three basic types:

### Voice/CW (Analog)

Analog satellites range from the low-orbit RS (Radio Sputnik) birds built and launched from Russia, to the high-orbit Phase III satellites, AO-10 and AO-13. Operating on analog satellites is much like operating on HF—you'll find lots of SSB and CW contacts, with some RTTY and even SSTV signals thrown in.

### Packet (Digital)

Most of the digital satellites are orbiting packet mailboxes with some extra features. Many digital satellites carry one or more video cameras. These cameras snap pictures of Earth and space and make them available for downloading. Because most digital satellites are in low orbits, some clever software has been designed to allow ground stations to download images (or other data files) by monitoring a few orbital passes.

Several digital satellites carry an experiment called RUDAK, a versatile system that allows experimentation with packet, analog and crossband FM modes. The Fujisats from Japan also carry sophisticated systems that allow these birds to switch from analog to digital operation.

### SAREX and MIR

The American and Russian space programs both recognize the value of Amateur Radio in space. The space shuttles often carry a mission called SAREX (Shuttle Amateur Radio Experiment) that allows hams to make packet or voice contacts with the astronauts onboard. SAREX gives many schoolchildren the opportunity to talk to the astronauts and ask questions about their work.

The Russian *MIR* space station carries a permanent packet and FM station on board. *MIR* can occasionally be heard with a very strong signal, even on 2-m hand-held radios, and some hams have made contacts with mobile rigs.

Both of these orbiting amateur stations have proven their worth time and again. Their educational value is immense, and in case of normal communication failure Amateur Radio equipment provides a ready backup.

## REPEATERS

Many amateurs make their first contacts on repeaters. Repeaters carry the vast majority of VHF/UHF traffic, making local mobile communication possible for many hams.

Hams in different regions have different opinions on repeater usage. In some areas, hams use repeaters only for brief contacts, while those in other areas encourage socializing and ragchewing. All repeater users give priority to mobile emergency communications.

The best way to learn the customs of a particular repeater is to listen for a while before transmitting. This avoids the misunderstandings and embarrassment that can occur when a newcomer jumps in. For example, in some repeater systems it is assumed that the word "break" indicates an urgent or emergency situation. Other systems recognize "break" as a simple request to join or interrupt a conversation in progress. Neither usage is more "correct," but you can imagine what might happen to a traveling ham who was unaware of the local customs!

Most repeaters are *open*, meaning that any amateur may use the repeater. Other repeaters are *closed*, meaning that usage is restricted to members. Many repeaters have an *autopatch* capability that allows amateurs to make telephone calls. However, most autopatches are closed, even on otherwise open repeaters. The *ARRL Repeater Directory* shows repeater loca-

tions, frequencies, capabilities and whether the repeater is open or closed.

Most repeaters are maintained by clubs and other local organizations. If you use a particular repeater frequently, you should join and support the repeater organization. Some hams set up their own repeaters as a service to the community.

## IMAGE COMMUNICATIONS

Several communications modes allow amateurs to exchange still or moving images over the air. Advances in technology in the last few years have brought the price of image transmission equipment within reach of the average ham's budget. This has caused a surge of interest in image communication.

### ATV

Amateur TV is full-motion video over the air. (It is sometimes referred to as *fast scan*, or *FSTV*.) ATV signals use the same format as broadcast (and cable) TV. Watching an ATV transmission is the same as watching your own television. With ATV, however, you can turn a small space in your home into your own television studio. Amateur communication takes on an exciting, new dimension when you can actually *see* the person you're communicating with!

The costs of ATV equipment have declined steadily over the years. The popularity of the camcorder has also played a significant role. (The family camcorder can do double duty as a station camera!) It is now possible to assemble a versatile station for well under \$1000. Amateur groups in many areas have set up ATV repeaters, allowing lower-powered stations to communicate over a fairly wide area. If you're fortunate enough to live

within range of an ATV repeater, you won't need complicated antenna arrays or high power.

If you can erect high-gain directional antennas for your ATV station, you can try your hand at DXing. When the bands are open, it's not uncommon to enjoy conversations with stations several hundred miles away. In addition to your directional antennas, you must run moderate power levels to work ATV DX. Most DXers use at least 50 W or more.

Since this is a wide-bandwidth mode, operation is limited to the UHF bands (70 cm and higher). The *ARRL Repeater Directory* and the *ARRL Operating Manual* list band plans. The *Repeater Directory* includes lists of ATV repeaters. The **Modulation Sources** chapter provides details on setting up an ATV station with dedicated or converted video gear.

### SSTV

SSTV, or slow-scan TV, is a narrow-bandwidth image mode. Instead of full-motion video at roughly 24 frames per second, SSTV pictures are transmitted at 8, 16 or 32 seconds per frame. In the beginning, SSTV was strictly a black-and-white mode. The influx of computers (and digital interfaces) have spawned color SSTV modes. Since SSTV is a narrow-band mode, it is popular on HF. Some experimenters run an SSTV net on OSCAR 13 as well.

An SSTV signal is generated by breaking an image into individual *pixels*, or dots. Each color or shade is represented by a different audio tone. This tone is fed into the audio input of an SSB transmitter, converting the tones into RF. On the receive end, the audio tones are regenerated and fed into a dedicated SSTV con-

Give him the specifications and Sam, K6LVM, can show you the radiation pattern of your antenna—via ATV! (photo by Tom O'Hara, W6ORG)

An SSTV image as seen on a standard TV set using a digital scan converter.

verter or into a simple computer interface to regenerate the picture. For more information about SSTV, see the **Modulation Sources** chapter.

## Fax

Fax, or *facsimile* transmission, is one of the original image communication modes. Fax was once unavailable to amateurs due to FCC regulations, but is now a legal communication mode on most HF and higher bands.

Amateur Radio fax works much like old analog fax systems: an image is scanned from paper and converted into a series of tones representing white or black portions of a page. Amateurs are working on standards for the use of digital fax machines over radio as well.

Uses for amateur fax are as limitless as your imagination. Suppose you were having trouble with the design of your new home-brewed widget. You could fax a copy of the schematic to a sympathetic ham, who could mark in some changes and fax it back to you. And how about faxing QSL cards? No hunting for stamps or waiting for the mail to arrive!

## DIGITAL COMMUNICATIONS

Digital communications predate the personal computer by many years. In fact, some amateurs consider CW to be a digital mode in which the amateur's mind handles the encoding and decoding of information. For the purposes of this *Handbook*, however, we consider digital modes to be those traditionally encoded and decoded by mechanical or electronic means. Common digital modes in use today include RTTY, AMTOR, PacTOR, G-TOR and packet radio.

As personal computers continue decreasing in price and increasing in power, many have found their way into ham shacks. Amateurs' computers perform tasks as mundane as keeping station logs and as exciting as controlling a worldwide data network!

## Packet

Packet radio is one of the fastest-growing modes of operation within the amateur community. Packet radio's strongest suits include networking and unattended operation. Do you need to give some information to an absent friend? Send an electronic mail message (or *e-mail* in networking parlance). Is your friend out of range of your 2-meter packet radio? Send your message through the packet network.

In packet radio, transmitted data is broken into "packets" of data by a TNC (terminal node controller). Before send-

## QSLing

A QSL card (or just "QSL") is an Amateur Radio tradition. QSL cards are nearly as old as Amateur Radio itself, and the practice has spread so that SWLs can get cards from commercial shortwave and AM broadcast stations.

Most amateurs have printed QSL cards. QSL card printers usually have several standard layouts that you can choose from. Some offer customized designs at extra cost. If you are just starting out, or anticipate changing your call sign (just think, you could get a call like "KC4WZK"), you may want to purchase a pack of "generic" QSL cards available from many ham stores and mail-order outlets.

## Filling Out Your Cards

QSL cards must have certain information for them to be usable for award qualification. At a minimum, the card must have:

- ┐ Your call sign, street address, city, state or province and country. This information should be preprinted on one side of your QSL card.
- ┐ The call of the station worked.
- ┐ The date and time (in UTC) of the contact.
- ┐ The signal report.
- ┐ The band and mode used for the contact.

Awards for VHF and UHF operations may also require the grid locator (or "grid square") in which your station is located. If you have no plans to operate VHF and UHF, you can omit the grid square (you can always write it in later if required).

Many hams provide additional information on their QSL cards such as the equipment and antennas used during the contact, power levels, former calls and friendly comments.

## Sending and Receiving Domestic QSLs

Most QSL cards can be sent as post cards within the United States, usually saving some postage costs. Back when postage was cheap, you could send out 100 post cards for a few dollars and domestic stations would send QSLs as a matter of course. Nowadays, if you really need a particular QSL, it is best to send a self-addressed stamped envelope along with your card.

QSLing for DX stations is somewhat more involved and is discussed elsewhere in this chapter.

**WB8IMY's QSL is a properly formatted card. Notice how all of the information is on one side of the card.**

ing these packets over the air, the TNC calculates each packet's checksum and makes sure the frequency is clear. On the receive end, a TNC checks packets for accuracy and requests retransmission of bad packets to ensure error-free communication.

Packet radio works best on frequencies that are relatively uncrowded. On busy frequencies (or LANs), it is possible for two stations to begin transmitting at once, garbling both packets (this is called a *collision*). Another common problem is the *hidden transmitter*, which happens when

one of two stations (that are out of range of each other) is in contact with a third station within range of *both* (see **Fig 2.1**). Collisions can easily occur at the third station since neither of the other two stations can hear each other and thus may transmit simultaneously.

Thousands of packet radio stations have formed a worldwide network, one that parallels (and overlaps in some places) the massive Internet. Services available on the packet radio network include global e-mail, callbook servers, "white pages" servers (that provide network addresses

Dave Patterson, WB8ISZ, checks into his local packet bulletin board as his cat Sam looks on. (photo by WB8IMY)

John Shew, N4QQ, (at a portable station set up by KG5OG) makes an EME CW contact with VE3ONT. (photo by WB8IMY)

of amateurs on the network) and gateways to (and from) the Internet. Other services, available in various locations, include libraries of program and text files, databases of equipment modifications, gateways to packet frequencies on HF and packet satellites.

Most amateur networkers use VHF or UHF radios to access the packet network. Many amateurs, however, can be found using packet on HF and the packet satellites. Both HF and satellites see a great deal of internode network traffic as well.

### AMTOR/PacTOR/G-TOR

AMTOR (*Amateur Teleprinting Over Radio*) is an "RF-hardened" digital mode. It is based on the SITOR mode (used in marine communications) and is an error-correcting mode.

A transmitting station using AMTOR sends three characters then waits for a response from the receiving station. (This

produces the "cricket" sound unique to AMTOR.) The receiving station sends an ACK (send the next three characters) or a NAK (repeat the last three characters). This exchange of ACKs and NAKs ensures that only error-free text arrives at the receiving station.

Actually, there is much more than this to AMTOR; there are several submodes for calling CQ, or for reliable sending to multiple receivers.

PacTOR is a packet-like mode based on AMTOR, but with slightly longer packets and AX.25 compatibility. Unlike standard packet radio, PacTOR does not allow frequency sharing. PacTOR is much faster than AMTOR while still retaining AMTOR's ability to communicate through moderate noise or interference without errors. In addition, PacTOR uses the complete ASCII character set (with upper- and lower-case letters) and can easily handle binary data transfers.

G-TOR uses several compression, checking and correction techniques along with automatic repeat requests. These techniques speed data transfer on the HF bands over that possible with AMTOR or PacTOR. The "G" in G-TOR stands for "Golay," a kind of forward-error-correction coding.

### RTTY

RTTY is the original data communication mode, and it remains in use today. While RTTY does not support the features of the newer data modes, such as frequency sharing or error correction, RTTY is better suited for "roundtable" QSOs with several stations.

RTTY was originally designed for use

with mechanical teleprinters, predating personal computers by several decades. Amateurs first put RTTY on the air using surplus teletypewriters (TTYs) and home-brewed vacuum-tube-based interfaces. Today, of course, RTTY uses computers or dedicated controllers, many of which also support other digital modes such as CW, PacTOR, AMTOR and packet.

### CLOVER

CLOVER is a relatively new digital communications mode. It utilizes a four-tone modulation system and digital signal processing (DSP) to pass data on the HF bands at a rate much faster than AMTOR or even PacTOR. In addition, CLOVER's signal bandwidth is relatively narrow (500 Hz at -50 dB). When two CLOVER stations are linked, they share information concerning signal conditions and power output levels. As a result, CLOVER has the remarkable ability to adjust output power *automatically* to maintain a stable communication pathway. For example, if the signal begins to deteriorate at the receiving station, the transmitting station is "aware" of this fact and increases power until conditions improve. Under excellent conditions, power is adjusted *down*—sometimes to as little as a few watts!

The complete CLOVER system is contained on a card that plugs into the expansion slot of an IBM-PC or compatible computer (80286 microprocessor or better). An SSB transceiver is also required. The transceiver must be very stable because CLOVER cannot tolerate more than approximately 15 Hz of drift after the link is established. As this *Handbook* went to

Fig 2.1—The "hidden transmitter" problem. Site B has established contact with site C, but cannot hear site A. However, site C can hear *both* stations. If site B transmits while site A is transmitting, or vice versa, a packet collision occurs.

press, CLOVER was primarily used as a means to move high-volume digital traffic (messages and files) on the HF bands.

## MICROWAVE AND VHF/UHF WEAK-SIGNAL OPERATING

Hams use many modes and techniques to extend the range of line-of-sight signals. Those who explore the potential of VHF/UHF communications are often known as *weak-signal* operators. Weak-signal enthusiasts probe the limits of propagation. Their goal is to discover just how far they can communicate.

They use directional antennas (beams or parabolic dishes) and very sensitive receivers. In some instances, they employ considerable output power, too. As a result of their efforts, distance records are broken almost yearly! On 2-m, for example, conversations between stations hundreds and even thousands of miles apart are not uncommon. The distances decrease as frequencies increase, but communications have spanned several hundred miles even at microwave frequencies.

### EME, Meteor Scatter and Aurora

EME communication, also known as “moonbounce,” continues to fascinate many amateurs. The concept is simple: use the moon as a passive reflector for VHF and UHF signals. With a total path length of about 500,000 miles, EME is the ultimate DX.

Amateur involvement in moonbounce grew out of experiments by the military after World War II. While the first amateur signals reflected from the moon were received in 1953, it took until 1960 for the first two-way amateur EME contacts to take place. Using surplus parabolic dish antennas and high-power klystron amplifiers, the Eimac Radio Club, W6HB, and the Rhododendron Swamp VHF Society, W1BU, achieved the first EME QSO in

July 1960 on 1296 MHz. Since then, EME activity has proliferated onto most VHF and higher amateur bands.

Advances in low-noise semiconductors and Yagi arrays in the 1970s and 1980s have put EME within the grasp of most serious VHF and UHF operators. Further advances in technology will bring forth sophisticated receivers with digital signal processing (DSP) that may make EME affordable to most amateurs.

EME activity is primarily a CW mode. However, improvements in station equipment now allow the best-equipped stations to make SSB contacts under the right conditions. Regardless of the transmission mode, successful EME operating requires:

- Power output as close to the legal limit as possible.
- A good-sized antenna array. Arrays of 8, 16, or more Yagis are common on the VHF frequencies, while large parabolic dish antennas are common on UHF and microwave frequencies.
- Accurate azimuth and elevation.
- Minimal transmission line losses.
- The best possible receiving equipment, generally a receiver with a low system noise figure and a low-noise preamplifier mounted at the antenna.

The ARRL sponsors EME contests to stimulate activity. Given the marginal nature of most EME contacts, EME contests designate a “liaison frequency” on HF where EME participants can schedule contacts. Contest weekends give smaller stations the opportunity to make many contacts with stations of all sizes. See the **Repeaters, Satellites, EME and DF** chapter for more about EME.

### Meteor Scatter

As a meteor enters the Earth’s atmosphere, it vaporizes into an ionized trail of matter. Such trails are often strong enough

to reflect VHF radio signals for several seconds. During meteor showers, the ionized region becomes large enough (and lasts long enough) to sustain short QSOs.

Amateurs experimenting with meteor scatter propagation use high power (100 W or more) and beam antennas with an elevation rotor (to point the beam upward at the incoming meteors). Most contacts are made using CW, as voice modes experience distortion and fading. Reflected CW signals often have a rough note.

The *ARRL UHF/Microwave Experimenter’s Handbook* contains detailed information about the techniques and equipment used for meteor scatter.

### Auroral Propagation

During intense solar storms, the Earth’s magnetic field around the poles can become heavily charged with ions. In higher latitudes, this often produces a spectacular phenomenon called the *aurora borealis* (or northern lights) in the Northern Hemisphere and the *aurora australis* (or southern lights) in the Southern Hemisphere. The ionization is often intense enough to reflect VHF radio signals. Many amateurs experiment with aurora contacts on 10 and 2 m. Aurora contacts are often possible even when the aurora is not visible.

Equipment used to make aurora contacts is similar to that used for meteor-scatter contacts: high power, directional antennas and CW. Antenna pointing is less critical, however, since the antenna need only be aimed at the aurora curtain. Reflected CW signals often have a rough buzzsaw-like note and can also be Doppler-shifted.

The *ARRL UHF/Microwave Experimenter’s Handbook* contains detailed information about the techniques and equipment used for auroral propagation.

# Modes

## 3

United States Amateur Radio operators are encouraged by the Federal Communications Commission (FCC) to explore, investigate and experiment, with wide latitude. The government wants hams to try new things, test new ideas and push the capabilities of two-way radio-frequency (RF) communications. In this chapter, written by Brian Battles, WS1O, you'll learn basic information about the most popular amateur operating modes. You'll see what each one is used for and its advantages and disadvantages, and you'll get a general idea of the resources needed to try each one. Details of how radio signals are created and how those signals are made to carry information is explained in later chapters of this book. This is an introduction; the other chapters of this *Handbook*, the *ARRL Operating Manual*, *QST*, *QEX* and a whole Amateur Radio publishing industry cover the continuously evolving realm of Amateur Radio modes. Look in the **References** chapter for a list of Amateur Radio publications that describe specific practices, techniques and circuits you can use for deeper investigation.

### WHAT IS A MODE?

In Amateur Radio, a mode is considered to be any modulation technique that permits two-way communication with another station using an identical or compatible system to receive and demodulate it. If that sounds confusing, just think of a simple analogy, such as the way we use money in modern society: A certain amount of American dollars can be used to purchase an item that may also be purchased with an equivalent amount in Japanese yen. The dollar and the yen, however, are not directly compatible—you

can't simply exchange them one for one. Yet they are both forms of payment for goods and services.

This is typical of most ham radio modes. You can talk over an FM repeater, but a person with a CW receiver who tunes to your frequency won't hear a thing you say. FM and CW aren't compatible. Most Amateur Radio operating modes are incompatible with each other, and each has advantages and disadvantages that make it worthwhile to select the best mode for the intended communication. Because its information is transmitted by varying the carrier frequency substantially, an FM signal uses a relatively large amount of RF bandwidth. On a relatively wide band such as 2 m (144-148 MHz, 4 MHz wide), many hams use narrow-bandwidth FM (NBFM). NBFM requires about 15-20 kHz of spectrum for each conversation (hams call them "QSOs"). Several such FM signals would easily use up all of a narrow band such as 30 m (10.1-10.15 MHz, 0.05 MHz wide), and few conversations could take place at the same time. Other modes, such

as single-sideband suppressed-carrier amplitude modulation (SSBSCAM, or SSB) and continuous wave (CW), require much less bandwidth. Here's the trade-off: while FM has enhanced audio fidelity and relatively little background noise, SSB and CW permit many more simultaneous QSOs in any given range of frequencies.

The radio amateur has a variety of frequencies to select from when attempting to establish two-way communications. At the low end are the *medium frequencies* (MF), specifically the 160-m band (1.8-2.0 MHz). Then there are the *high frequency* (HF) or "shortwave" bands (80-10 m, or 3.5-29.7 MHz). The next steps up are the *very high frequency* (VHF) bands (6-1.25 m, or 50-225 MHz). Above these are the *ultra high frequency* (UHF) bands (70-23 cm, or 420-2450 MHz). Above all these are the *super high frequency* (SHF), *extremely high frequency* (EHF) and other segments, more simply referred to as *microwaves* (2900-250,000 MHz). The band you choose affects your signal's range (see the chapter on **Propagation**). But the mode you select is also important, for many reasons.

The key to successful Amateur Radio communications is *signal-to-noise ratio* (*S/N*). This means you can communicate with anyone if your signals are loud enough to be heard through any noise present. Sometimes the noise wins; there's always *some* noise present on any radio frequency. Similarly, there's *some* propagation available to any desired location. The propagation path may not be sufficient to help conduct a weak signal halfway around the world, but theoretically, if you transmitted enough power, if there were absolutely no noise, you could contact al-

Rick Castaldo, KD1BR, keeps in touch with his friends using 80-meter SSB.

most anyone in the world at any time propagation conditions permitted your signal to reach its destination. The challenge in radio communications is to work within the practical constraints of your license privileges, budget, physical capabilities and atmospheric conditions to maximize your chances of being heard. If the S/N at the receiving end is sufficient, you will be heard. If the noise level is too great, you won't get anywhere.

Every portion of the radio-frequency spectrum exhibits its own unique characteristics of propagation and noise. For example, the MF or lower-frequency HF amateur bands are in a range that is particularly subject to noise. Frequencies below 5 MHz exhibit ever-present random atmospheric noise from storms, and the background of "hash" generated by man-made electrical gadgets, appliances and machinery is often very loud. If you live in an urban environment, it can be difficult to hear anyone most of the time, especially in the summer, when thunderstorms rage throughout your hemisphere. On the other hand, radio amateurs fortunate enough to live in rural settings far from factories, congested housing and other sources of noise can enjoy good reception on 160 m, especially in the winter, when thunderstorm activity is lowest.

In addition to considering the noise and propagation conditions on the various bands, an Amateur Radio operator must intelligently select the *mode* of transmission most likely to succeed. The factors of concern are (1) What modes can your transmitter produce? (2) What mode is the intended recipient using? (3) What mode will provide the receiving station with the best S/N?

The first is easiest to determine—just look in the manual or at your rig's front panel controls. The second may be more of a mystery. Unless you have some means of predicting the mode the other station is using, you must make an educated guess. The third requires an understanding of what each mode is best suited to accomplish and how to take advantage of its characteristics.

Let's examine factors (2) and (3). To make communications convenient, hams have established standard operating techniques that make it easier to choose a mode. For example, most amateur voice communications on the 160, 80 and 40-m bands (1.8-7.3 MHz) are conducted via lower sideband (LSB), while upper sideband (USB) is the normal mode on 20, 17, 15, 12 and 10 m (14-28 MHz). On 2 m (144-148 MHz) and 1.25 m (222-225 MHz), the predominant mode is frequency modulation (FM) for voice and data com-

munications. Above 420 MHz there is a mixture of FM and SSB voice communications, fast-scan amateur television (ATV), CW and experimental modes.

There are exceptions to these "rules." Data communications, such as radioteletype (RTTY) and packet, are operated almost entirely on LSB at HF; DXing (long-distance communication) on VHF and UHF is mainly conducted using USB and Morse code; 10-m repeaters use FM. Aside from such exceptions, however, you can normally assume that stations operating voice on 20 m are likely to be using USB, a 2-m repeater is almost certainly using FM, and a packet station on 30 m will be running LSB. You should set your transceiver accordingly.

Once you know what modes are used by most operators on a given frequency, what frequency and mode should you select to have the best chance of establishing contact? You won't be heard unless your signal significantly exceeds the noise at the receiving end.

There are five main categories of communications in Amateur Radio: Radiotelegraph (Morse code), radiotelephone (voice), radioteletype (Baudot and ASCII RTTY and AMTOR), digital (packet, PACTOR, CLOVER, G-TOR) and image (SSTV, FSTV and fax). Let's look at the main Amateur Radio operating modes and compare their uses and characteristics.

## CW

CW (*continuous wave*) is the oldest mode of ham transmission in use today. It

**CW is the perfect mode for weak-signal work. John Shew, N4QQ, uses CW to operate EME (moonbounce) during the 1993 AMSAT Space Symposium.**

consists of a plain, unmodulated RF signal (or "carrier") which is transmitted by the closure of a manual key or an electronic keyer circuit (sometimes called "on-off keying"). CW conveys intelligence through the International Morse code. (This is a variation on the American Morse code used by commercial telegraphers on wired lines in the late 19th century.)

## AM

*Amplitude modulation* was the earliest technique used to transmit the human voice over radio. It was the dominant 'phone mode until the late 1940s and 1950s, when single sideband (SSB) came along. AM uses a full carrier with two modulated sidebands, and takes up a fair amount of bandwidth. In practice, two SSB signals or eight CW signals could be

**Sounding like a broadcaster from radio's Golden Age, Paul Courson, WA3VJB, operates classic AM equipment from his well-equipped shack in West Friendship, Maryland. ## Morse Code: A Language, Not a Mode

Digital signals are those that can be represented accurately in terms of integer numbers. Morse code has been called the most basic form of digital radio communication. It involves nothing more than three elements: a short tone, a long tone and a space. In digital perspective, these could be represented by the numerals 0, 1 and 2. If all we can do is send separate elements, we are limited to three possible pieces of information. (In practice, there would actually be only two definite expressions, the 0 and 1, or short tone and long tone. A space by itself would be the same as no signal at all.)

Mixing and matching the tones and spaces created a system to denote letters of the alphabet, the digits 0-9 and a few punctuation marks. As a result, no individual character requires more than six elements to be unique and clear.

Language expressed in nothing but long and short tones (dahs and dits) has been in use since before Samuel F. B. Morse devised the American Morse system of telegraphy. In prehistoric times, it was discovered that a prearranged method of sending signals could use a small set of such symbols, yet be a potentially powerful means of conveying complex information. The arrangement of the signals (long/short, loud/soft, bright/dim, single/double, on/off) could be used to signify much more than just two alphabetic or numeric symbols. Morse and his colleagues developed a standard code that took advantage of the frequency with which certain English letters are used in language, and made efficient use of the way our ears and minds work. Learning Morse code is as easy as learning about 40 words in a foreign language. With practice, a "speaker" of Morse code can decipher a string of long and short tones and spaces at almost half the speed of everyday spoken English conversation.

Now that we have a language, we need a means to transmit and receive it at two separate locations. Wired telegraphy was the earliest means, but the invention of

wireless radio transmissions less than 50 years later made it a simple matter of turning the transmitter on and off in a particular sequence to produce a corresponding sound at the receiving end. The first equipment used to create such radio signals were spark-gap transmitters. Spark transmitters sent an electromagnetically noisy pulse to a resonant antenna system where the pulse essentially reverberated until its energy was either radiated or dissipated in the resistance of the circuit. During the reverberation, the amplitude gradually decreased, so the result is a damped wave—a wave with changing strength. The part that was radiated became an electromagnetic field. The field was strong enough for a sensitive, specially designed antenna and receiver to respond to the electromagnetic bursts by rendering an audible sound in a headset or other transducer. As experiments continued, it wasn't long before the vacuum tube was perfected. By using a tube in a tuned electrical circuit, a transmitter could generate an almost-pure, constant unmodulated radio signal on a specific frequency. The signal generated by the tube was smoother and occupied much less space on the electromagnetic spectrum.

So how did the term *continuous wave (CW)* come about? Many beginning hams mistakenly think that it somehow means the transmitter is emitting a constant RF signal. But how could this be? Wouldn't this mean that each press of a code key actually breaks the circuit, rather than closes it? Of course, that's backwards. A code key closes the circuit when it's pressed (or squeezed, in the case of a paddle). No, the transmitted carrier is called *continuous* because it's not damped as were the spark signals; it's continuous in the sense that the RF sent when the key is pressed is transmitted as a single radio-frequency wave of continuous strength. CW is the simplest mode to implement in a radio. You can learn more about the principles of CW in the **Modulation Sources** chapter.

transmitted within the bandwidth used by one AM signal. Because it's less spectrum efficient, it has been reduced to a "curiosity" on the air. There are many antique wireless enthusiasts who derive great joy from the warm, rich sound of a strong AM signal, especially when generated by a properly adjusted and maintained vintage transmitter. AM operators use specific frequencies on almost every amateur band, and most polite hams respect the rights of AMers to operate, just as AM fans avoid transmitting on portions of the bands generally used for SSB, CW, amateur television and digital modes.

## ANGLE MODULATION: FM AND PM

FM is by far the most popular mode of Amateur Radio communication. The majority of newcomers to the hobby use FM transceivers to operate on VHF and UHF frequencies; the most popular activ-

**FM offers clear, reliable voice communication. This is especially critical during public-service activities. Using FM portable transceivers and directional antennas, hams operate from the Command HQ tent at the Big Sur International Marathon.**

**Table 3-1****Equipment Requirements for Amateur Radio Operating Modes**

<i>Mode</i>	<i>Typical activity</i>	<i>Radio(s)</i>	<i>Antenna(s)</i>	<i>Other</i>
<b>CW, HF</b>	Ragchewing, contesting, DXing, traffic handling	CW transmitter/receiver, Transceiver, single or multiband	Ranges from simple fixed wire antennas to tower-mounted rotatable, multi-element Yagis and phased arrays	Antenna tuner (optional) Tower (optional) Rotator (for Yagis) Amplifier (optional) CW key, paddles or keyer
<b>CW, VHF/UHF</b>	Ragchewing, contesting, DXing, satellites	All-mode transceiver	Omnidirectional vertical; long, extended Yagi ("boomer"), quagi or helix (depending on the application)	Tower or roof-mount for antenna desirable, Rotator (for Yagis) Key or paddle and keyer
<b>SSB, HF</b>	Ragchewing, contesting, DXing, traffic handling	SSB transceiver	Ranges from simple wire antennas up to tower-mounted, rotatable, multi-element Yagis and phased arrays	Antenna tuner (optional) Tower (optional) Rotator (for beams) Amplifier (optional)
<b>SSB, VHF/UHF</b>	Ragchewing, contesting, DXing satellites	All-mode transceiver	Omnidirectional vertical, long, extended Yagi ("boomer"), quagi or helix (depending on the application)	Tower or roof-mount for antenna desirable since DX is mostly line of sight Rotator (for Yagis)
<b>AM, HF</b>	Ragchewing	AM or multimode transceiver	Fixed wire or beam antennas	Antenna tuner (optional) Tower (optional) Amplifier (optional) Microphone
<b>FM, HF</b>	Ragchewing, repeaters	Multimode transceiver	Omnidirectional vertical or beam	Antenna tuner (optional) Tower (optional) Amplifier (optional) Microphone
<b>FM, VHF/UHF</b>	Ragchewing, repeaters, contesting	FM or multimode transceiver	Omnidirectional vertical or Yagi	Tower (optional) Amplifier (optional)
<b>Digital</b>	Ragchewing, message handling, data networking, satellites	HF or VHF/UHF transceiver	Omnidirectional or directional	Amplifier (optional) TNC or multimode processor Computer or terminal
<b>Image</b>	Ragchewing	HF SSB transceiver or UHF video transceiver	Omnidirectional or directional	Amplifier (optional) TV camera or image scanner Computer (for SSTV and fax) Demodulator (for SSTV and fax)

ity is voice operation via 2-m FM repeaters. In fact, many amateurs who get their start on the air using 2-m FM and repeaters are unfortunately never exposed to other kinds of operation; they miss the pleasure of using other modes and bands. Considering that it's mainly limited to local contacts, the 2-m band offers reliable communication quality over a reasonably long range. Most VHF and UHF repeaters use FM, a great deal of direct, nonrepeater (simplex) traffic is conducted using FM, and there's an FM segment on the 10-m band (29.2-29.8). Above 30 MHz, virtu-

ally all amateur packet radio is conducted using FM transmissions. Repeater operation typically permits hams to use handheld and mobile transceivers to make clear contacts over ranges of 100 miles or more. FM is a quiet mode, because the technique of angle modulation greatly minimizes the effects of static and noise. The trade-off is that a rather strong signal is needed at the receiver to produce the "quieting" effect that distinguishes FM communications.

Frequency modulation and its sibling, phase modulation, is accurately known as *angle modulation* because the frequency

or the phase of a transmitted signal's carrier can be shifted to provide an "FM" signal. Amateurs use a form of FM called narrowband FM, which is about 3-20 kHz wide. This is just enough to afford decent voice communication. Commercial FM broadcast stations (88-108 MHz in the US) use wideband (200 kHz) FM, which permits transmitted audio frequencies in the range of 50-12,000 Hz.

### SSB

*Suppressed-carrier single sideband*, what we call "single sideband" is an AM

signal from which the carrier and one sideband have been removed. The receiving station picks up the SSB signal, adds a carrier, and converts the RF signal back into voice.

Operators who enjoy making long-distance contacts on the VHF and UHF bands find that SSB is a better choice than FM. Even though there are many more VHF/UHF transceivers on the market that offer only FM, SSB is useful because it's much easier to copy a weak sideband signal than a weak FM transmission. The signal strength needed to quiet an FM receiver is relatively high. With low signal-to-noise ratios, it's nearly impossible to make out the other operator's voice. In conditions where weak signals are common, SSB can provide intelligible audio through a background of considerable noise.

## DIGITAL MODES

Technically, any means of communication based on a simple "black-and-white" value can be considered a digital mode, because it can be expressed with simple whole numbers. A CW transmission can be viewed as a mixture of "on/off" signals, to which we could assign the values 1 and 0. Conversely, a series of 1s and 0s, in the proper order, could signify a Morse code message. In fact, many devices use this technique to encode and decode Morse code communication automatically.

In addition to simply turning a signal on and off, there are other ways to designate those digital 1s and 0s, or changes in *state*. Frequency shift keying (FSK) uses the principle of switching between two frequencies, which are used to designate the *mark* and *space* (on and off state, or digital 1 or 0). FSK is achieved by using a control circuit to switch a transmitted carrier up and down by a few Hz. We can achieve the same result by modulating an SSB transceiver with high- and low-pitched audio signals produce the functional equivalent of true FSK.

The next step toward smooth, effective Amateur Radio communications makes use of machines, specifically, electronic digital computer processing. Fortunately, the FCC permits certain kinds of amateur digital communications because they help provide error-free communications even in difficult conditions.

## RTTY

Before there was radio, there was *teletype* (abbreviated *TTY*), a system of sending printed text by typing on a terminal that was connected by wires to a similar machine. The military began connecting mechanical teletype machines to HF radios during World War II. This was the

birth of *radioteletype*, or *RTTY*. After some experimentation with simple on-off keying, the designers switched to FSK, which proved effective.

In the days before personal computers, enterprising hams obtained inexpensive surplus TTY machines and modified them to provide output signals that could be fed into an SSB transceiver's microphone input. The resulting signals fit within the bandwidth permitted for voice transmissions. A typical modern RTTY installation consists of three parts: a computer, a communications processor and an FSK or SSB transceiver.

In basic radioteletype (RTTY, pronounced **RIT-ee**), the operator types a continuous string of characters on the computer. A terminal program sends the characters through the serial port to the communications processor, which translates the characters into the appropriate mark/space signals as either control signals for an FSK transceiver (or audio tones for the audio input of an SSB transceiver). At the receiving station, the transceiver audio is translated by the communications processor into characters, which are sent to the computer screen via the serial port and terminal program. Amateur Radio operators use several kinds of RTTY.

*Baudot* (named after French engineer Émile Baudot [1845-1903], pronounced **baw-DOE**), is a method of exchanging alphanumeric characters over wires and radio links. Baudot is sometimes referred to as International Teletype Alphabet 2 (ITA2). It produces letters, numbers and a limited number of punctuation symbols with a five-bit code. Because five bits per character permit a limited number (32) of symbols, the alphabet is sent in capital (upper-case) letters. Baudot RTTY is the most widely used form of amateur RTTY on the HF bands.

*ASCII* (an acronym for the American Standard Code for Information Interchange, and pronounced **ASK-ee**) is a form of RTTY that transmits seven bits per symbol. ASCII is the same code used on most modern computers. It contains the entire upper- and lower-case alphabet, punctuation and some special symbols.

## AMTOR

In a standard RTTY transmission, only one station transmits, while the other receives. Characters may be printed incorrectly if the S/N is inadequate. Atmospheric static, fading or noise bursts can garble incoming characters. A partial solution to this challenge is a form of RTTY called *AMTOR* (*Amateur Teleprinting Over Radio*), which uses a computer processor to maintain a virtually error-free

communications link. Instead of one station transmitting while the other passively receives, both stations maintain a link by exchanging transmissions. The sending station sends short bursts of data and the receiving station sends shorter acknowledgment (ACK) bursts between them. Characters are sent in groups of three. The receiving station checks each character, looking for a 4:3 bit ratio. If the ratio is correct for each of the three characters, they are displayed on the receiving terminal and the receiving station sends an ACK, telling the transmitting station to continue. If errors exist, the receiving station sends a negative acknowledgment (NAK) signal, which commands the transmitting station to resend the incorrectly received group.

Because AMTOR runs a continuous validity check on the characters exchanged, it's more reliable than "plain" RTTY, which can produce lots of incorrect text. AMTOR is well suited to traffic handling and passing messages when accuracy is worth a slight trade-off in speed. A disadvantage of AMTOR is that both stations must "hear" each other well, or the communication is reduced to a lengthy exchange of poorly received character groups and NAKs.

## Packet

Packet radio is an error-free mode that uses the complete ASCII character set and supports the transfer of binary data. It is called "packet" because data is not sent as a single, continuous string of characters, but rather transmitted in small bursts, or *packets*. Each packet contains not only the data to be transferred, but also *overhead* information used to route the packets and reassemble them into their original continuous whole. The overhead includes data that identifies the sending and receiving stations, enabling the packet transmission to reach the proper destination. It also provides the FCC-required station identification of the sender.

When two packet stations are exchanging data, they are said to be *connected*. One station sends a packet and then waits a specified amount of time for a reply. The receiving station checks the packet for errors and sends an ACK if the packet is error-free. If not, the receiving station does nothing. When the waiting time expires, the originating station retransmits the packet on the assumption that it did not arrive error-free. Packet stations communicate directly in many cases. If the path is too long to support a direct connection, however, packet relays known as *nodes* or *digipeater*s are used.

Packet radio stations are able to com-

municate with each other because they conform to a standard format, or protocol, described as AX.25. This is a specification derived from a similar protocol, X.25, used by commercial packet networks. AX.25 version 2.0 was approved by the ARRL Board of Directors in 1984; it is the general amateur packet radio protocol currently authorized by the FCC.

Packet data rates are limited to a maximum of 300 bit/s within the Amateur Radio bands below 28 MHz. Even at this relatively slow rate, noise and interference makes efficient packet communication difficult on the HF bands. Unless conditions are good at both ends of the path, packets must be repeated many times before they arrive error-free.

Above 28 MHz, data rates are not so limited. Most VHF packet users operate their systems at 1200 bit/s using 2-m FM. However, networks have been established that use much higher data rates—9600 bit/s and beyond—to link nodes and packet bulletin board systems over a wide area. The most popular networking system is NET/ROM, but there are several contenders such as TexNet, ROSE and TCP/IP. Through these systems the packet-radio network has become accessible to amateurs throughout the nation and the world.

## PacTOR

Two German hams, Hans-Peter Helfert, DL6MAA, and Ulrich Strate, DF4KV, worked together to find a solution to the problems of HF data communication. The result of their effort is a blend of the best parts of packet radio and AMTOR: *PacTOR*.

Helfert and Strate liked AMTOR because it's a simple system that works well with marginal signal-to-noise levels. However, they disliked its inadequate error-correction capabilities, its slow effective maximum data rate (less than

35 bauds) and its use of the five-bit Baudot code character set (all upper-case letters). To make up for the deficiencies of AMTOR, Helfert and Strate devised a new system based on AMTOR that adopted some features of packet radio.

Advantages of PacTOR include:

- An error-correction algorithm called *Memory ARQ*, a method for reconstructing an original block of data by adding

**This suitcase houses a complete portable PacTOR station: transceiver, PacTOR controller, wire antenna and cables, all in one convenient package. Its owner, Joe Mehaffey, K4IHP, of Atlanta, Georgia, connects it to his laptop computer to operate mobile or from almost anywhere he pleases. He even used it to maintain a regular schedule with ham family members and neighbors while traveling around the Australian countryside. (photo by K4IHP)**

together the broken pieces of that block as it's repeated until the block is whole.

- Data-compression techniques (Huffman coding) that can increase the data transfer rate by up to 400% over uncompressed data.
- Compatibility with ASCII and binary data transfers.
- Automatic adjustment of its data rate to compensate for changes in radio conditions.
- Mark or space polarity is inconsequential because it is frequency-shift independent.
- Tolerates interference well, while maintaining the communication link.
- It uses unique addresses (the complete call sign of a station is its PacTOR address).
- Fast, reliable changes of transmission direction and end of transmission confirmation at both ends of a connection.

Like packet and AMTOR, PacTOR is a two-way affair: A transmitting station sends data and a receiving station sends back electronic acknowledgment of each burst of characters. Unlike packet or AMTOR, however, PacTOR dynamically adapts to conditions. Rather than relying on each transmission to provide a solid block of clear characters, PacTOR can accept a series of imperfect or incomplete data segments and "intelligently" attempt to reassemble them into a solid group. In this way, the number of transmissions is reduced because the receiving station may be able to "make out" enough detail from two or three successive bursts to provide an errorless segment of data.

## G-TOR

G-TOR was developed by Kantronics with twin goals: to provide greater throughput on HF channels than AMTOR and PacTOR and to be compatible with existing multimode TNCs. (In spring 1995, only the KAM Plus implements G-TOR. The mode is expected to be implemented on MFJ-1278s later in 1995.) To increase throughput, G-TOR uses Huffman encoding to compress data, Golay forward error correction, a cyclic redundancy check to detect errors, data interleaving and automatic repeat requests to replace data that cannot be corrected. Golay encoding and interleaving work together to provide forward error correction that is effective even when long bursts of bits are corrupted. Headquarters operators have seen G-TOR provide twice the throughput of PacTOR and four times that of AMTOR under difficult conditions. More tests are needed, however. We simply don't have enough data yet to know for sure which technique is best.

**PacTOR is becoming the digital HF mode of choice for many hams. This dedicated PacTOR controller by PacComm also supports Baudot, AMTOR and CW. Many amateurs who once used AMTOR and packet on the bands below 30 MHz have switched to PacTOR for its more robust capabilities.**

## CLOVER

No matter which digital mode you use—packet, AMTOR, PacTOR or RTTY—data communications on the low bands can be a struggle because of the nature of HF. When HF conditions are perfect, almost anything works, but how often are HF conditions “perfect”? Under the less-than-perfect conditions typically encountered, digital modes begin to fail. It used to be that as conditions deteriorated, all that was left was Morse code. But now there’s *CLOVER*. It’s a rather complex system invented for the purpose of relaying files and text on HF bands at higher speeds than packet, with faster throughput and versatile self-adjusting parameters. Developed by Ray Petit, W7GHH, and HAL Communications Corp president Bill Henry, K9GWT, *CLOVER* is named for the cloverleaf waveform it produces when displayed on a monitor scope. *CLOVER* offers improved data communication in the HF spectrum by using a high-speed, bandwidth-efficient modem and an error-correction protocol designed to counteract changing propagation conditions.

HAL Communications implemented *CLOVER* in a hardware/software system called PCI-4000/PC-CLOVER, for IBM-compatible computers (with 80286 CPUs or better). The user plugs a PCI-4000 board into one PC expansion slot and installs the *PC-CLOVER* software on the computer’s disk drive, connects the *CLOVER* card to an HF transceiver, and is ready to go on the air.

On-air experience and tests indicate that the current version of *CLOVER* can reli-

ably pass error-corrected 8-bit data on HF at rates of 10-60 bytes/second. Under average conditions, throughput is in the 20-40 bytes/second range—1.5-10 times faster than AMTOR, PacTOR or HF packet.

The *CLOVER* system includes an “AUTO-ARQ” mode that provides a three-pronged attack against the problems caused by HF data signal distortion. This forward-error-correction will correct as many as 31 bytes of erroneous data for every 188 bytes of transmitted data, without requiring repeat transmissions. (AMTOR, PacTOR and packet correct errors only by retransmitting data.) When erroneous data exceeds 31 of 188 transmitted bytes, only the damaged data blocks are repeated. (AMTOR and PacTOR repeat all the data of a transmitted pulse, even for one character error.)

The *CLOVER* modem samples the characteristics of each received block of data (the signal-to-noise ratio, frequency offset and phase dispersion) to determine the current operating conditions. With this information, *CLOVER* optimizes the other station’s transmitting parameters to match the measured conditions. (AMTOR and packet have no adaptive capabilities, and PacTOR uses an adaptive algorithm.)

AUTO-ARQ is available in three flavors, or “bias” settings, for three types of band conditions. For average HF conditions, the “normal” bias setting offers a good balance between error correction, data rate and throughput. For extreme HF conditions, the “robust” or “fast” bias settings are available. The robust bias setting

provides the greatest degree of error correction, but to achieve this, throughput is decreased. Robust bias is recommended for fixed-frequency operation (below 7 MHz) where maintaining a connection over an unstable path is more important than the amount of data throughput. For ideal conditions (stable paths at frequencies near the MUF), the fast bias setting provides reduced error correction, greater data rates and maximum data throughput.

The PCI-4000 board includes a DSP560001 digital signal processor and a 68EC000 control processor, which perform the *CLOVER* modem and protocol processing. New PCI-4000 software is downloaded to the board from your PC, making software upgrades simple, with no need to replace ROM or EPROM chips. The *PC-CLOVER* software provides a menu-driven, split-screen user interface for *CLOVER* communications. Third-party software writers have written *CLOVER* bulletin board software, and *CLOVER* BBSs (CBBSs) are well established on the HF bands.

There are many advantages and unique features in a *CLOVER* system. For example, if conditions and propagation permit a high-quality link between two *CLOVER* stations, they can automatically signal each other to lower power and increase the data-transmission speed. Under poor conditions, a station can request the other to increase power and lower transmission speed to try to reduce errors. At this writing, *CLOVER* is implemented in hardware only. This means that it’s sold as a special plug-in card that goes into a stan-

Bill Henry, K9GWT, and Ray Petit, W7GHH, are the fathers of *CLOVER*, an extraordinarily powerful mode of digital communication. It’s an adaptive, error-correcting mode that can pass information over long-distance radio links under severe conditions of poor propagation. This is the original *CLOVER* adapter, the HAL PCI 4000, a one-slot add-on board for IBM-compatible personal computers.

**Hams can say "I'll fax you" with ease, by using a home computer with the right hardware and software. Ralph Taggart, WB8DQT, of Mason, Michigan, transmitted this picture of his daughter Jennifer with a system that doubles as a slow-scan TV adapter. (photo by WB8DQT)**

dard expansion slot in an IBM-compatible personal computer.

### Image—FSTV, SSTV and Fax

Amateur television (ATV) comes in two main categories: fast-scan TV (FSTV) and slow-scan TV (SSTV). ATV allows hams to send television pictures over the airwaves. SSTV originated earlier; it is a technique used to send color or black-and-white still pictures over HF, using bandwidth comparable to that used by SSB voice. Because of the large amount of information required to transmit a video image, the bandwidth restrictions for HF operation limit the mode to still pictures. FSTV, on the other hand, is used on the UHF bands, where the FCC permits hams to use much broader bandwidths. Therefore, a UHF FSTV picture can be a real-time moving picture.

Many amateur TV experimenters use home camcorders to supply the input to their FSTV transmitters. Watching a received FSTV signal looks almost the same as a commercial TV broadcast. In fact, some FSTV enthusiasts outfit their stations with "professional" video and processing equipment, such as cameras, monitors, switchers, special-effects devices and computers to control and manipulate images. There are numerous FSTV repeaters around the US.

*Fax* is an additional form of image communications. Fax is an abbreviation for *facsimile*, a form of transmission that sends a visual "photocopy" of a two-dimensional image, such as a piece of paper, a photograph or a diagram. The first fax machines were mechanical devices with paper wrapped around a rotating drum, or scanned by a moving light source. The light and dark spots on the paper (that

is blank space and typewritten characters) were converted to electrical impulses. These impulses were sent along wires to a receiving device that converted the impulses back into an image on paper.

Modern amateur faxes are sent using PCs and special software. The images may be almost any computer file format. Images are often created by using a device called a scanner to convert a printed image into a digital format. The software converts the image into audio tones that are sent via the transmitter for decoding at the receiving end. The receiving station can display the faxed image on a computer monitor screen or printer. Fax images can also be "captured" as they are received and saved to a disk file for later access (for example viewing, printing, resending, modification). When a fax transmission begins, the receiving station must be tuned in and listening so that it can receive and decode the synchronization data sent at the beginning of the fax. Without the sync data, the receiving station can't properly interpret the image. This presents a challenge: In voice, Morse code, RTTY, packet or ATV, the operator may identify his or her station using that mode. Faxing is different: The FCC doesn't accept a faxed station identification as a fulfillment of the legal requirement to identify at least once every 10 minutes during a transmission, and interrupting a fax transmission to send a Morse code or voice identification causes the transmitting and receiving stations to lose synchronization. Because faxes can take a long time to transmit, new operators must learn what size file can be faxed in the span of 10 minutes before the transmission must be interrupted to send the required station identification.

### SPREAD SPECTRUM

Each mode has its limits. Whether it's voice, Morse code, visual images or computer data, only a particular, calculable quantity of information can be transmitted via Amateur Radio. This limit is imposed by the laws of physics, FCC regulations, or both, or by the state of technology (or its cost). Two obstacles to sending greater amounts of information are bandwidth and frequency congestion. *Spread spectrum* implies the use of a wide bandwidth, and that's correct, in a way. It doesn't mean that a station transmits a single "wide" signal, but that it slices a whole band into a belt of frequencies that it can use virtually simultaneously. Although a signal is actually present only on one frequency at a time, the effect is that of having a whole band to operate within.

The bandwidth of an amateur emission is restricted by FCC specifications. A signal may only take up a given amount of space. If so much information is to be carried that the transmitted signal becomes too broad, it reduces the number of stations that can use a band. If several stations wish to transmit simultaneously on one part of a band, one of two things happens: They interfere with each other or they must take turns, thereby reducing the total amount of information that can go through each RF circuit over a period of time.

On the other hand, what if a station could transmit information over a wide range of radio frequencies, but use only one at a time? Assuming the transmitter and receiver were synchronized, a signal could jump from one frequency to another in a matter of milliseconds. Each "hop" would last a mere blink of an eye (or actually, much less time than it takes a human to blink an eye). Now several stations could occupy the same bandwidth at the same time, as long as their respective hops didn't coincide too often. With the proper electronic processing (computer hardware and/or software), each pair of stations could have the equivalent of a whole band to themselves. And several pairs of stations could see almost the same "free space" on a band because the only time they would be aware of each other would be if a random hop happened to coincide. Mathematical formulas can be used to minimize the odds of frequent "collisions" and a list of specific "plug-in" frequency schedules could be used to allow outsiders to monitor a frequency-hopping QSO or to locate and respond to a CQ. (In fact, the FCC has stated that hams may use only a narrow range of spread-spectrum schemes. This makes it possible to monitor such operations. It also precludes hams from using protocols that might effectively amount to data encryption.)

Spread spectrum remains largely an experimental mode. It's limited to certain frequencies and methods of implementation, and requires equipment and designs that are on the edge of radio technology. Advanced amateur and commercial development, however, may lead to wider use of this technique of conserving limited radio spectrum.

### ACSSB

Amplitude-Companded Single Sideband uses a suppressed-carrier, single-sideband AM signal passed through a compressor and an expander. This is an experimental mode in which voice audio is "compressed" electronically to mini-

mize its bandwidth, then transmitted as SSB signals over the air. The receiving station "expands" (uncompresses) the audio back to its original bandwidth. The theory is that a high-quality audio signal can be passed over a narrow radio bandwidth, which provides good communication while conserving spectrum

space. For ACSSB to work, the sending and receiving stations must operate in nearly perfect synchronization. Extremely stable transmitters and receivers must be used to make the compression-expansion "loop" work. Most radio equipment capable of such stability isn't commercially available at typical "amateur" prices.

Variations of only a couple of Hz can make a mess of the received audio, and the effects of fading and frequency drift can render the system almost unintelligible. When it works properly, though, ACSSB provides a good audio link. Most ACSSB experimentation in Amateur Radio is performed on VHF and UHF.

## Glossary

**ACK**—An abbreviation for "acknowledgment." AMTOR and PacTOR stations exchange ACKs to verify that information has been received without errors.

**ACSSB**—Amplitude Companded Single Sideband. A narrow-bandwidth, low-noise AM mode designed to compete with narrow-bandwidth FM in the Land Mobile Radio Service.

**AM**—Amplitude modulation. Full AM transmissions use a full carrier with two modulated sidebands, however, SSB and ACSSB are both AM modes.

**AMTOR**—Amateur Teleprinting Over Radio. A popular method of digital communication on the HF bands.

**ASCII**—American Standard Code for Information Interchange. A standard method of encoding data so that it can be understood by many computers.

**AX.25**—The Amateur Radio version of the CCITT X.25 packet protocol (x.25

is used for computer communications over telephone lines).

**Bit**—A binary digit, 0 or 1, mark or space.

**Connect**—To establish a data communications link between two packet stations.

**CW**—Continuous wave. A transmission consisting of an unmodulated carrier.

**Digipeater**—Digital repeater. A device that receives, temporarily stores, and then retransmits packet radio transmission directed specifically to it.

**DXing**—Operation to contact far-distant stations (foreign countries on HF, beyond the radio horizon on VHF and higher bands).

**FM**—Frequency modulation. A form of modulation where the RF carrier shifts frequency according to the amplitude of the modulating audio signal.

**FSK**—Frequency shift keying. Modulating a transmitter by using data signals to

shift the carrier frequency. Commonly used for digital transmissions.

**NAK**—An abbreviation for "nonacknowledgment." AMTOR and PacTOR stations exchange NAKs to request retransmission of data (due to errors).

**Node**—A junction point in a packet network where data is relayed to other destinations. A node can support more than one user at a time and operate on several different frequencies simultaneously.

**TNC (terminal node controller)**—Software or hardware that processes packets.

**RTTY**—Radioteletype. A method of sending text information using shifting MARK/SPACE signals or audio tones.

**SSB**—A form of amplitude modulation (AM) in which the carrier and one sideband are removed.

**Yagi**—A multielement antenna made up of one driven element and one, or more, parasitic elements.

# Mathematics for Amateur Radio

sooner or later, most hams will find they need to make some sort of measurement or perform a calculation as part of their hobby. This is true whether they are calculating an antenna length or designing a new piece of station equipment. When they do, they will be using mathematics. The math skills required for most electronics calculations

can be developed and used by just about anyone.

This chapter, written by Larry Wolfgang, WR1B, provides a brief review of the most important math concepts needed for electronics and Amateur-Radio-related use. It will serve as a refresher for those hams who may have been

familiar with the topics, but who have long since forgotten how to apply them. The examples will also help those who have no prior math background to work through many of the calculations associated with this *Handbook*. Those readers who would like a more detailed explanation should turn to the Math Unit of ARRL's *Understanding Basic Electronics*.

## Mathematical Terms and Symbols

Mathematics uses letters, symbols and odd-looking characters to represent various quantities in a kind of short-hand notation we call equations. To those unfamiliar with the language of mathematics, these strange names and symbols can be very confusing. Once you have learned some basic terms and understand what the symbols represent, the elegance of an equation can begin to come through. In this section we will introduce some of the most common mathematical terms and symbols.

### DEFINITIONS OF MATHEMATICAL TERMS

**Algebra**—The branch of mathematics that uses letter symbols to represent various quantities, and which establishes rules for manipulating these expressions. Much of the discussion in this chapter involves the rules of algebra.

**Binary number system**—A number system that uses only two symbols, 0 and 1. The binary system is very useful in digi-

tal electronics, because most digital electronics circuits only have to measure two voltage or current conditions: **on** or **off**. Most of these circuits represent the **on** condition as a 1 and the **off** condition as a 0. (See also **Decimal number system**, **Hexadecimal number system** and **Octal number system**.)

**Cross multiplication**—The most common equation-solving technique used with proportions. This involves moving terms diagonally across the equal sign. We can use the letters a, b, c and d to represent four terms of a proportion:

$$\frac{a}{b} = \frac{c}{d}$$

Then by cross multiplication, we can also write the following equivalent expressions:

$$ad = bc \text{ and } \frac{a}{c} = \frac{b}{d}$$

**Cube**—Multiplying a number or quantity by itself three times. Cubing a quantity

means it is raised to the third power, or has an **exponent** of 3. ( $2^3 = 2 \times 2 \times 2 = 8$ )

**Cube root**—That value which, when multiplied by itself three times, gives the value whose cube root you want to find. ( $\sqrt[3]{8} = 8^{1/3} = 2$  and  $\sqrt[3]{-8} = -8^{1/3} = -2$ ) Odd powered roots have only one possible value.

**Decimal number system**—A number system that uses ten symbols, 0 through 9, to count, measure and calculate. The most common number system. (See also **Binary number system**, **Hexadecimal number system** and **Octal number system**.)

**Equation**—A statement of mathematical balance. All that appears on one side of the equal sign (=) is equivalent to any expression on the other side. The two sides usually don't appear identical ( $2 = 2$ ), but the expression on one side represents the expression on the other side ( $x = 2$ ). The  $x$  here represents a **variable**, or unknown quantity.

**Exponent**—A value following a number, raised above the line of the number, or written as a *superscript*, to show the number is to be multiplied by itself. ( $10^3$  indicates that 10 is to be multiplied by itself three times —  $10 \times 10 \times 10$ ). The rules of working with exponents are covered later in this chapter.

**Formula**—Another name for an *equation*, especially when it represents a procedure used to calculate some quantity. ( $E = IR$  is a formula that tells us to multiply current times resistance to find voltage.)

**Hexadecimal number system**—A number system that has 16 characters; labeled 0 through 9, A, B, C, D, E and F. The hexadecimal system (often abbreviated *hex*) is convenient for use with digital computers because hexadecimal digits can be coded as groups of four binary digits. In this case, 0001 represents hex 1, 1000 represents hex 8, 1010 represents hex A and 1111 represents hex F. (See also *Binary number system*, *Decimal number system* and *Octal number system*.)

**Infinity**—The term used to describe the mathematical concept of having no boundaries. There is no “largest number” or “smallest number,” because you can always add 1 to obtain a larger number, or further divide to obtain a smaller one.

**Integers**—The “counting numbers,” such as 1, 2, 3, 4, 5. Integers also include negative values. The number line of **Fig 4.1** is helpful to picture positive and negative integers. (See also *Real numbers*.)

**Octal number system**—A number system that uses eight characters, 0 through 7. This system is often used with digital computers, because groups of three binary digits can be coded to represent an octal digit. For example, 001 represents octal 1, 010 is the same as octal 2 and 111 represents octal 7. (See also *Binary number system*, *Decimal number system* and *Hexadecimal number system*.)

**Power of 10**—The exponent used with 10 when a number is written in exponential

or scientific notation. The exponent tells how many places and in what direction the decimal point is moved.

**Proportion**—Two ratios that are equal to each other (or both equal to the same quantity). Proportions are a powerful mathematical tool because you can often write an equation to calculate some unknown quantity based on your knowledge of another ratio. Proportions are useful because when you know three of the four quantities, it is a simple matter to find the fourth. Later in this chapter we show you how to use proportions to convert between US Customary and metric system measurements.

**Radical sign**— $\sqrt{\quad}$ . A symbol written with a number or mathematical expression under the line, to represent a square root, such as  $\sqrt{4} = 2$ . If there is a superscript number in front of the radical sign, then it represents the root indicated.

$$\sqrt[3]{8} = 2$$

**Ratio**—A fraction, with one quantity divided by another. The value of  $\pi$  is the

**Table 4.1**

**The Greek Alphabet and Common Electronics Quantities**

<i>Greek letter</i>	<i>Pronunciation</i>	<i>Upper Case</i>	<i>Common Use</i>	<i>Lower Case</i>	<i>Common Use</i>
Alpha	'al-feh	A	Angle of a triangle	$\alpha$	Transistor common-base current gain
Beta	'bā t-eh	B	Angle of a triangle	$\beta$	Transistor common-emitter current gain
Gamma	'gam-eh	$\Gamma$	Transmission line voltage reflection coefficient	$\gamma$	Phase
Delta	'del-teh	$\Delta$	Change in quantity	$\delta$	
Epsilon	'ep-seh-lān	E		$\epsilon$	Dielectric constant, permittivity
Zeta	'zāt-eh	Z		$\zeta$	
Eta	'āt-eh	H		$\eta$	
Theta	'thāt-eh	$\Theta$	Angles	$\theta$	Angles
Iota	i-'ot-eh	I		$\iota$	
Kappa	'kap-eh	K		$\kappa$	
Lambda	'lam-deh	$\Lambda$		$\lambda$	Wavelength
Mu	myū	M		$\mu$	Metric prefix for $10^{-6}$ , permeability
Nu	nū	N		$\nu$	
Xi	ksi	$\Xi$		$\xi$	
Omicron	'ām-eh-krān	O		$\omicron$	
Pi	pī	$\Pi$		$\pi$	3.14159 (ratio of circumference to diameter of a circle)
Rho	rō	P		$\rho$	Transmission line reflection coefficient, resistivity
Sigma	'sig-meh	$\Sigma$	Summation of a series	$\sigma$	
Tau	tau	T		$\tau$	Time constant, LC circuits
Upsilon	'yūp-seh-lān	Y		$\upsilon$	
Phi	fi	$\Phi$	Angles	$\phi$	Angles
Chi	ki	X		$\chi$	
Psi	si	$\Psi$		$\psi$	
Omega	o-'meg-eh	$\Omega$	Ohm, resistance, normalized frequency	$\omega$	Frequency in radians per second ( $2\pi f$ ), angular velocity

ratio of the circumference of a circle (C) to the diameter of the circle (d), for example.

$$\left(\pi = \frac{C}{d}\right)$$

Voltage standing-wave ratio (VSWR or SWR) is the ratio of maximum voltage on a feed line to the minimum voltage on the feed line. Written as a fraction, we use this ratio to form an equation that shows one way to calculate SWR:

$$SWR = \frac{V_{\max}}{V_{\min}}$$

**Real numbers**—All possible numbers, including all the fractions between integers. (Fractions can be written as a ratio of two numbers, or as a decimal value that is the result of the division. 4.5 and  $4\frac{1}{2}$  represent the same real number. The decimal value is often only an approximation, however, such as 6.333 and  $6\frac{1}{3}$ .)

**Reciprocal**—A quantity divided into 1 (often written as  $1/x$ ). Reciprocals are so important that the quantity is often given a name of its own. For example, in electronics, the reciprocal of resistance is called conductance. Using letter symbols to represent the quantities (R is resistance and G is conductance).

$$\left(\frac{1}{R} = G \text{ and } \frac{1}{G} = R\right)$$

**Root (of a number)**—A value which, when multiplied by itself the specified number of times, gives the value whose root you want to find. Most common in electronics is the **square root** of a number, and occasionally the **cube root**. Roots may be written with

a **radical** sign ( $\sqrt{\quad}$ ) or as a fractional **exponent**. ( $\sqrt{4} = 4^{1/2} = 2$ )

**Square**—Multiplying a number or quantity by itself. Squaring a quantity means it is raised to the second power, or has an **exponent** of 2. ( $2^2 = 2 \times 2 = 4$ )

**Square root**—That value which, when multiplied by itself, gives the value whose square root you want to find. Actually, there are two values for a square root. ( $\sqrt{4} = 4^{1/2} = +2$  and  $-2$ ) Even-powered roots have both the positive and negative values possible.

**Subscript**—A number or expression following a variable, written slightly lower than the line of the variable;  $R_1$ ,  $R_2$ ,  $E_3$  and  $E_4$  are examples of quantities with subscripts to distinguish similar, but different quantities.

**Superscript**—A number or expression written following a number or variable, written slightly higher than the line of the number or expression;  $5^2$ ,  $x^3$ ,  $(25 + I)^2$  and  $E^2$  are examples of expressions with superscripts.

**Variable**—An expression that can take on different values. Variables are sometimes given **subscripts**.

## GREEK ALPHABET

Upper- and lower-case characters of the Greek alphabet are often used to represent various measurements and constant values. Few English-speaking people are familiar with Greek, so some of these characters can look pretty strange. **Table 4.1** shows the upper and lower case Greek alphabet, the character pronunciations, and the electrical and electronics quantities some of these characters often represent.

## TABLE OF MATHEMATICAL SYMBOLS

In addition to Greek characters and other letter symbols, there are many special math symbols used when we write equations. **Table 4.2** shows many of these common math symbols.

**Table 4.2**

### Some Common Mathematical Symbols

Symbol	Meaning
+	Addition, plus
−	Subtraction, minus
±	Plus or minus
×, •, *	Multiplication, multiply by
÷, /	Division, divide by
=	Equal to
≠	Not equal to
≈	Approximately equal to
~	Similar, equivalent
<	Less than
≤	Less than or equal to
>	Greater than
≥	Greater than or equal to
:	Ratio of, is to
∝	Proportional, varies directly as
∴	Therefore
°	Degree
∠	Angle
⊥	Right angle
⊥	Perpendicular to
∥	Parallel to
≡	Identical to
∞	Infinity
√	Radical, square root (Also written with a superscript before the symbol to express other roots, such as $\sqrt[3]{\quad}$ to represent a cube root.)
∫	Integration
Σ	Summation

**Fig 4.1** — The number line gives us a way to represent all numbers, both positive and negative, and is useful for remembering arithmetic operations.

# Significant Figures and Decimal Places

Any measurement is only as good as the measuring instrument used, and as reliable as the person making the measurement. The *accuracy* of a measurement refers to how close the value is to an accepted value or standard. You might use a dip oscillator to measure the resonant frequency of a radio circuit. The measured value will probably not be very accurate, since dip oscillators are usually designed only to measure a general range. If you want to ensure that your transmitter is operating inside the amateur band edge, you might try a frequency counter or crystal calibrator, for example. So the measuring instrument plays the greatest role in determining the accuracy of a measurement. (This assumes the person taking the measurement understands how to use the instrument to take full advantage of it. An operator who does not know how to use or read the instrument properly will not obtain accurate measurements!)

*Precision* refers to the repeatability of a

measurement. You might take five frequency readings using the dip meter mentioned above, with all five readings being 7.14 MHz. This set of measurements would have good *precision*, but because the instrument is not designed for high *accuracy*, you can't be sure of the actual frequency. Other factors might affect the precision of a measurement, such as the operator's skill at adjusting the measuring instrument, errors in reading the scale and the operation of the instrument itself.

The value you can read from the scale of a measuring instrument helps determine its precision. If you are using a ruler marked off only to the nearest quarter inch, you may be able to estimate measurements to an eighth inch, but you certainly can't read that scale to the nearest thirty-second of an inch! It will be difficult to measure two objects that differ in length by a sixteenth of an inch with this ruler. Precision also indicates the *resolution* of a measurement, or how small a change can really be detected.

The *significant figures* of a measurement represent all the digits that you can read directly from the scale, plus one digit that is estimated. **Fig 4.2** shows a voltmeter scale marked from 0 to 10 V, with lines indicating every 0.2 V. You can see that the needle indicates a value between 4.6 and 4.8 V, and perhaps you can even tell if the needle is more or less than half way between the marks. You know the reading is a little less than 4.7 V, but you really can't be sure how much less. You can estimate that the reading is 4.68 perhaps, but the 8 can't be read directly from the scale. Someone else might look at the same reading on the same meter and estimate the value at 4.67 V or even 4.69 V. None of these readings is more correct than any other, because each represents an *estimate* of the value of the last digit. This reading has three significant figures.

Any calculations made involving this

measurement are limited by the accuracy of the reading. It would be completely unreasonable to say that 4.68 V produces a current of 17.01818 mA when connected to a 275- $\Omega$  resistor, even though your calculator shows all these digits.

The rules of significant figures tell us how many digits to include in any calculation based on a measured quantity. They also help us predict the accuracy of a calculation based on real component tolerances. These rules allow us to specify the accuracy of the calculated value, as it relates to the measurements on which the calculation is based. There are six rules to tell you how to count and write significant figures in a measured or calculated quantity.

1. All nonzero digits are significant: 275.4 mA has four significant digits.
2. All zeros between nonzero digits are significant: 25.004 m has five significant digits.
3. Zeros to the right of a nonzero digit, but to the left of an understood decimal point are not significant unless they are specifically indicated to be significant. You can indicate such zeros to be significant by drawing a bar over the rightmost significant zero: 21100000 hertz has three significant figures; 21100000 hertz has five significant figures.
4. Zeros to the right of a nonzero digit, but to the left of an expressed decimal point are significant: 21100. kHz has five significant figures.
5. Zeros to the right of a decimal point but to the left of all nonzero digits are not significant: 0.001702 A has four significant figures. (There is a zero before the decimal point to indicate that no digits to the left of the decimal point were dropped. Also notice that the zero between the 7 and the 2 is significant — remember rule 2.)
6. All zeros to the right of a decimal point and following a nonzero digit are significant: 2.00 V has three significant figures.

There are a few rules for determining the number of significant figures that result when you use measured values in a calculation. These rules are important to ensure that you don't imply a result to a greater precision than the measurements would allow.

Notice we said *measured* values here. Never use the number of digits in the value of a physical constant to limit the number of significant figures in a calculation. For example, the constant 2 or the value of  $\pi$  won't limit the number of significant fig-

**Fig 4.2** — This voltmeter scale reads from 0 to 10 V, with marks every 0.2 V. The meter is reading a value greater than 4.6 but less than 4.7 V. With care you may be able to estimate the reading as 4.68 V, but the digit 8 really only represents a guess. That digit is uncertain because you cannot read it directly from the scale.

**Fig 4.3** — This parallel circuit has four branches connected to the battery. Ammeters measure the current through the branches, with the readings indicated. This circuit illustrates measurements with two, three and four significant figures ( $I_1$  and  $I_4$ ,  $I_2$ ,  $I_3$  respectively).

ures in a calculation of reactance. ( $X_L = 2\pi fL$ ) Likewise, values of trigonometric functions and logarithm values aren't usually limited by the number of significant figures in the number used to find the function value.

When adding or subtracting measurements, remember that the rightmost significant figure represents an uncertain value. The rightmost significant figure in a sum or difference calculation occurs in the leftmost place that an uncertain value occurs in any of the measured quantities. The following example illustrates this rule.

**Fig 4.3** shows a parallel circuit with four branches. Ammeters measure the current through each branch. The four current measurements are 1200 mA, 256 mA, 105.4 mA and 780 mA. What is the total current supplied to this circuit? The first measurement has only two significant figures, and the hundreds column represents an uncertain value. The second measurement has three significant figures and the units column is uncertain. The third current has four significant figures, with the tenths column being uncertain. The last current value has two significant figures, and the tens column is uncertain. **Fig 4.4** shows how to determine the last significant place in the answer. Round off the result of this addition to the hundreds place, so this circuit has a total current of 2300 mA. (The rules for rounding numbers are covered later in this section.)

When you multiply or divide measured quantities, the answer cannot have more significant figures than the least precise factor. As an example, use Ohm's Law to calculate the resistor values in **Fig 4.3**. **Fig 4.5** shows how to determine the significant figures for these calculations.

## ROUNDING VALUES

After you determine which digit is the last significant figure in a calculation, you will have to round off the arithmetic answer. Four rules govern how to round off values properly.

1. If the first digit to be dropped is 4 or less, the preceding digit is not changed: 456351 rounded to three significant figures becomes 456000 (with no decimal point at the end).
2. If the first digit to be dropped is 5 or more, the preceding digit is increased by 1: 456351 rounded to two significant figures becomes 460000 (with no decimal point at the end).

3. If the digits to be dropped are 5 followed by digits other than zeros, the preceding digit is increased by 1: 456351 rounded to four significant figures becomes 456400 (with no decimal point at the end).
4. If the digits to be dropped are 5 followed by zeros (the digit to be dropped is exactly 5) the preceding digit is *not* changed if it is even; it is raised by 1 if it is odd: 456350 rounded to four significant figures becomes 456400 but 456450 rounded to four significant figures also becomes 456400 (with no decimal point at the end). (Another way to think of this rounding rule is that when the digit to be dropped is exactly 5, we round to the *even* value.)

$  \begin{array}{r}  1200 \text{ mA} \\  256 \text{ mA} \\  105.4 \text{ mA} \\  + 780 \text{ mA} \\  \hline  2341.4  \end{array}  $		Left most uncertain value in measurements
$  \begin{array}{r}  2341.4 \\  2300  \end{array}  $		Right most significant figure in answer
2300		Total current value rounded off to show the hundreds column as the last significant figure

**Fig 4.4** — This calculation shows the proper use of the rule for addition and subtraction using significant figures. The current measurements from **Fig 4.3** are added to calculate the total circuit current. The resulting value is then rounded off to make the hundreds column the last significant figure.

### Three Significant Figures

$$R_1 = \frac{E}{I_1} = \frac{24.0 \text{ V}}{1200 \text{ mA}} = \frac{24.0 \text{ V}}{1.2 \text{ A}} = 20. \Omega$$

Two Significant  
Figures

Two Significant  
Figures

### Three Significant Figures

$$R_2 = \frac{E}{I_2} = \frac{24.0 \text{ V}}{256 \text{ mA}} = \frac{24.0 \text{ V}}{0.256 \text{ A}} = 93.75 \Omega = 93.8 \Omega$$

Three Significant  
Figures

Three Significant  
Figures

### Three Significant Figures

$$R_3 = \frac{E}{I_3} = \frac{24.0 \text{ V}}{105.4 \text{ mA}} = \frac{24.0 \text{ V}}{0.1054 \text{ A}} = 227.70398 \Omega = 228 \Omega$$

Four Significant  
Figures

Three Significant  
Figures

### Three Significant Figures

$$R_4 = \frac{E}{I_3} = \frac{24.0 \text{ V}}{780 \text{ mA}} = \frac{24.0 \text{ V}}{0.78 \text{ A}} = 30.76923 \Omega = 31 \Omega$$

Two Significant  
Figures

Two Significant  
Figures

**Fig 4.5** — These calculations show the proper use of the rule for multiplication and division using significant figures. The battery voltage and current measurements from **Fig 4.3** are used to calculate the four resistor values. The resulting values are rounded off to show the proper number of significant figures.

# Laws of Exponents

Exponents tell how many times a number or quantity is to be multiplied by itself. Equations often involve terms that include exponents. Two special cases with exponents are worth mention before we cover the rules for mathematical operations with exponents:

$$a^1 = a \text{ and } a^0 = 1$$

Any value raised to a power of 1 gives the value itself, and any value raised to the zero power is 1. We can also use numbers to give a few examples:

$$10^1 = 10, 5^1 = 5 \text{ and } 3^1 = 3$$

$$10^0 = 1, 5^0 = 1 \text{ and } 3^0 = 1$$

When you know the basic rules of algebra involving exponents, you will be able to manipulate the terms in an equation. There are only a few rules to remember, and they involve multiplication and division of numbers with exponents.

1. If you are adding, subtracting, multiplying or dividing two numbers involving exponents, calculate the values indicated by the exponents first, then perform the indicated operation on the numbers:

$a^x \times b^y$  can't be simplified unless you know the values of the variables.

$$2^3 \times 4^2 = 8 \times 16 = 128$$

2. If the multiplication involves a variable raised to different exponents, you can add the exponents:

$$a^x \cdot a^y = a^{x+y}$$

$$2^3 \cdot 2^4 = 2^{3+4} = 2^7 = 8 \cdot 16 = 128$$

Notice the "multiplication dot" used in this example. It is also common practice to omit any symbol when multiplication of variables is intended, and there is no chance of confusion, such as would occur if you were writing two numbers:

We can write this as  $a^x a^y = a^{x+y}$  but we would not write 8 16 to indicate  $8 \cdot 16$ .

3. For division of a variable with exponents, subtract the denominator (bottom of the fraction) exponent from the numerator exponent.

$$\frac{a^x}{a^y} = a^{x-y}$$

(This is only true if  $a \neq 0$ )

$$\frac{2^4}{2^2} = 2^{4-2} = 2^2 = 4$$

As another example, the denominator exponent can be larger than the numerator exponent, resulting in a calculation with a negative exponent:

$$\frac{2^2}{2^4} = 2^{2-4} = 2^{-2} = 0.25$$

A negative exponent indicates you are to find a **reciprocal** of the quantity. We could also write the example above as:

$$\frac{1}{2^{4-2}} = \frac{1}{2^2} = \frac{1}{4} = 0.25$$

From the examples shown here, you should notice a related rule of exponents. Any factor with an exponent can be moved between the numerator and denominator of a fraction simply by changing the sign of the exponent. You will probably want to use a calculator to raise numbers to various powers. This will be much easier than doing the repeated multiplications by hand.

4. To raise a number with an exponent to some power, multiply the exponents.

$$(a^x)^y = a^{x \cdot y}$$

$$(2^3)^2 = 2^{3 \cdot 2} = 2^6 = 64$$

5. The product of two variables raised to a power is the same as raising each variable to the power and then finding the product.

$$(a \cdot b)^m = a^m \cdot b^m$$

$$(2 \cdot 4)^3 = 2^3 \cdot 4^3 = 8 \cdot 64 = 512$$

6. The ratio of two variables raised to a power is the same as the ratio of each variable raised to the power.

$$\left(\frac{a}{b}\right)^m = \frac{a^m}{b^m}$$

(This is only true if  $b \neq 0$ )

$$\left(\frac{4}{2}\right)^3 = \frac{4^3}{2^3} = \frac{64}{8} = 8$$

A quantity or expression can also have an exponent, indicating the entire quantity is to be multiplied by itself:  $(3x + 12)^2$  means the quantity inside the parentheses is to be multiplied by itself. Calculating *squares* and *cubes*, *square roots* and *cube roots*, are common mathematical operations.

## EXPONENTIAL AND SCIENTIFIC NOTATION

Electronics measurements and calculations often involve numbers that are very large or very small. We can represent the metric prefixes as multiples of 10. It is also convenient to use multiples of 10 to represent very large and very small numbers. Any number expressed as some multiple of 10 is written in *exponential notation* (sometimes called *engineering notation*) because the 10 is written with an *exponent*. This exponent, often called a power

of 10, represents how many times the number is multiplied by 10 to write it in *exponential notation*, or the "normal" format.

We can write 250000 in exponential notation as  $25 \times 10^4$ . All we had to do here was replace the four zeros with " $\times 10^4$ ." As another example, we can write 0.000025 as  $25 \times 10^{-6}$ . In this case we would have to divide 25 by 10 six times. A negative exponent means divide. If you move the decimal point to the right when you write the number in exponential notation, then use a negative exponent.

A number expressed with a single digit to the left of the decimal point and a power of 10 is written in *scientific notation*. This is just a particular form of engineering notation.

We could write the speed of light as 300000000 meters per second, for example, but it is more convenient to write this number as  $3 \times 10^8$  meters per second. Notice that this number indicates one significant figure. If you wanted to indicate three significant figures, for example, you would write it as  $3.00 \times 10^8$  meters per second.

You may see several other forms of exponential notation. Sometimes an E is written in place of the 10. ( $3.56E6 = 3.56 \times 10^6$ ) Other times a P is used to represent a positive power of 10 while an N represents a negative power of 10. ( $3.56P6 = 3.56 \times 10^6$  and  $2.44N3 = 2.44 \times 10^{-3}$ )

To write any number in scientific notation, first move the decimal point so there is one nonzero digit to the left of the decimal point. Then count how many places left or right you moved the decimal point. You will use this number as the exponent in the " $\times 10$ " factor. If you moved the decimal to the left, use a positive exponent and if you moved the decimal to the right, use a negative exponent.

$25.40 \times 10^3$	
$+ 0.05 \times 10^3$	
$31.60 \times 10^3$	
(A)	
$25.40 \times 10^{-3}$	
$- 6.15 \times 10^{-3}$	
$19.25 \times 10^{-3}$	
(B)	

**Fig 4.6 — Examples of addition and subtraction with numbers written in exponential notation. Be sure all the numbers have the same power of 10, and then write the numbers so the decimal points align. Add or subtract the number part, and use the common power of 10 with the answer.**

## Arithmetic Operations with Scientific Notation

One advantage of writing very large and very small numbers in exponential notation is that you don't have to keep track of so many zeros during arithmetic operations. When you work with numbers written in exponential or scientific notation you must remember a few rules, however.

To **add** or **subtract**, be certain to express all the numbers with the same power of 10. Write the numbers in a column so the decimal points align. Then add or subtract the "plain number" part as you normally would. The power of 10 for your answer is the same power in which all the numbers are expressed. **Fig 4.6** shows a sample addition and a sample subtraction using exponential notation.

To **multiply** numbers using exponential notation, first multiply the "plain number" part. Next, add the exponents for the powers of 10. Your answer is the plain-

$$\begin{array}{r} 25.40 \times 10^3 \\ \times 6.15 \times 10^3 \\ \hline 12700 \\ 2540 \\ \hline 15240 \\ 156.2100 \times 10^6 \\ 156 \times 10^6 \end{array}$$

**Fig 4.7** — This example shows how to multiply two numbers using exponential notation. First multiply the number parts, then add the exponents for the powers of 10.

number answer times a power of 10 equal to the sum of the exponents. **Fig 4.7** shows a sample multiplication using exponential notation.

The rule for division using exponential notation is similar to the multiplication rule. To **divide** numbers written in exponential notation, first divide the "plain

$$\frac{25.40 \times 10^3}{6.15 \times 10^3} = \frac{25.40 \times 10^3 \times 10^{-3}}{6.15}$$

**Fig 4.8** — This example shows how to divide two numbers using exponential notation. First divide the number parts, then subtract the denominator (the bottom part of the fraction) exponent from the numerator (the top part of the fraction) exponent. Notice in this example we moved the denominator power of 10 into the numerator and changed the sign of the exponent.

number" parts. Then subtract the denominator power from the numerator power. (The denominator is the bottom part of a fraction and the numerator is the top part.) **Fig 4.8** shows a sample division. Notice that we moved the denominator power of 10 into the numerator and changed the sign of the exponent.

## Equations

Much of algebra involves manipulating equations. We know the quantities on each side of the equal sign are equivalent. Usually the goal is to find the value of some unknown quantity. We do this by isolating that unknown quantity on one side of the equal sign, and then evaluating the expression on the other side.

Here is the most important rule to remember when you try to *solve* an equation for the unknown quantity: **Be neat!** Write each step clearly. In a jumbled mess of numbers and symbols, you will soon be hopelessly lost.

The second-most-important rule is just as significant: Anything you do to one side of the equation you must also do to the other side. A few examples will illustrate some of the most common procedures.

$$2x + 4 = 8$$

We can simplify this equation by subtracting 4 from both sides of the equation:

$$(2x + 4) - 4 = 8 - 4$$

$$2x = 4$$

Now we can complete the solution by dividing both sides of the equation by 2. (This is the same as multiplying both sides by the reciprocal of the term associated with the unknown,  $x$ .)

$$\begin{array}{l} \frac{1}{2} \bullet 2x = \frac{1}{2} \bullet 4 \\ x = 2 \end{array}$$

Other techniques that can be used to manipulate equations were described earlier in this chapter. See *cross multiplication*, *reciprocal* and the discussion of the Laws of exponents for some important equation-solving principles.

In electronics, we often find problems in which there is more than one unknown quantity. In such cases, try to write a series of equations with the unknowns. If there are two unknown quantities, then find two equations involving those quantities. If there are three unknown quantities, find three equations, and so on. Such *systems of simultaneous* equations can help solve some challenging problems.

**Fig 4.9** shows the schematic diagram of a simple electronics circuit. We would like to know the power dissipated in the resistor. (Power is equal to current times voltage.) In this example, we only know voltage, however. So we have two unknown quantities; current and power. Since we also know resistance, we can write a second equation from Ohm's Law, to calculate current by dividing the voltage by the resistance:

$$P = IE$$

$$I = \frac{E}{R}$$

From these two equations, we can substitute the expression for current from the second equation for current in the first equation:

$$P = \frac{E}{R} E$$

You probably recognize that E times E can be written as  $E^2$ , so we simplify this equation as:

$$P = \frac{E^2}{R}$$

**Fig 4.9** — This circuit includes a 20-V battery and a 50-Ω resistor. The text explains how we can calculate the power dissipated in the resistor.

Now it is a simple matter to fill in the known quantities of voltage and resistance to calculate power:

$$P = \frac{(20 \text{ V})^2}{50 \Omega} = \frac{400 \text{ V}^2}{50 \Omega} = 8 \text{ W}$$

This example illustrates several important techniques. First, we used *substitution* to solve this problem. We substituted one expression for an equal quantity. We also used *literal equations* to solve the problem. This means we used letter symbols to represent the quantities until the last step. We could have put numbers in the equations right at the beginning, but it is often easier (and there are fewer opportunities to copy a number incorrectly) to use letter symbols. Finally, we used *dimensional analysis* with the calculation. That means we included the units associated with each measurement, and performed all the algebra operations on the units as well as the numbers. You can see this because we have volts squared in the numerator. You should check **Table 4.5** to see that volts squared divided by ohms is equivalent to watts.

Dimensional analysis is a very helpful mathematical tool if you take advantage of it. You can often use this method to help you remember the proper equation for a calculation. For example when you know that the unit of a watt can be expressed as an amp times a volt (see **Table 4.5**) you can write an equation that gives power as current times voltage. You can also use dimensional analysis to write a power equation involving current and resistance or voltage and resistance. Try writing

these equations with the help of **Table 4.5**.

*Linear equations* involve only unknown terms with exponents no larger than 1. For any value of one variable ( $x$ ) there is a corresponding value for the second variable ( $y$ ). A graph of such an equation will often help you visualize the relationship between variables. For example, if  $x$  represents the current through a circuit,  $y$  might represent the voltage across a resistor. A general expression of a linear equation is:

$$y = mx + b$$

where  $m$  represents the *slope* of the line (the change in  $y$  divided by the corresponding change in the  $x$  variable) often written as

$$\frac{\Delta y}{\Delta x}$$

and  $b$  represents the *y intercept*, or the point where the line crosses the vertical axis when  $x = 0$ .

An equation that involves a variable term with an exponent of 2 (a squared term) is called a *quadratic equation*. The general form of a quadratic equation is:

$$ax^2 + bx + c = 0$$

where  $a$ ,  $b$  and  $c$  are constant terms, or values for a particular equation, and  $x$  is the variable quantity.

Quadratic equations always have two solutions, which means there are two values for  $x$  that satisfy the equation. Perhaps the most straightforward way to solve a quadratic equation for the unknown quantity is to use the *quadratic formula*. This

formula can be used to solve any quadratic equation.

$$x = \frac{-b \pm \sqrt{b^2 - 4ac}}{2a}$$

Notice the plus or minus symbol in front of the radical sign. This tells us that one solution requires that we add the resulting term to  $-b$  and the other solution requires that we subtract the resulting term from  $-b$ . This comes about because when you square a negative number, you get a positive result. There are always two solutions to a square root. A simple example will illustrate the use of the quadratic formula.

$$2x^2 + 4x - 6 = 0$$

$$x = \frac{-b \pm \sqrt{b^2 - 4ac}}{2a}$$

$$x = \frac{-4 \pm \sqrt{4^2 - (4 \times 2 \times (-6))}}{2 \times 2}$$

$$x = \frac{-4 \pm \sqrt{16 - (-48)}}{4}$$

$$x = \frac{-4 \pm \sqrt{64}}{4} = \frac{-4 \pm 8}{4}$$

$$x = \frac{-4 + 8}{4} = \frac{4}{4} = 1$$

$$x = \frac{-4 - 8}{4} = \frac{-12}{4} = -3$$

## Measurement Units and Constants

Nearly every time we use a number, it represents some measured physical quantity. We might use a measuring tape to find the correct length of wire for an antenna, or an ohmmeter to measure the value of a resistor.

Each measurement includes a number representing its size and a unit that allows it to be compared with other measurements of a similar type. One dipole may be 126 ft, 6 inches long and another dipole may be 65 ft, 11 inches long, for example. The units used with any measurement represent standards that are generally accepted, so meaningful comparisons can be made. These comparisons are only meaningful if the measurements use the same units. It is difficult to compare a dipole

that is 65 ft 11 inches long with one specified as a 40-m dipole, because the units are not the same.

### US CUSTOMARY SYSTEM

Most US residents are familiar with units like the inch, foot, quart, gallon, ounce and pound. These units represent standard measurement values used in the *US Customary* measuring system. **Table 4.3** lists some common US Customary units, and some not-so-common ones. This table shows the relationships between various *linear*, *area*, *liquid volume*, *dry volume* and *weight* measurements.

The primary disadvantage of the US Customary measuring system is that there is no logical relationship between various-

sized units of a similar type. Most electronics measurements are made in the internationally accepted *metric* system, for this reason.

### METRIC SYSTEM

In the metric system, measuring units are always a multiple of 10 times larger or smaller than other units of the same type. Metric-system measurements are always based on a measurement unit and a set of prefixes to describe the larger and smaller variations of that unit. For example, a millimeter is ten times smaller than a centimeter, a meter is a hundred times larger than a centimeter and a kilometer is a thousand times larger than a meter. (In nearly every country of the world except the US,

**Table 4.3**  
**US Customary Units**

**Linear Units**  
12 inches (in) = 1 foot (ft)  
36 inches = 3 feet = 1 yard (yd)  
1 rod = 5½ yards = 16½ feet  
1 statute mile = 1760 yards = 5280 feet  
1 nautical mile = 6076.11549 feet

**Area**  
1 ft² = 144 in²  
1 yd² = 9 ft² = 1296 in²  
1 rod² = 30¼ yd²  
1 acre = 4840 yd² = 43,560 ft²  
1 acre = 160 rod²  
1 mile² = 640 acres

**Volume**  
1 ft³ = 1728 in³  
1 yd³ = 27 ft³

**Liquid Volume Measure**  
1 fluid ounce (fl oz) = 8 fluidrams = 1.804 in³  
1 pint (pt) = 16 fl oz  
1 quart (qt) = 2 pt = 32 fl oz = 57¾ in³  
1 gallon (gal) = 4 qt = 231 in³  
1 barrel = 31½ gal

**Dry Volume Measure**  
1 quart (qt) = 2 pints (pt) = 67.2 in³  
1 peck = 8 qt  
1 bushel = 4 pecks = 2150.42 in³

**Avoirdupois Weight**  
1 dram (dr) = 27.343 grains (gr) or (gr a)  
1 ounce (oz) = 437.5 gr  
1 pound (lb) = 16 oz = 7000 gr  
1 short ton = 2000 lb, 1 long ton = 2240 lb

**Troy Weight**  
1 grain troy (gr t) = 1 grain avoirdupois  
1 pennyweight (dwt) or (pwt) = 24 gr t  
1 ounce troy (oz t) = 480 grains  
1 lb t = 12 oz t = 5760 grains

**Apothecaries' Weight**  
1 grain apothecaries' (gr ap) = 1 gr t = 1 gr a  
1 dram ap (dr ap) = 60 gr  
1 oz ap = 1 oz t = 8 dr ap = 480 gr  
1 lb ap = 1 lb t = 12 oz ap = 5760 gr

**Table 4.4**

oping this measuring system based on multiples of ten. The original intent was to develop a measuring system based on measuring units that could be reproduced as needed. The meter was first defined as one ten millionth of the distance between the equator and the north pole, as measured along the longitude line running through Paris, France. A kilogram was originally defined as the mass of 1 liter (spelled *litre* throughout the rest of the world) of water at 4°C. As measuring instruments improve, the definitions are revised to reflect the greater measuring accuracy. For example, in 1960 the definition of a meter was revised to be a multiple of the wavelength of a particular orange-red light wave.

The metric system is based on the definitions of certain fundamental units, with all other units being based on those units. These fundamental, or defined units represent length (meter), mass — you might think of this as somewhat equivalent to weight — (gram), time (second), thermodynamic temperature (kelvin or degree celsius), luminous intensity of light (candela), the amount of substance — a measure of the number of atoms or molecules — (mole) and electric current (ampere).

All other units represent combinations of these fundamental units. For example, the unit of power (watt) is a measure of the energy required to move a one kilogram object a vertical distance of one meter in one second. **Table 4.5** lists some common units and their expression in terms of the base SI units.

Suppose you measure the frequency of a radio wave as 3825000 hertz. If we move the decimal point six places to the left, we would write this frequency as  $3.825 \times 10^6$

hertz. Looking at **Table 4.4**, you can replace the “ $\times 10^6$ ” part with the prefix mega. So we can write this frequency as 3.825 MHz (using the abbreviations M for mega and Hz for hertz). Similarly, you can use other metric-system prefixes to replace powers of 10 in large and small numbers.

As another example, suppose you find a capacitor marked with a value of 25 microfarads or 25 μF. From **Table 4.4**, you can find the multiplication factor of 10<sup>-6</sup> for the prefix micro. That means you can write this capacitor value as  $25 \times 10^{-6}$  farads, or 0.000025 F.

## CONVERTING BETWEEN US CUSTOMARY AND METRIC SYSTEMS

Sometimes it is convenient to convert between these two common measuring systems. You may know an antenna length in meters, but want to use your tape measure marked in feet and inches to cut the antenna, for example. **Table 4.6** lists most of the conversion factors you will ever need.

## Using Proportions to Solve Conversion Problems

To solve US Customary and metric conversions we will use proportions. This method also illustrates some other very useful mathematical tools. The advantage of using proportions to solve conversions is that you never have to figure out if you must multiply or divide. The proportion shows you what to do!

To set up a conversion between metric and US Customary units, just make a ratio of the conversion factors and an-

this unit of distance measurement is spelled *metre*, which helps distinguish the distance unit from an electrical measuring instrument, also called a meter.) **Table 4.4** shows the common metric prefixes, their abbreviations and the multiplication factor associated with each one.

## SI

The metric units make up an internationally recognized measuring system used by most scientists throughout the world. We call this the International System of Units, abbreviated SI (for the French, *Système International d'Unités*).

By the late 1700s, scientists were devel-

Table 4.5

## SI Fundamental Units

other of the measurements. Set the two ratios equal to each other and solve the proportion for the unknown measurement.

$$\frac{\text{metric conversion}}{\text{US conversion}} = \frac{\text{metric measurement}}{\text{US measurement}}$$

Suppose we know that a dipole antenna is 126 ft 6 inches long. (For simplicity, change that to 126.5 ft.) How long is this antenna in meters? Look down the *Metric Unit* column of Table 4.6 until you find an “m” for “meters.” Then go across to the *US Unit* column to find “foot.” Notice there are two conversion factors for

meters; one for “foot” and another for “yard.” When you’ve located the proper conversion factor, you will see there is 0.3048 meter in 1 ft. (A meter is a little more than 3 ft.) We know the US measurement in this case, and want to find the metric measurement.

$$\frac{0.3048 \text{ m}}{1 \text{ ft}} = \frac{\text{metric measurement}}{126.5 \text{ ft}}$$

In this example we will **cross multiply** the US measurement term to leave the unknown measurement by itself on one side of the equal sign. When you cross multiply, just take any part of the

proportion diagonally across the equal sign.

$$\begin{aligned} \frac{0.3048 \text{ m} \times 126.5 \text{ ft}}{1 \text{ ft}} &= \text{metric measurement} \\ &= \frac{38.56 \text{ m ft}}{1 \text{ ft}} = 38.56 \text{ m} \end{aligned}$$

Notice that we include the appropriate units with the metric and US conversion factors. After we cross multiply, the units of feet that go with the dipole length cancel with the units of feet that go with the US conversion factor, leaving only units of meters in our answer. *Dimensional analysis* ensures we have solved the proportion properly.

# Trigonometry

Trigonometry refers to the mathematics of angles, especially as they relate to triangles. When two lines meet or cross, they form angles. The point where the lines meet or cross is called the *vertex* of the angle. We usually measure an angle as an arc of a circle across the smallest opening between the lines. We can describe an angle as falling in one of three categories. Fig 4.10 shows a *right angle*, an *acute angle* and an *obtuse angle*.

The figure shows the angles in terms of a degree measurement. A degree is  $1/360^{\text{th}}$  of a circle, or  $1/360^{\text{th}}$  of a complete revolution. We can also measure angles in radians. A radian is an angle measure obtained by taking the length of the radius of a circle and laying that length along the circumference of that circle. See Fig 4.11. There are  $2\pi$  radians in one circle, or  $360^{\circ}$ . Two useful conversion relationships are:

$$1^{\circ} = 1.745 \times 10^{-2} \text{ radians, and:}$$

$$1 \text{ radian} = 57.296^{\circ}$$

When three lines cross in such a manner that they form three angles, these lines form a *triangle*. We normally identify a triangle by the largest angle that it includes. This means there are three types of triangles. Fig 4.12 shows examples of the three types of triangles. In electronics, we will use right triangles in a variety of calculations.

If you add the three angles in a triangle, you will always get a total of  $180^{\circ}$ . For a right triangle, then, the sum of the other two angles must be  $90^{\circ}$ .

The triangles shown in Fig 4.12 have their angles labeled with upper-case letters and their sides labeled with corresponding lower-case letters. Notice that the side opposite each angle uses the lower-case letter of its opposite angle. With a right triangle, the side opposite the right angle has a special name. It is called the *hypotenuse* of the right triangle. In Figure 4-12B, side *a* is *opposite* angle A, side *b* is *opposite* angle B and the hypotenuse (side *c*) is opposite the right angle (angle C). We can also say that side *a* is *adjacent* to angle B and side *b* is *adjacent* to angle A. (The hypotenuse is also adjacent to both angles A and B, but since the hypotenuse is otherwise uniquely identified we don't use this name for the hypotenuse.) The Greek letters theta ( $\theta$ ) and phi ( $\phi$ ) are often used to represent angles. Sometimes you will also see the Greek letters alpha ( $\alpha$ ), beta ( $\beta$ ) and gamma ( $\gamma$ ) used to represent the angles in a triangle.

## WORKING WITH RIGHT TRIANGLES

Trigonometry defines relationships between the lengths of the sides of a right triangle and its angles. With these relationships and any combination of three sides or angles we can calculate any of the quantities we don't know. For example, if you know two sides and one angle, you can calculate the third side and the other two angles. While there are six functions defined for any right triangle, you can perform any required calculations if you know three of those functions.

The three functions we will use are the sine, cosine and tangent. Each function is defined in terms of an angle and two sides of the triangle.

$$\text{sine } \theta = \frac{\text{side opposite}}{\text{hypotenuse}}$$

$$\text{cosine } \theta = \frac{\text{side adjacent}}{\text{hypotenuse}}$$

$$\text{tangent } \theta = \frac{\text{side opposite}}{\text{side adjacent}}$$

Fig 4.12B shows the definitions of the three important trigonometry functions associated with angles A and B.

These functions are usually abbreviated as *sin*, *cos* and *tan*. Each function represents a ratio of two sides of the triangle, and this ratio is the same for any given angle, no matter how large or small the triangle. For example, Fig 4.13 shows two

right triangles that each include a  $30^{\circ}$  angle. The sine of the  $30^{\circ}$  angle is 0.5 no matter which triangle we are working with. Likewise, each of these triangles also includes a  $60^{\circ}$  angle, and the sine of the  $60^{\circ}$  angle is always 0.866.

Fig 4.10 — Three types of angles. A shows a right angle, B shows an acute angle and C shows an obtuse angle.

Fig 4.11 — Part A illustrates the measure of  $1^{\circ}$  as part of a circle. Part B shows the measure of 1 radian as part of a circle.

Fig 4.12 — Part A shows an acute triangle, Part B shows a right triangle and Part C shows an obtuse triangle.

**Fig 4.13** — This drawing shows two right triangles that each include a  $30^\circ$  angle and a  $60^\circ$  angle. Notice that values of the trigonometry functions don't depend on how long the sides of the triangles are; the same values of  $\sin$ ,  $\cos$  and  $\tan$  apply to each of these triangles.

Most scientific calculators include keys to find these function values. It is important to know if the calculator will understand the angle you enter as measured in degrees or radians. Most calculators work with angles measured in degrees, but some use radians. Some calculators will also use radians if you enter the proper keystrokes before starting. Computers usually work with angles measured in radians.

Suppose you know the ratio of sides, and want to know what angle is associated with that value. This is a question of finding the *inverse function*. Suppose you know that the side opposite an angle divided by the hypotenuse equals 0.5. What is the angle? Since opposite over hypotenuse is the definition of sine, we want to find the inverse sine, or arcsine (often abbreviated *arcsin*). In this example, the answer is  $30^\circ$ . Likewise, we can also find the arccosine (*arccos*) and arctangent (*arctan*) of an angle. You will also see these inverse functions written as  $\sin^{-1}$ ,  $\cos^{-1}$  and  $\tan^{-1}$ . Here the  $-1$  exponent is simply a short-hand notation to indicate the inverse function. Do not try to follow the rules of significant figures when you find the value of a trigonometry function or its inverse function. Do follow the rules when you calculate the sides and angles of a triangle, however. For example, if you know an angle measurement to three or four significant figures, express the other angles you calculate with the same number of significant figures. If you know the length of a side to four significant figures, express the calculated sides to four significant figures.

The sine and cosine functions are used in many ways in electronics. You will often see graphs of these functions used

Sine Function  
(A)

Cosine Function  
(B)

Tangent Function  
(C)

**Fig 4.14** — Part A shows a graph of the sine function for angles from 0 to  $360^\circ$ . Part B is a graph of the cosine function and Part C is a graph of the tangent function for angles from 0 to  $360^\circ$ . (Note that the horizontal axis also indicates angles in radians.)

to represent the waveform of an alternating current signal. **Fig 4.14** shows graphs of the sine, cosine and tangent functions for angles from 0 to 360°. (The horizontal axis on the graph is also marked in radians, from 0 to  $2\pi$  radians.)

In addition to the three trigonometry functions described here, there is one other very important relationship for working with right triangles. This principle was discovered by a Greek mathematician, Pythagoras. The *Pythagorean Theorem* states that the square of the hypotenuse is equal to the sum of the squares of the other two sides. Written as an equation, this is:

$$c^2 = a^2 + b^2$$

We can take the square root of both sides to solve this equation for the hypotenuse.

$$c = \sqrt{a^2 + b^2}$$

We can also solve the original equation for either of the other sides and then take the square root.

$$a^2 = c^2 - b^2$$

$$a = \sqrt{c^2 - b^2}$$

There is no single correct procedure for calculating the parts of a right triangle. Select a "trig" function or the Pythagorean Theorem depending on what parts of the triangle you know. **Fig 4.15** shows a right triangle. The drawing shows the two sides, and you have to calculate the hypotenuse and the two angles. We could use the Pythagorean Theorem to calculate the hypotenuse, but let's use the tangent function to find angle A first.

$$\tan A = \frac{\text{side opposite}}{\text{side adjacent}}$$

$$\tan A = \frac{25.0}{43.3} = 0.577$$

Next we must find the arctangent of this ratio:

$$A = 30.0^\circ$$

Since the two acute angles of a right

**Fig 4.15 — Find the hypotenuse and the two acute angles of this right triangle. You can use any of the "trig" functions and the Pythagorean Theorem.**

triangle must add up to 90°, we can see that angle B must be 60.0°. Then we can use the sine, cosine or Pythagorean Theorem to calculate the hypotenuse. Let's use the sine function for this example. (You can use the cosine to verify that it gives the same answer.)

$$\sin A = \frac{\text{side opposite}}{\text{hypotenuse}}$$

Cross multiply to solve this literal equation for the hypotenuse, and calculate the value.

$$\text{hypotenuse} = \frac{\text{side opposite}}{\sin A}$$

$$\text{hypotenuse} = \frac{25.0}{\sin 30.0^\circ} = \frac{25.0}{0.500} = 50.0$$

As an example of using the Pythagorean Theorem, we will use that to solve for hypotenuse of this triangle also.

$$c = \sqrt{a^2 + b^2}$$

$$c = \sqrt{25.0^2 + 43.3^2} = \sqrt{625 + 1870}$$

$$c = \sqrt{2500} = 50.0$$

Notice that we have followed the rules for significant figures through these examples. In this last step, we had to round off the 43.3<sup>2</sup> term. Then the addition term under the radical was limited to the hundreds place, or three significant figures.

### WORKING WITH ACUTE AND OBTUSE TRIANGLES

All the trigonometry functions and

techniques described in the last section apply *only* to *right triangles*. You may occasionally need to work with an acute or obtuse triangle. In this case it will be handy to remember the *Law of Sines* and the *Law of Cosines*. The Law of Sines tells us that the length of any side is proportional to the sine of the opposite angle:

$$\frac{a}{\sin A} = \frac{b}{\sin B} = \frac{c}{\sin C}$$

If you know one of the angles, the side opposite that angle, and one other side or angle, you can use this relationship to calculate the fourth side or angle. The Law of Sines is a simple proportion, and can be solved for the unknown quantity using cross multiplication. See **Fig 4.16**.

The Law of Cosines equation will remind you a bit of the Pythagorean Theorem. You can find any side of the triangle if you know the other two sides and the angle opposite the unknown side. (This is just the opposite of the Law of Sines, where you must know one angle and its opposite side.)

$$a^2 = b^2 + c^2 - 2bc \cos(A)$$

We could write similar equations solved for  $b^2$  and  $c^2$ , but that isn't necessary, since it really doesn't matter which side is labeled a, b or c as long as each angle and its side opposite use the same letter. We can take the square root of both sides of this equation to solve for a:

$$a = \sqrt{b^2 + c^2 - 2bc \cos(A)}$$

$A = 45.0^\circ$   
 $B = 60.0^\circ$   
 $C = ?$   
 $a = 5.00$   
 $C = 180.0^\circ - 45.0^\circ - 60.0^\circ$   
 $C = 75.0^\circ$

$$\frac{a}{\sin A} = \frac{b}{\sin B}$$

$$\frac{5.00}{\sin 45.0^\circ} = \frac{b}{\sin 60.0^\circ}$$

$$\frac{5.00 \times \sin 60.0^\circ}{\sin 45.0^\circ} = b$$

$$\frac{5.00 \times 0.866}{0.707} = 6.12 = b$$

$$\frac{a}{\sin A} = \frac{c}{\sin C}$$

$$\frac{5.00}{\sin 45.0^\circ} = \frac{c}{\sin 75.0^\circ}$$

$$\frac{5.00 \times \sin 75.0^\circ}{\sin 45.0^\circ} = c$$

$$\frac{5.00 \times 0.966}{0.707} = 6.83 = c$$

**Fig 4.16 — The Law of Sines is used to calculate sides b and c of this acute triangle.**

# Coordinate Systems

A coordinate system helps us draw graphs to represent quantities and equations. A coordinate system provides a scale with a set of numbers to represent the location of a point on a surface. There are several such coordinate systems used in electronics. In this section we will briefly discuss three coordinate systems: the *rectangular*, or *cartesian coordinate system*, the *polar coordinate system* and the *spherical coordinate system*.

## RECTANGULAR COORDINATES

Fig 4.17 shows a portion of a *rectangular*, or *cartesian coordinate system*. It is simply a pair of number lines that cross at a  $90^\circ$  angle. The scale on the number lines is chosen to suit the particular needs of any given situation. The graduations on one scale can be larger than the other, one or both lines can be far from 0, with an arbitrary crossing point to show the region of interest. This coordinate system represents a plane, two-dimensional surface. You have probably used graph paper drawn as a rectangular coordinate system.

The horizontal line, or *axis*, is often labeled X. This usually represents the independent, or controlled variable when an equation is being graphed.

The vertical line is often labeled Y. This usually represents the dependent variable (the value depends on the conditions set for the controlled variable).

Any point on a rectangular coordinate system can be specified by a pair of numbers, such as  $(-2, 5)$  or  $(5, 3)$ . These numbers represent the distance along the X axis and the distance along the Y axis to reach the point.

## POLAR COORDINATES

We specify the distance to a point with measurements along the X and Y axes with a rectangular coordinate system. Sometimes it is more convenient to specify the shortest distance from the center or *origin* to the point. In that case we can use a *polar coordinate system*. Fig 4.18 shows an example of this system. The lines help mark the center of the system and provide a reference by dividing the circle into four equal parts, but they are not really necessary. Again we specify the location of any point on the surface with a pair of numbers, but this time the numbers represent the direct distance from the origin to the point, and an angle. The angle is usually measured counterclockwise from the line extending to the right side. The distance represents the *magnitude* or length of the value, measured as a straight line (the shortest distance) from the center to the point.

The circles represent increasing distances from the origin. You can choose any convenient scale for the radius of these circles. You don't always need the complete circles. Often you will only need one quarter or one half of the circle. You can buy graph paper marked off with a polar coordinate system, although you seldom need such graph paper. You can even use

rectangular coordinate graph paper or plain paper, with a drawing compass, ruler and protractor if you do want a scale drawing.

Many times you will have to convert between rectangular and polar coordinate systems. You will find the trigonometry functions especially helpful at such times. Fig 4.19 shows a right triangle drawn to illustrate such a conversion. The sides of

Fig 4.17 — A set of horizontal and vertical lines, marked off with a number scale, forms a rectangular coordinate system. We usually label the horizontal line, or axis, the X axis, and the vertical line the Y axis. Any point on the surface can be identified with a pair of numbers, representing the distance along the X axis and the distance along the Y axis to reach the point. When the point is identified with a pair of numbers, the convention is to list the X value first, then the Y value, as  $(X, Y)$ .

Fig 4.18 — This drawing shows a polar coordinate system. Any point on this surface is identified with a pair of numbers representing the distance from the origin directly to the point, and an angle or direction.

**Fig 4.19 —** The right triangle on this graph shows how we can specify the same point in rectangular coordinates and in polar coordinates. The rectangular coordinates (4, 3) and the polar coordinates (5,  $\angle 36.9^\circ$ ) both represent the same point on this graph. You can use the trigonometry functions discussed earlier to convert between these two systems.

the triangle represent the X (4) and Y (3) values of a rectangular coordinate system. The hypotenuse of the right triangle represents the distance between the origin and the end point on a polar coordinate system. Angle A represents the polar-coordinate angle.

You should be able to use the various “trig” functions and the Pythagorean Theorem to calculate the hypotenuse (5) and angle A ( $36.9^\circ$ ) for this problem. If you knew the hypotenuse and angle A you should also be able to calculate the other two sides of the triangle, to convert from polar to rectangular coordinates.

### SPHERICAL COORDINATES

Both of the coordinate systems described above represent a two-dimensional surface. This is fine for most electronics problems, but occasionally it is helpful to have a three-dimensional coordinate system.

It is possible to add a third axis to the rectangular coordinates, which forms a  $90^\circ$  angle with the other two. (Look at the corner of a room, with the two lines along the floor and walls representing the X and Y axes. Then the corner between the two walls represents the Z axis.) A set of three numbers (X, Y, Z) will represent any point in the three-dimensional space this system represents.

It is also possible to rotate the circles of the polar coordinate system to create a sphere. The resulting *spherical coordinate system* gives us another way to represent a point in three dimensions. In this system we use the radius, or distance from the center to the point, and two angles — one representing an angle measured “horizontally” and the other representing an angle measured “vertically.” (Think about our Earth, and the way we draw lines of longitude and latitude.)

## Complex Algebra

We most often use the rectangular and polar coordinate systems for electronics problems involving resistance, reactance and impedance (and conductance, susceptance and admittance, their reciprocals). When we work with these quantities we draw the resistance or conductance along the X axis and the reactance or susceptance along the Y axis. The hypotenuse represents impedance or admittance.

We must use some special mathematical techniques when working with these quantities because we must always distinguish between them. It is most convenient to use the algebra of what mathematicians call *imaginary numbers*, although there is nothing imaginary about these electronics quantities. Mathematicians use these techniques when they work with quantities that involve the square root of minus 1, written as  $\sqrt{-1}$ . It is impossible to find a number that when multiplied by itself gives  $-1$ , so this quantity is *imaginary*, yet it does show up in some mathematical procedures. Mathematicians represent this quantity with a lower-case italic *i*. Quantities that include real and imaginary parts are called *complex numbers*.

In electronics, we use a lower-case italic *j* to represent numbers on the reactance or susceptance line, or Y axis of a graph. The algebra of complex numbers provides a way to add, subtract, multiply and divide quantities that include both resistive and

reactive components. You can best think of the *j* as an *operator* that produces a  $90^\circ$  rotation from the resistance line. An operator is just a mathematical procedure applied to a quantity. An exponent is an operator that tells you how many times to multiply a quantity times itself and the radical sign ( $\sqrt{\quad}$ ) is an operator that tells you to take the square root.

When you see a reactance expressed as  $j250\ \Omega$ , place this quantity along the Y axis on your graph. A reactance expressed as  $-j300\ \Omega$  tells you to rotate  $90^\circ$  in the clockwise direction instead of the normal counterclockwise direction.

Inductive reactance is specified with a  $+j$  for series circuits, because the voltage across an inductor *leads* the current through it. Since voltage and current are in phase in a resistor, the voltage across the inductor leads the voltage across the resistor by  $90^\circ$ . (For parallel circuits, the voltage across the resistor and inductor is the same, so they are in phase. In that case the current through the inductor *lags* the current through the resistor, so the current associated with the inductive reactance gets a  $-j$  operator.)

Capacitive reactance is just the opposite. It is specified with a  $-j$  operator for series circuits because the voltage across a capacitor lags the current, so the current across the capacitor *lags* the voltage across the resistor — or is  $90^\circ$  behind. (For parallel circuits, the same voltage is applied

to the resistor and capacitor, so the capacitor current *leads* the resistor current. The current associated with the capacitive reactance gets a  $+j$  operator for parallel circuits.)

A handy memory device for these relationships is the saying, “ELI the ICE man.” The E represents voltage, I represents current, L is inductance and C is capacitance.

Impedance is a combination of resistance and reactance. When we specify a series-circuit impedance as  $50 + j200\ \Omega$ , you know this represents a circuit with a  $50\text{-}\Omega$  resistance in series with a  $200\text{-}\Omega$  inductive reactance. Likewise, an impedance of  $50 - j200\ \Omega$  represents a circuit with a  $50\text{-}\Omega$  resistance in series with a  $200\text{-}\Omega$  capacitive reactance.

Both of these impedances can be expressed in polar-coordinate form. Plot the values on a graph and calculate the hypotenuse of the right triangle and angle A as shown on Fig 4.20. Then you can write these impedances as

$206\ \Omega \angle 76^\circ$  and  $206\ \Omega \angle -76^\circ$ .

### RULES FOR WORKING WITH COMPLEX NUMBERS

Addition and subtraction of complex numbers are best done using rectangular-coordinate form. When you add complex numbers written in rectangular notation you add the parts along the X axis, and you add the parts along the Y axis. The result gives a new set of X, Y coordinates, representing

the addition of the two complex values. To subtract complex numbers you subtract one X part from the other, and subtract the corresponding Y parts. The result is a new set of X, Y coordinates, representing the subtraction of the two values.

For example, what is the total impedance of a circuit that has an impedance of  $30 + j150 \Omega$  in series with an impedance of  $40 - j100 \Omega$ ? We can write this addition as:

$$\begin{array}{r} 30 + j150 \Omega \\ + 40 - j100 \Omega \\ \hline 70 + j50 \Omega \end{array}$$

If you have to add or subtract impedances given in polar notation (a magnitude or length and an angle), first convert these values to rectangular-coordinate form. Use the trigonometry functions and Pythagorean Theorem described earlier in this chapter. If you need the answer specified in polar-coordinate form you can convert back to that notation after performing the addition.

Multiplication and division of complex numbers is best done in polar-coordinate form. When you multiply complex numbers in polar-coordinate form, you multiply the magnitudes and add the angles. When you divide complex numbers in polar notation you divide the magnitudes and subtract the angles.

Suppose you want to find the impedance of a circuit that has a resistor in parallel with a capacitor. When you apply 10.0 V to the circuit, you measure 0.250 A

of current. You measure the phase angle between the current and the voltage, and find the current leads the voltage by  $30.0^\circ$ . We can calculate the impedance of this circuit (represented by a capital Z) using Ohm's Law.

$$Z = \frac{E}{I}$$

$$Z = \frac{10.0 \text{ V} \angle 0.0^\circ}{0.250 \text{ A} \angle 30.0^\circ}$$

The components are in parallel, so the same voltage is applied to both the resistor and capacitor. Use the voltage as the phase reference for parallel-circuit calculations, so the voltage has a  $0^\circ$  phase angle. To perform this division, first divide the voltage magnitude by the current magnitude. Then subtract the denominator phase angle from the numerator phase angle.

$$\frac{10.0 \text{ V}}{0.250 \text{ A}} = 40.0 \Omega$$

and

$$0.0^\circ - (30.0^\circ) = -30.0^\circ$$

These two values specify the impedance of the circuit in this example. We can put them together and write the circuit impedance in polar-coordinate form as:

$$40.0 \Omega \angle -30.0^\circ$$

The negative phase angle tells us there is a capacitive reactance as part of the impedance.

**Fig 4.20** — The two triangles shown on this graph represent the impedances of two circuits. Triangle A represents a 50- $\Omega$  resistance in series with a 200- $\Omega$  inductive reactance ( $50 + j200 \Omega$ ). Triangle B represents a 50- $\Omega$  resistance in series with a 200- $\Omega$  capacitive reactance ( $50 - j200 \Omega$ ).

## Logarithms

A logarithm is an exponent. *Common logarithms* use the number 10 as their *base*. You have some experience with “powers of 10” from writing numbers in exponential or scientific notation.

A common log, as it is usually called, is the exponent or power to which you must raise 10 to get a certain number. In the examples above, we raised 10 to the third power to get 1000. The log of 1000, then, is 3. The log of 1000000 is 6. In general, we define a common logarithm with two equations. If:

$$N = 10^x, \text{ then:}$$

$$\log(N) = x$$

Sometimes you will see this written as  $\log_{10}(N) = x$ . This is simply to ensure that you know the base of the logarithm is 10.

Finding the log of a multiple of 10 is easy, as these examples show. You may wonder to what power you can raise 10 to get a number like 2. That is a good question, and the answer is 0.301. Logs are usually decimal fractions rather than whole numbers. Logs for numbers smaller than 10 are less than 1; logs for numbers larger than 10 are greater than 1. From the definition of a log, we can write the expression:

$$2 = 10^{0.301}$$

The easiest way to find any logarithm is with your calculator. Simply enter the

number whose log you want to find, and then push the button labeled “log.” It is easy to find that  $\log(5) = 0.699$ , for example.

It is interesting to note that  $\log(1) = 0$ , because anything (including 10) raised to the zero power is 1. The log of 0 is undefined, because there is no power to which you can raise 10 and get 0.

The inverse log is called the *antilog* (often written  $\log^{-1}$ ). When we know the log and want to find the original number, we want the antilog. To find an antilog, simply raise 10 to the given power. Your calculator probably has a button labeled “10<sup>x</sup>” or something similar. What is the antilog of 1.845?  $10^{1.845} = 70$ . Don’t try to

follow the rules for significant figures when finding logs or antilogs. Do follow the rules with the values you calculate from logs and antilogs, however.

The second base that is frequently used for logarithms is a number usually represented by  $e$ . (Sometimes the Greek letter epsilon ( $\epsilon$ ) is used to represent  $e$  although this is an incorrect representation.) This number is approximately 2.71828. This is not an exact value, because the decimal fraction doesn't end with this last 8. This value is rounded off, but there is no exact value for  $e$  because you can never find the last digit. Mathematicians call such numbers with no exact value, *irrational numbers*. The number represented by  $e$  appears in several electronics calculations, and is called the *natural number*, because it appears as a constant of nature. You will use  $e$  to calculate the voltage on a capacitor as it charges or discharges, for example.

Logarithms that use  $e$  for their base are called *natural logarithms*, or *Naperian logarithms*. This can be written as  $\log_e$ , but to more easily distinguish it from common logs, we usually abbreviate it  $\ln$ . We define natural logs the same way we define common logs. If:

$$M = e^y, \text{ then} \\ \log_e (M) = \ln (M) = y$$

The easiest way to find a natural log is with a scientific calculator. Enter the number whose  $\ln$  you want to know, then press the "ln" button on the calculator. For example,  $\ln (2) = 0.693$  and  $\ln (20) = 2.996$ . As you might expect,  $\ln (e) = 1$ ,  $\ln (1) = 0$  and  $\ln (0)$  is undefined.

Inverse natural logs, or antilogs are also easy with a calculator. Just raise  $e$  to that power:  $e^{2.996} = 20$ .

Computers often work only with natural logarithms. Converting between common logarithms and natural logarithms is easy, however. If you want to find a common log, and know the natural log value, divide that by the natural log of 10.

$$\log(x) = \ln(x) / \ln(10) = \ln(x) / 2.3025851$$

$$\log(x) = 0.4342945 \ln(x)$$

If you know the common log, and want to find the natural log, divide that value by the common log of  $e$ .

$$\ln(x) = \log(x) / \log(e) = \log(x) / 0.4342945$$

$$\ln(x) = 2.3025851 \log(x)$$

## DECIBELS

The bel (abbreviated B) is named after Alexander Graham Bell, who did much pioneering work with sound and the way our ears respond to sound. Our ears respond to

sounds ranging from an intensity less than  $10^{-16}$  W/cm<sup>2</sup> to intensities larger than  $10^{-4}$  W/cm<sup>2</sup> (where we begin to experience pain). This is a range of more than  $10^{12}$  times from the softest to the loudest sounds. Logarithms provide a convenient way to represent these values, because they compress this scale into a range of 12, rather than a range of a billion.

A bel is defined as the logarithm of a power ratio. It gives us a way to compare power levels with each other and with some reference power.

$$\text{bel} = \log \left( \frac{P_1}{P_0} \right)$$

where  $P_0$  is the reference power, or the power you want to use for comparison and  $P_1$  is the power you are comparing to the reference level.

While the bel was first defined in terms of sound power, to describe sound intensities, in electronics we often use it to compare electrical power levels. The decibel is one-tenth of a bel, and is abbreviated dB.

It takes 10 decibels to make 1 bel, so we can write an equation to find dB directly:

$$\text{dB} = 10 \log \left( \frac{P_1}{P_0} \right)$$

How many decibels does the power increase if an amplifier takes a 1-W signal and boosts it to 50 W? Let  $P_1$  be the 1-W signal in this example, since that is the starting point for the comparison.

$$\text{dB} = 10 \log \left( \frac{50 \text{ W}}{1 \text{ W}} \right) = 10 \log (50)$$

$$\text{dB} = 10 (1.699) = 16.99 \text{ dB}$$

The amplifier in this example has a gain of nearly 17 dB.

Sometimes when we are comparing signal levels in an electronic circuit, we know the voltage or current of the signal, but not the power. Of course we can always calculate the power, as long as we know the impedance of the circuit. We can take a shortcut to comparing the signal levels in decibels, however, *as long as the impedance is the same* in both circuits, or as long as the impedance of the circuit doesn't change when we change the voltage or current. Remember from Ohm's Law and the power equation that  $P = E^2 / R$  and  $P = I^2 \times R$ . So we can use  $E^2$  or  $I^2$  in place of power in the decibel equation, *as long as the impedance is the same* in both cases.

$$\text{dB} = 10 \log \left( \frac{E_1^2}{E_0^2} \right)$$

$$\text{dB} = 20 \log \left( \frac{E_1}{E_0} \right)$$

and

$$\text{dB} = 10 \log \left( \frac{I_1^2}{I_0^2} \right)$$

$$\text{dB} = 20 \log \left( \frac{I_1}{I_0} \right)$$

Here we have also illustrated another important property of logarithms. If the quantity inside the log expression has an exponent, you can move the exponent outside the log. In this case, we move the 2 from the squared terms out front, and multiply it times the 10 already there.

Sometimes there is confusion about whether the decibel was calculated using power, voltage or current. Since the current and voltage equations use 20 instead of 10 times the log term, some hams believe the "voltage" or "current" decibel is different than one calculated using power. This is not true, however. There is only one decibel definition, and that is ten times the log of a power ratio.

There are several power ratios that you should learn to recognize and remember the decibel values that go with them. These are the decibel values for a doubling of the power and for halving the power. Let's look at the effect of doubling the power first. It doesn't matter if we are going from 1 W to 2, 50 to 100 or 500 to 1000 W. In each case the new power is twice the starting power. To find the decibel increase multiply 10 times the log of 2:

$$\text{dB} = 10 \log (2)$$

$$\text{dB} = 10 \times 0.301 = 3.01$$

Anytime you double the power, it represents approximately a 3-dB increase in power.

What is the decibel change when you cut the power in half? Again, it doesn't matter if you are going from 1000 W to 500, 100 to 50 or 2 W to 1 W; the power ratio is still 0.5.

$$\text{dB} = 10 \log (0.5)$$

$$\text{dB} = 10 \times -0.301 = -3.01$$

A negative value indicates a decrease in power. Anytime you cut the power in half there is about a 3-dB decrease in power.

Table 4.7 shows the relationship between several common decibel values and the power change associated with those values. The current and voltage changes are also included, but these are only valid if the impedance is the same for both values.

Suppose you double the power, and then double it again? The final power is four times the starting power, so you can calcu-

late the decibel increase using the equation given. You can also calculate the total power change “by inspection” because you know each time you double the power there is a 3-dB increase. In this example

you have a 3-dB increase, plus a second 3-dB increase. If you add these two decibel values, you have a 6-dB total increase. If you double the power again, you have a 9-dB total increase. Doubling the power a fourth time gives a 12-dB total increase.

The same relationship is true of power decreases. Each time you cut the power in half you have a 3-dB decrease. Cutting the power in half and then in half again is a 6-dB decrease, and so on.

The addition and subtraction of decibel values is very important in electronics. Amplification factors, gains and losses of antennas, antenna feed lines and all kinds of circuits can simply be added when they are expressed in decibels.

It is often convenient to compare a certain power level with some standard reference. For example, suppose you measured the signal coming into a receiver from an antenna and found the power to be  $2 \times 10^{-13}$  mW. As this signal goes through the receiver it increases and decreases in strength until it finally produces some sound in the receiver speaker or head-

phones. It is convenient to describe these signal levels in terms of decibels. A common reference power is 1 mW. The decibel value of a signal compared to 1 mW is specified as “dBm” to mean decibels compared to 1 mW. In our example, the signal strength at the receiver input is:

$$\text{dBm} = 10 \log \left( \frac{2 \times 10^{-13} \text{ mW}}{1 \text{ mW}} \right)$$

$$\begin{aligned} \text{dBm} &= 10 \log (2 \times 10^{-13}) \\ &= 10 \times -12.7 = -127 \text{ dBm} \end{aligned}$$

There are many other reference powers used, depending upon the circuits and power levels. If you use 1 W as the reference power, then you would specify dBW. Antenna power gains are often specified in relation to a dipole (dBd) or an isotropic radiator (dBi). Anytime you see another letter following the dB, you will know some reference power is being specified.

**Table 4.7**

**Some Common Decibel Values and Power-Ratio Equivalents**

dB	$P_2 / P_1$	$V_2 / V_1$ or $I_2 / I_1$
-20	$10^{-2}$	0.1000
-10	0.1000	0.3162
(-6.0206)	(0.2500)	(0.5000)
-6	0.2512	0.5012
(-3.0103)	(0.5000)	(0.7071)
-3	0.5012	0.7079
-1	0.7943	0.8913
0	1.000	1.000
1	1.259	1.122

(3.0103)	(2.0000)	(1.4142)
6	3.981	1.995
(6.0206)	(4.0000)	(2.0000)
10	10.00	3.162
20	$10^2$	10.00

## Integration and Differentiation

You don’t have to be familiar with calculus to understand modern electronics. Sometimes it is helpful to be familiar with some calculus *terminology* to understand how a circuit works or what its function is, however.

### INTEGRATION

When you read that a certain op-amp circuit is designed as an “integrator” it will be easier to understand what the circuit does if you know a simple definition of *integration*. Integration is the process of calculating the area under a curve plotted on a graph.

**Fig 4.21** — This graph represents one cycle of a square wave. The text explains how to *integrate* this signal waveform, or find the area under the pulse.

Area always implies certain boundaries, and you want to find how much space there is inside the boundaries. A square may be the simplest surface for which to find the area. If you know the length of a side you simply square that length to find the area. If you know the length and width of a rectangle you multiply these values to calculate area.

**Fig 4.21** shows a graph of a square-wave signal. If you want to *integrate* this signal, you have to find the *area* of the pulse. The scales on this graph represent voltage (on the Y axis) and time (on the X axis) so this isn’t area in the most common sense, but we can perform a similar calculation. As you can imagine, if the pulse has a larger amplitude or a longer duration it will have a larger area.

**Fig 4.22** illustrates a more difficult signal to integrate. Calculus methods can calculate this area from the equation that represents the curve, but we can make a reasonable approximation by drawing a series of rectangles and adding their areas. Integration is normally done over some range of values, such as  $x_1$  and  $x_2$  as shown on this graph. Part B shows that we can draw a series of rectangles so the *midpoint*

**Fig 4.22** — This graph shows an irregular curve. If we want to know the area under the curve between  $x_1$  and  $x_2$ , we can draw a series of rectangles and add their areas, as shown in Part B.

of the side of each rectangle crosses the curve. Part of the rectangle corner lies above the curve, but there is a nearly equal space below the curve that is not included. If we draw more rectangles, with smaller widths, the approximation becomes better. The concept of integration is that you can make the interval smaller and smaller until it is no longer an approximation, but an exact value.

Fig 4.23 compares a series of square-wave pulses fed into an op-amp integrator and the output waveform from the integrator. In this example the integrator changes a square-wave signal into a triangle-wave signal. The integrated signal increases while the input pulse is positive, then decreases while the signal is negative.

## DIFFERENTIATION

*Differentiation* is another calculus procedure that may be helpful. Integration and differentiation are opposite procedures. If you integrate a function and then differentiate the result, you get the original function back again. Likewise, if you differentiate a function and then integrate the result, you get the original function back.

While integration represents a summation of *area* values over some range, differentiation represents the *slope* of a line or curve at some specific point. The slope of a straight line is equal to the change in value along the x axis divided by the corresponding change in value along the y axis.

Look at the triangle waveform of Fig 4.23 B. While the voltage is increasing, this line has a constant slope,  $m$ , such that it satisfies the equation  $y = mx + b$ . Since the differentiation process represents the slope of the line, the *derivative* is a constant. When the waveform begins to decrease the slope suddenly changes to a new value, which is negative this time. The derivative is again a constant value, this

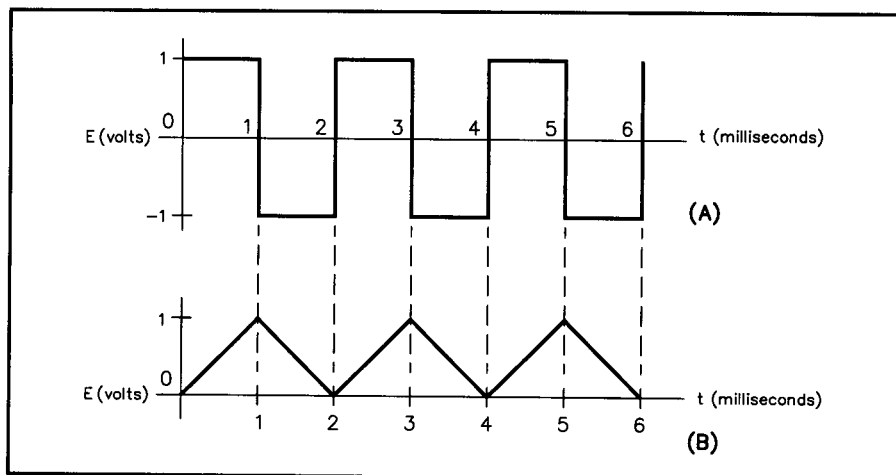

Fig 4.23 — Part A shows a series of square-wave pulses and Part B shows the output from an op-amp integrator with the square-wave input.

time with a negative sign. If the graph in Fig 4.22B represents a signal waveform that is fed into a differentiator circuit, the waveform at A represents the output signal waveform!

We approximated the integration process for a curved-line graph by adding the areas of many small rectangles drawn to divide a curve into small segments. Similarly, we can approximate the differentiation process of a curved-line graph by finding the slope of a straight line drawn *tangent* to the curve. A tangent line touches the curve at a single point. The simplest way to show a tangent line is with a circle, as shown in Fig 4.24. The tangent line is perpendicular to (forms a  $90^\circ$  angle with) a radius line.

We can approximate the derivative of a curved-line graph at any point by drawing a tangent line at that point and calculating the slope of the line. We can even find the general trend of the derivative function by drawing a series of tangent lines at points along the line. By calculating the slope of each of those lines you can get some idea

Fig 4.24 — This diagram illustrates the concept of a tangent line. Line AB is tangent to the circle at point P, and is perpendicular to the radius line,  $r$ .

of how it is changing. By selecting points closer and closer together you will find a better and better approximation to the derivative.

# DC Theory and Resistive Components

## 5

### Glossary

**Alternating current** — A flow of charged particles through a conductor, first in one direction, then in the other direction.

**Ampere** — A measure of flow of charged particles per unit time. One ampere represents one coulomb of charge flowing past a point in one second.

**Atom** — The smallest particle of matter that makes up an element. Consists of protons and neutrons in the central area called the nucleus, with electrons surrounding this central region.

**Coulomb** — A unit of measure of a quan-

tity of electrically charged particles. One coulomb is equal to  $6.25 \times 10^{18}$  electrons.

**Direct current** — A flow of charged particles through a conductor in one direction only.

**EMF** — Electromotive Force is the term used to define the force of attraction between two points of different charge potential. Also called voltage.

**Energy** — Capability of doing work. It is usually measured in electrical terms as the number of watts of power consumed during a specific period of time, such as

watt-seconds or kilowatt-hours..

**Joule** — Measure of a quantity of energy. One joule is defined as one newton (a measure of force) acting over a distance of one meter.

**Ohm** — Unit of resistance. One ohm is defined as the resistance that will allow one ampere of current when one volt of EMF is impressed across the resistance.

**Power** — Power is the rate at which work is done. One watt of power is equal to one volt of EMF, causing a current of one ampere.

**Volt** — A measure of electromotive force,

### Introduction

This chapter was written by Roger Taylor, K9ALD.

The atom is the primary building block of the universe. The main parts of the atom include protons, electrons and neutrons. Protons have a positive electrical charge, electrons a negative charge and neutrons have no electrical charge. All atoms are electrically neutral, so they have the same number of electrons as protons. If an atom loses electrons, so it has more protons than electrons, it has a net positive charge. If an atom gains electrons, so it has more electrons than protons, it has a negative charge. Particles with a positive or negative charge are called ions. Free electrons are also called ions, because

they have a negative charge.

When there are a surplus number of positive ions in one location and a surplus number of negative ions (or electrons) in another location, there is an attractive force between the two collections of particles. That force tries to pull the collections together. This attraction is called electromotive force, or EMF.

If there is no path (conductor) to allow electric charge to flow between the two locations, the charges cannot move together and neutralize one another. If a conductor is provided, then electric current (usually electrons) will flow through the conductor.

Electrons move from the negative to the

positive side of the voltage, or EMF source. *Conventional current* has the opposite direction, from positive to negative. This comes from an arbitrary decision made by Benjamin Franklin in the 18th century. The conventional current direction is important in establishing the proper polarity sign for many electronics calculations. Conventional current is used in much of the technical literature. The arrows in semiconductor schematic symbols point in the direction of conventional current, for example.

To measure the quantities of charge, current and force, certain definitions have been adopted. Charge is measured in *coulombs*. One coulomb is equal to  $6.25 \times 10^{18}$

electrons (or protons). Charge flow is measured in *amperes*. One ampere represents one coulomb of charge flowing past a point in one second. Electromotive force is measured in *volts*. One volt is defined as the potential force (electrical) between two points for which one ampere of current will do one *joule* (measure of energy) of work flowing from one point to another. (A joule of work per second represents a power of one watt. See the **Mathematics for Amateur Radio** chapter for more information about these unit definitions.)

Voltage can be generated in a variety of ways. Chemicals with certain characteristics can be combined to form a battery. Mechanical motion such as friction (static electricity, lightning) and rotating conductors in a magnetic field (generators) can also produce voltage.

Any conductor between points at different voltages will allow current to pass between the points. No conductor is perfect or lossless, however, at least not at normal temperatures. Charged particles such as electrons resist being moved and it requires energy to move them. The amount of resistance to current is measured in *ohms*.

### OHM'S LAW

One ohm is defined as the amount of resistance that allows one ampere of current to flow between two points that have a potential difference of one volt. Thus, we get Ohm's Law, which is:

$$R = \frac{E}{I} \quad (1)$$

where:

R = resistance in ohms,

E = potential or EMF in volts and

I = current in amperes.

Transposing the equation gives the other common expressions of Ohm's Law as:

$$E = I \times R \quad (2)$$

and

$$I = \frac{E}{R} \quad (3)$$

All three forms of the equation are used often in radio work. You must remember

**Fig 5.1 — A simple circuit consisting of a battery and a resistor.**

that the quantities are in volts, ohms and amperes; other units cannot be used in the equations without first being converted. For example, if the current is in milliamperes you must first change it to the equivalent fraction of an ampere before substituting the value into the equations.

The following examples illustrate the use of Ohm's Law. The current through a 20000- $\Omega$  resistance is 150. mA. See **Fig 5.1**. What is the voltage? To find voltage, use equation 2 ( $E = I \times R$ ). Convert the current from milliamperes to amperes. Divide by 1000 mA / A (or multiply by  $10^{-3}$  A / mA) to make this conversion. If you are uncertain how to do these conversions, see the **Mathematics for Amateur Radio** chapter. (Notice the conversion factor of 1000 does not limit the number of significant figures in the calculated answer.)

$$I = \frac{150. \text{ mA}}{1000 \frac{\text{mA}}{\text{A}}} = 0.150 \text{ A}$$

Then:

$$E = 0.150 \text{ A} \times 20000 \Omega = 3000 \text{ V}$$

If you are unfamiliar with the use of significant figures and rounding off calculated values, see the **Mathematics for Amateur Radio** chapter.

When 150 V is applied to a circuit, the current is measured at 2.5 A. What is the resistance of the circuit? In this case R is the unknown, so we will use equation 1:

$$R = \frac{E}{I} = \frac{150 \text{ V}}{2.5 \text{ A}} = 60. \Omega$$

No conversion was necessary because the voltage and current were given in volts and amperes.

How much current will flow if 250 V is applied to a 5000- $\Omega$  resistor? Since I is unknown,

$$I = \frac{E}{R} = \frac{250 \text{ V}}{5000 \Omega} = 0.05 \text{ A}$$

It is more convenient to express the current in mA, and  $0.05 \text{ A} \times 1000 \text{ mA} / \text{A} = 50 \text{ mA}$ .

### RESISTANCE AND CONDUCTANCE

Suppose we have two conductors of the same size and shape, but of different materials. The amount of current that will flow when a given EMF is applied will vary with the resistance of the material. The lower the resistance, the greater the current for a given EMF. The *resistivity* of a material is the resistance, in ohms, of a cube of the material measuring one centimeter on each edge. One of the best conductors is copper, and in making resistance calculations it is

**Table 5.1**

**Relative Resistivity of Metals**

Material	Resistivity Compared to Copper
Aluminum (pure)	1.60
Brass	3.7-4.90
Cadmium	4.40
Chromium	1.80
Copper (hard-drawn)	1.03
Copper (annealed)	1.00
Gold	1.40
Iron (pure)	5.68
Lead	12.80
Nickel	5.10
Phosphor bronze	2.8-5.40
Silver	0.94
Steel	7.6-12.70
Tin	6.70
Zinc	3.40

frequently convenient to compare the resistance of the material under consideration with that of a copper conductor of the same size and shape. **Table 5.1** gives the ratio of the resistivity of various conductors to the resistivity of copper.

The longer the physical path, the higher the resistance of that conductor. For direct current and low-frequency alternating currents (up to a few thousand hertz) the resistance is inversely proportional to the cross-sectional area of the path the current must travel; that is, given two conductors of the same material and having the same length, but differing in cross-sectional area, the one with the larger area will have the lower resistance.

### RESISTANCE OF WIRES

The problem of determining the resistance of a round wire of given diameter and length—or its converse, finding a suitable size and length of wire to provide a desired amount of resistance—can easily be solved with the help of the copper wire table given in the **Component Data** chapter. This table gives the resistance, in ohms per 1000 ft, of each standard wire size. For example, suppose you need a resistance of 3.5  $\Omega$ , and some #28 wire is on hand. The wire table in the **Component Data** chapter shows that #28 wire has a resistance of 66.17  $\Omega$  / 1000 ft. Since the desired resistance is 3.5  $\Omega$ , the required wire length is:

$$\begin{aligned} \text{Length} &= \frac{R_{\text{DESIRED}}}{\frac{R_{\text{WIRE}}}{1000 \text{ ft}}} = \frac{3.5 \Omega}{\frac{66.17 \Omega}{1000 \text{ ft}}} \\ &= \frac{3.5 \Omega \times 1000 \text{ ft}}{66.17 \Omega} = 53 \text{ ft} \quad (4) \end{aligned}$$

As another example, suppose that the resistance of wire in a circuit must not exceed 0.05  $\Omega$  and that the length of wire

required for making the connections totals 14 ft. Then:

$$\frac{R_{\text{WIRE}}}{1000 \text{ ft}} < \frac{R_{\text{MAXIMUM}}}{\text{Length}} = \frac{0.05 \Omega}{14.0 \text{ ft}} \quad (5)$$

$$= 3.57 \times 10^{-3} \frac{\Omega}{\text{ft}} \times \frac{1000 \text{ ft}}{1000 \text{ ft}}$$

$$\frac{R_{\text{WIRE}}}{1000 \text{ ft}} < \frac{3.57 \Omega}{1000 \text{ ft}}$$

Find the value of  $R_{\text{WIRE}}/1000 \text{ ft}$  that is less than the calculated value. The wire table shows that #15 is the smallest size having a resistance less than this value. (The resistance of #15 wire is given as 3.1810  $\Omega/1000 \text{ ft}$ .) Select any wire size larger than this for the connections in your circuit, to ensure that the total wire resistance will be less than 0.05  $\Omega$ .

When the wire in question is not made of copper, the resistance values in the wire table should be multiplied by the ratios shown in Table 5.1 to obtain the resulting resistance. If the wire in the first example were made from nickel instead of copper, the length required for 3.5  $\Omega$  would be:

$$\text{Length} = \frac{R_{\text{DESIRED}}}{\frac{R_{\text{WIRE}}}{1000 \text{ ft}}} \quad (6)$$

$$= \frac{3.5 \Omega}{\frac{66.17 \Omega}{1000 \text{ ft}} \times 5.1}$$

$$= \frac{3.5 \Omega \times 1000 \text{ ft}}{66.17 \Omega \times 5.1}$$

$$\text{Length} = \frac{3500 \text{ ft}}{337.5} = 10.0 \text{ ft}$$

## TEMPERATURE EFFECTS

The resistance of a conductor changes with its temperature. The resistance of practically every metallic conductor increases with increasing temperature. Carbon, however, acts in the opposite way; its resistance decreases when its temperature rises. It is seldom necessary to consider temperature in making resistance calculations for amateur work. The temperature effect is important when it is necessary to maintain a constant resistance under all conditions, however. Special materials that have little or no change in resistance over a wide temperature range are used in that case.

## RESISTORS

A package of material exhibiting a certain amount of resistance, made up into a single unit is called a resistor. Different resistors having the same resistance value may be considerably different in physical size and construction (see Fig 5.2). Current through a resistance causes the conductor to become heated; the higher the resistance and the larger the current, the greater the amount of heat developed. Resistors intended for carrying large currents must be physically large so the heat can be radiated quickly to the surrounding air. If the resistor does not dissipate the heat quickly, it may get hot enough to melt or burn.

The amount of heat a resistor can safely dissipate depends on the material, surface area and design. Typical carbon resistors used in amateur electronics ( $1/8$  to 2-W re-

sistors) depend primarily on the surface area of the case, with some heat also being carried off through the connecting leads. Wirewound resistors are usually used for higher power levels. Some have finned cases for better convection cooling and/or metal cases for better conductive cooling.

In some circuits, the resistor value may be critical. In this case, precision resistors are used. These are typically wirewound, or carbon-film devices whose values are carefully controlled during manufacture. In addition, special material or construction techniques may be used to provide temperature compensation, so the value does not change (or changes in a precise manner) as the resistor temperature changes. There is more information about the electrical characteristics of real resistors in the **Real-World Component Characteristics** chapter.

## CONDUCTANCE

The reciprocal of resistance ( $1/R$ ) is *conductance*. It is usually represented by the symbol  $G$ . A circuit having high conductance has low resistance, and vice versa. In radio work, the term is used chiefly in connection with electron-tube and field-effect transistor characteristics. The unit of conductance is the siemens, abbreviated  $S$ . A resistance of 1  $\Omega$  has a conductance of 1  $S$ , a resistance of 1000  $\Omega$  has a conductance of 0.001  $S$ , and so on. A unit frequently used in connection with electron devices is the  $\mu S$  or one millionth of a siemens. It is the conductance of a 1-M $\Omega$  resistance.

# Series and Parallel Resistances

Very few actual electric circuits are as simple as Fig 5.1. Commonly, resistances are found connected in a variety of ways. The two fundamental methods of connecting resistances are shown in Fig 5.3. In part A, the current flows from the source of EMF (in the direction shown by the arrow) down through the first resistance,  $R_1$ , then through the second,  $R_2$  and then back to the source. These resistors are connected in series. The current everywhere in the circuit has the same value.

In part B, the current flows to the common connection point at the top of the two resistors and then divides, one part of it

flowing through  $R_1$  and the other through  $R_2$ . At the lower connection point these two currents again combine; the total is

the same as the current into the upper common connection. In this case, the two resistors are connected in parallel.

**Fig 5.2 — Examples of various resistors.** In the right foreground are  $1/4$ -,  $1/2$ - and 1-W composition resistors. The two larger cylindrical components at the center are wire-wound power resistors. A surface-mount, or chip resistor is shown at the top right. The remaining two parts are variable resistors; a PC-board-mount device at the lower left and a panel-mount unit at the upper left.

## RESISTORS IN PARALLEL

In a circuit with resistances in parallel, the total resistance is less than that of the lowest resistance value present. This is because the total current is always greater than the current in any individual resistor. The formula for finding the total resistance of resistances in parallel is

$$R = \frac{1}{\frac{1}{R_1} + \frac{1}{R_2} + \frac{1}{R_3} + \frac{1}{R_4} + \dots} \quad (7)$$

where the dots indicate that any number of resistors can be combined by the same method. For only two resistances in paral-

lel (a very common case) the formula becomes:

$$R = \frac{R_1 \times R_2}{R_1 + R_2} \quad (8)$$

Example: If a 500.-Ω resistor is connected in parallel with one of 1200. Ω, what is the total resistance?

$$R = \frac{R_1 \times R_2}{R_1 + R_2} = \frac{500. \Omega \times 1200. \Omega}{500. \Omega + 1200. \Omega}$$

$$R = \frac{600000 \Omega^2}{1700. \Omega} = 353 \Omega$$

## KIRCHHOFF'S FIRST LAW (KIRCHHOFF'S CURRENT LAW)

Suppose three resistors (5.00 kΩ, 20.0 kΩ and 8.00 kΩ) are connected in parallel as shown in Fig 5.4. The same EMF, 250. V, is applied to all three resistors. The current in each can be found from Ohm's Law, as shown below. The current through R1 is I1, I2 is the current through R2 and I3 is the current through R3.

For convenience, we can use resistance in kΩ, which gives current in milliamperes.

$$I_1 = \frac{E}{R_1} = \frac{250. \text{ V}}{5.00 \text{ k}\Omega} = 50.0 \text{ mA}$$

$$I_2 = \frac{E}{R_2} = \frac{250. \text{ V}}{20.0 \text{ k}\Omega} = 12.5 \text{ mA}$$

$$I_3 = \frac{E}{R_3} = \frac{250. \text{ V}}{8.00 \text{ k}\Omega} = 31.2 \text{ mA}$$

Notice that the branch currents are inversely proportional to the resistances. The 20000-Ω resistor has a value four times larger than the 5000-Ω resistor, and has a current one quarter as large. If a resistor has a value twice as large as another, it will have half as much current through it when they are connected in parallel.

The total circuit current is:

$$I_{\text{TOTAL}} = I_1 + I_2 + I_3 \quad (9)$$

$$I_{\text{TOTAL}} = 50.0 \text{ mA} + 12.5 \text{ mA} + 31.2 \text{ mA}$$

$$I_{\text{TOTAL}} = 93.7 \text{ mA}$$

This example illustrates Kirchhoff's Current Law: The current flowing into a node or branching point is equal to the sum of the individual currents leaving the node or branching point. The total resistance of the circuit is therefore:

$$R = \frac{E}{I} = \frac{250. \text{ V}}{93.7 \text{ mA}} = 2.67 \text{ k}\Omega$$

You can verify this calculation by combining the three resistor values in parallel, using equation 7.

## RESISTORS IN SERIES

When a circuit has a number of resis-

tances connected in series, the total resistance of the circuit is the sum of the individual resistances. If these are numbered R1, R2, R3 and so on, then:

$$R_{\text{TOTAL}} = R_1 + R_2 + R_3 + R_4 + \dots \quad (10)$$

where the dots indicate that as many resistors as necessary may be added.

Example: Suppose that three resistors are connected to a source of EMF as shown in Fig 5.5. The EMF is 250. V, R1 is 5.00 kΩ, R2 is 20.0 kΩ and R3 is 8.00 kΩ. The total resistance is then

$$R_{\text{TOTAL}} = R_1 + R_2 + R_3$$

$$R = 5.00 \text{ k}\Omega + 20.0 \text{ k}\Omega + 8.00 \text{ k}\Omega$$

$$R = 33.0 \text{ k}\Omega.$$

The current in the circuit is then

$$I = \frac{E}{R} = \frac{250. \text{ V}}{33.0 \text{ k}\Omega} = 7.58 \text{ mA}$$

(We need not carry calculations beyond three significant figures; often, two will suffice because the accuracy of measurements is seldom better than a few percent.)

## KIRCHHOFF'S SECOND LAW (KIRCHHOFF'S VOLTAGE LAW)

Ohm's Law applies in any portion of a circuit as well as to the circuit as a whole. Although the current is the same in all three of the resistances in the example of Fig 5.5, the total voltage divides between them. The voltage appearing across each resistor (the voltage drop) can be found from Ohm's Law.

Example: If the voltage across R1 is called E1, that across R2 is called E2 and that across R3 is called E3, then

$$E_1 = IR_1 = 0.00758 \text{ A} \times 5000 \Omega = 37.9 \text{ V}$$

$$E_2 = IR_2 = 0.00758 \text{ A} \times 20000 \Omega = 152 \text{ V}$$

$$E_3 = IR_3 = 0.00758 \text{ A} \times 8000 \Omega = 60.6 \text{ V}$$

Notice here that the voltage drop across each resistor is directly proportional to the resistance. The 20000-Ω resistor value is four times larger than the 5000-Ω resistor, and the voltage drop across the 20000-Ω resistor is four times larger. A resistor that has a value twice as large as another will have twice the voltage drop across it when they are connected in series.

Kirchhoff's Voltage Law accurately describes the situation in the circuit: The sum of the voltages in a closed current loop is zero. The resistors are power sinks, while the battery is a power source. It is common to assign a + sign to power sources and a - sign to power sinks. This means the voltages across the resistors have the opposite sign from the battery voltage. Adding all the voltages yields zero. In the case of a single voltage source, algebraic manipulation implies that the sum of the individual voltage drops

Fig 5.3 — Resistors connected in series at A, and in parallel at B.

Fig 5.4 — An example of resistors in parallel. See text for calculations.

Fig 5.5 — An example of resistors in series. See text for calculations.

in the circuit must be equal to the applied voltage.

$$E_{\text{TOTAL}} = E_1 + E_2 + E_3 \quad (11)$$

$$E_{\text{TOTAL}} = 37.9 \text{ V} + 152 \text{ V} + 60.6 \text{ V}$$

$$E_{\text{TOTAL}} = 250. \text{ V}$$

(Remember the significant figures rule for addition.)

In problems such as this, when the current is small enough to be expressed in milliamperes, considerable time and trouble can be saved if the resistance is expressed in kilohms rather than in ohms. When the resistance in kilohms is substituted directly in Ohm's Law, the current will be milliamperes, if the EMF is in volts.

### RESISTORS IN SERIES-PARALLEL

A circuit may have resistances both in parallel and in series, as shown in Fig 5.6A. The method for analyzing such a circuit is as follows: Consider R2 and R3 to be the equivalent of a single resistor,  $R_{\text{EQ}}$  whose value is equal to R2 and R3 in parallel.

$$R_{\text{EQ}} = \frac{R_2 \times R_3}{R_2 + R_3} = \frac{20000 \Omega \times 8000 \Omega}{20000 \Omega + 8000 \Omega}$$

$$= \frac{1.60 \times 10^8 \Omega^2}{28000 \Omega}$$

$$R_{\text{EQ}} = 5710 \Omega = 5.71 \text{ k}\Omega$$

This resistance in series with R1 forms a simple series circuit, as shown in Fig 5.6B. The total resistance in the circuit is:

$$R_{\text{TOTAL}} = R_1 + R_{\text{EQ}} = 5.00 \text{ k}\Omega + 5.71 \text{ k}\Omega$$

$$R_{\text{TOTAL}} = 10.71 \text{ k}\Omega$$

The current is:

$$I = \frac{E}{R} = \frac{250. \text{ V}}{10.71 \text{ k}\Omega} = 23.3 \text{ mA}$$

The voltage drops across R1 and  $R_{\text{EQ}}$  are:

$$E_1 = I \times R_1 = 23.3 \text{ mA} \times 5.00 \text{ k}\Omega = 117 \text{ V}$$

$$E_2 = I \times R_{\text{EQ}} = 23.3 \text{ mA} \times 5.71 \text{ k}\Omega = 133 \text{ V}$$

with sufficient accuracy. These two voltage drops total 250. V, as described by Kirchhoff's Current Law. E2 appears across both R2 and R3 so,

$$I_2 = \frac{E_2}{R_2} = \frac{133 \text{ V}}{20.0 \text{ k}\Omega} = 6.65 \text{ mA}$$

$$I_3 = \frac{E_3}{R_3} = \frac{133 \text{ V}}{8.00 \text{ k}\Omega} = 16.6 \text{ mA}$$

where:

$I_2$  = current through R2 and

$I_3$  = current through R3.

The sum of  $I_2$  and  $I_3$  is equal to 23.3 mA, conforming to Kirchhoff's Voltage Law.

### THEVENIN'S THEOREM

Thevenin's Theorem is a useful tool for simplifying electrical networks. Thevenin's Theorem states that any two-terminal network of resistors and voltage or current sources can be replaced by a single voltage source and a series resistor. Such a transformation can simplify the calculation of current through a parallel branch. Thevenin's Theorem can be readily applied to the circuit of Fig 5.6A, to find the current through R3.

In this example, R1 and R2 form a voltage divider circuit, with R3 as the load (Fig 5.7A). The current drawn by the load (R3) is simply the voltage across R3, divided by its resistance. Unfortunately, the value of R2 affects the voltage across R3, just as the presence of R3 affects the potential appearing across R2. Some means of separating the two is needed; hence the Thevenin-equivalent circuit.

The voltage of the Thevenin-equivalent battery is the open-circuit voltage, measured when there is no current from either terminal A or B. Without a load connected between A and B, the total current through the circuit is (from Ohm's Law):

$$I = \frac{E}{R_1 + R_2} \quad (12)$$

and the voltage between terminals A and B ( $E_{\text{AB}}$ ) is:

$$E_{\text{AB}} = I \times R_2 \quad (13)$$

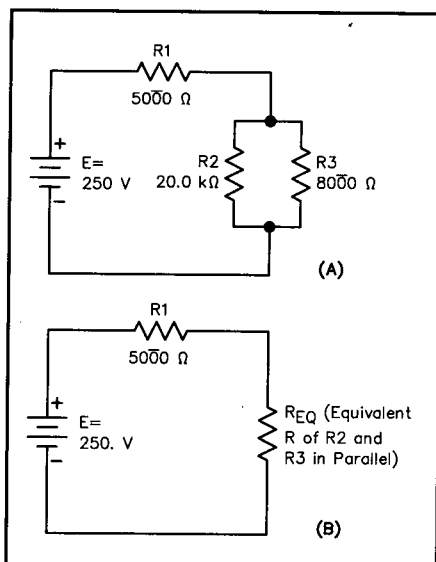

Fig 5.6 — At A, an example of resistors in series-parallel. The equivalent circuit is shown at B. See text for calculations.

By substituting the first equation into the second, we can find a simplified expression for  $E_{\text{AB}}$ :

$$E_{\text{AB}} = \frac{R_2}{R_1 + R_2} \times E \quad (14)$$

Using the values in our example, this becomes:

$$E_{\text{AB}} = \frac{20.0 \text{ k}\Omega}{25.0 \text{ k}\Omega} \times 250. \text{ V} = 200. \text{ V}$$

when nothing is connected to terminals A or B. With no current drawn, E is equal to  $E_{\text{AB}}$ .

The Thevenin-equivalent resistance is the total resistance between terminals A and B. The ideal voltage source, by defini-

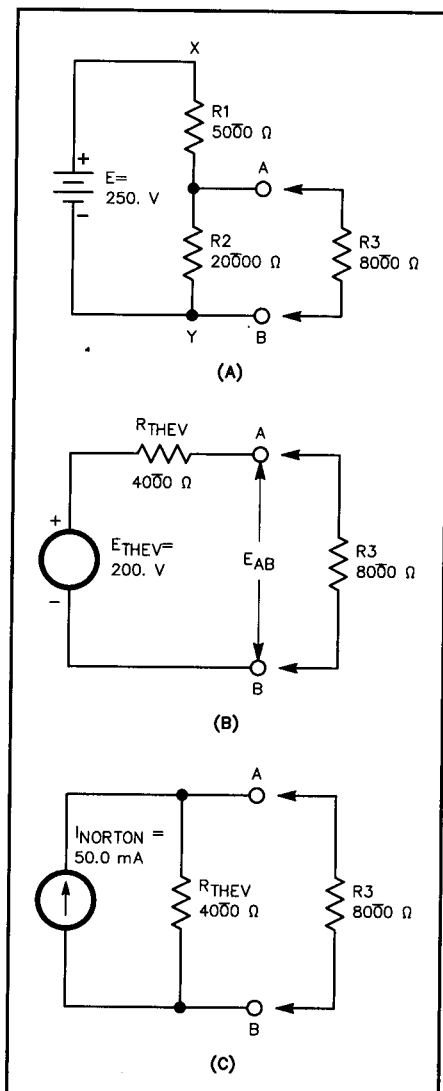

Fig 5.7 — Equivalent circuits for the circuit shown in Fig 5.6. A shows the load resistor (R3) looking into the circuit. B shows the Thevenin-equivalent circuit, with a resistor and a voltage source in series. C shows the Norton-equivalent circuit, with a resistor and current source in parallel.

tion, has zero internal resistance. Assuming the battery to be a close approximation of an ideal source, put a short between points X and Y in the circuit of Fig 5.7A. R1 and R2 are then effectively placed in parallel, as viewed from terminals A and B. The Thevenin-equivalent resistance is then:

$$R_{THEV} = \frac{R1 \times R2}{R1 + R2} \quad (15)$$

$$R_{THEV} = \frac{5000 \Omega \times 20000 \Omega}{5000 \Omega + 20000 \Omega}$$

$$R_{THEV} = \frac{1.00 \times 10^8 \Omega^2}{25000 \Omega} = 4000 \Omega$$

This gives the Thevenin-equivalent circuit as shown in Fig 5.7B. The circuits of Figs. 5.7A and 5.7B are equivalent as far as R3 is concerned.

Once R3 is connected to terminals A and B, there will be current through R<sub>THEV</sub>, causing a voltage drop across R<sub>THEV</sub> and reducing E<sub>AB</sub>. The current through R3 is equal to

$$I3 = \frac{E_{THEV}}{R_{TOTAL}} = \frac{E_{THEV}}{R_{THEV} + R3} \quad (16)$$

Substituting the values from our example:

$$I3 = \frac{200. V}{4000 \Omega + 8000 \Omega} = 16.7 \text{ mA}$$

This agrees with the value calculated earlier.

### NORTON'S THEOREM

Norton's Theorem is another tool for analyzing electrical networks. Norton's Theorem states that any two-terminal network of resistors and current or voltage sources can be replaced by a single current source and a parallel resistor. Norton's Theorem is to current sources what Thevenin's Theorem is to voltage sources. In fact, the Thevenin resistance calculated previously is also used as the Norton equivalent resistance.

The circuit just analyzed by means of Thevenin's Theorem can be analyzed just as easily by Norton's Theorem. The equivalent Norton circuit is shown in Fig 5.7C. The current I<sub>SC</sub> of the equivalent current source is the short-circuit current through terminals A and B. In the case of the voltage divider shown in Fig 5.7A, the short-circuit current is:

$$I_{SC} = \frac{E}{R1} \quad (17)$$

Substituting the values from our example, we have:

$$I_{SC} = \frac{E}{R1} = \frac{250. V}{5000 \Omega} = 50.0 \text{ mA}$$

The resulting Norton-equivalent circuit consists of a 50.0-mA current source placed in parallel with a 4000-Ω resistor. When R3 is connected to terminals A and B, one-third of the supply current flows through R3 and the remainder through R<sub>THEV</sub>. This gives a current through R3 of 16.7 mA, again agreeing with previous conclusions.

A Norton-equivalent circuit can be transformed into a Thevenin-equivalent circuit and vice versa. The equivalent resistor stays the same in both cases; it is placed in series with the voltage source in the case of a Thevenin-equivalent circuit and in parallel with the current source in the case of a Norton-equivalent circuit. The voltage for a Thevenin-equivalent source is equal to the no-load voltage appearing across the resistor in the Norton-equivalent circuit. The current for a Norton-equivalent source is equal to the short-circuit current provided by the Thevenin source.

## Power and Energy

Regardless of how voltage is generated, energy must be supplied if current is drawn from the voltage source. The energy supplied may be in the form of chemical energy or mechanical energy. This energy is measured in joules. One joule is defined from classical physics as the amount of energy or work done when a force of one newton (a measure of force) is applied to an object that is moved one meter in the direction of the force.

Power is another important concept. In the USA, power is often measured in horsepower in mechanical systems. We use the metric power unit of watts in electrical systems, however. In metric countries, mechanical power is usually expressed in watts also. One watt is defined as the use (or generation) of one joule of energy per second. One watt is also defined as one volt of potential pushing one ampere of current through a resistance. Thus,

$$P = I \times E \quad (18)$$

where:

- P = power in watts
- I = current in amperes
- E = EMF in volts.

When current flows through a resistance, the electrical energy is turned into heat. Common fractional and multiple units for power are the milliwatt (one thousandth of a watt) and the kilowatt (1000 W).

Example: The plate voltage on a transmitting vacuum tube is 2000. V and the plate current is 350. mA. (The current must be changed to amperes before substitution in the formula, and so is 0.350 A.) Then:

$$P = I \times E = 2000. V \times 0.350 A = 700. W$$

By substituting the Ohm's Law equivalent for E and I, the following formulas are obtained for power:

$$P = \frac{E^2}{R} \quad (19)$$

and

$$P = I^2 \times R \quad (20)$$

These formulas are useful in power calculations when the resistance and either the current or voltage (but not both) are known.

Example: How much power will be converted to heat in a 4000.-Ω resistor if the

potential applied to it is 200. V? From equation 19,

$$P = \frac{E^2}{R} = \frac{(200. V)^2}{4000. \Omega}$$

$$= \frac{40000 V^2}{4000. \Omega} = 10.0 W$$

As another example, suppose a current of 20. mA flows through a 300.-Ω resistor. Then:

$$P = I^2 \times R = 0.020^2 A^2 \times 300. \Omega$$

$$P = 0.00040 A^2 \times 300. \Omega$$

$$P = 0.12 W$$

Note that the current was changed from milliamperes to amperes before substitution in the formula.

Electrical power in a resistance is turned into heat. The greater the power, the more rapidly the heat is generated. Resistors for radio work are made in many sizes, the smallest being rated to dissipate (or carry safely) about 1/16 W. The largest resistors commonly used in amateur equipment will dissipate about 100 W. Large resistors such as those used in dummy-load anten-

nas, are often cooled with oil to increase their power-handling capability.

If you want to express power in horsepower instead of watts, the following relationship holds:

$$1 \text{ horsepower} = 746 \text{ W} \quad (21)$$

This formula assumes lossless transformation; practical efficiency is taken up shortly. This formula is especially useful if you are working with a system that converts electrical energy into mechanical energy, and vice versa, since mechanical power is often expressed in horsepower, in the US.

## GENERALIZED DEFINITION OF RESISTANCE

Electrical energy is not always turned into heat. The energy used in running a motor, for example, is converted to mechanical motion. The energy supplied to a radio transmitter is largely converted into radio waves. Energy applied to a loudspeaker is changed into sound waves. In each case, the energy is converted to other forms and can be completely accounted for. None of the energy *just disappears*! This is a statement of the Law of Conservation of Energy. When a device converts energy from one form to another, we often say it *dissipates* the energy, or power. (Power is energy divided by time.) Of course the device doesn't really "use up" the energy, or make it disappear, it just converts it to another form. Proper operation of electrical devices often requires that the power must be supplied at a specific ratio of voltage to current. These features are characteristics of resistance, so it can be said that any device that "dissipates power" has a definite value of resistance.

This concept of resistance as something that absorbs power at a definite voltage-to-current ratio is very useful; it permits substituting a simple resistance for the load or power-consuming part of the device receiving power, often with considerable simplification of calculations. Of course, every electrical device has some resistance of its own in the more narrow sense, so a part of the energy supplied to it is converted to heat in that resistance even

though the major part of the energy may be converted to another form.

## EFFICIENCY

In devices such as motors and vacuum tubes, the objective is to convert the supplied energy (or power) into some form other than heat. Therefore, power converted to heat is considered to be a loss, because it is not useful power. The efficiency of a device is the useful power output (in its converted form) divided by the power input to the device. In a vacuum-tube transmitter, for example, the objective is to convert power from a dc source into ac power at some radio frequency. The ratio of the RF power output to the dc input is the efficiency of the tube. That is:

$$\text{Eff} = \frac{P_O}{P_I} \quad (22)$$

where:

Eff = efficiency (as a decimal)

$P_O$  = power output (W)

$P_I$  = power input (W).

Example: If the dc input to the tube is 100 W, and the RF power output is 60 W, the efficiency is:

$$\text{Eff} = \frac{P_O}{P_I} = \frac{60 \text{ W}}{100 \text{ W}} = 0.6$$

Efficiency is usually expressed as a percentage — that is, it tells what percent of the input power will be available as useful output. To calculate percent efficiency, just multiply the value from equation 22 by 100%. The efficiency in the example above is 60%.

Suppose a mobile transmitter has an RF power output of 100. W with 52% efficiency at 13.8 V. The vehicle's alternator system charges the battery at a 5.0-A rate at this voltage. Assuming an alternator efficiency of 68%, how much horsepower must the engine produce to operate the transmitter and charge the battery? Solution: To charge the battery, the alternator must produce  $13.8 \text{ V} \times 5.0 \text{ A} = 69 \text{ W}$ . The transmitter dc input power is  $100. \text{ W} / 0.52 = 190 \text{ W}$ . Therefore, the total electrical power required from the alternator is  $190 + 69 = 260 \text{ W}$ . The engine load then is:

$$P_I = \frac{P_O}{\text{Eff}} = \frac{260 \text{ W}}{0.68} = 380 \text{ W}$$

We can convert this to horsepower using the formula given earlier to convert between horsepower and watts:

$$380 \text{ W} \times \frac{1 \text{ horsepower}}{746 \text{ W}} = 0.51 \text{ horsepower}$$

## ENERGY

When you buy electricity from a power company, you pay for electrical energy, not power. What you pay for is the *work* that electricity does for you, not the rate at which that work is done. Work is equal to power multiplied by time. The common unit for measuring electrical energy is the watt-hour, which means that a power of 1 W has been used for one hour. That is:

$$\text{W hr} = P T$$

where:

W hr = energy in watt-hours

P = power in watts

T = time in hours.

Actually, the watt-hour is a fairly small energy unit, so the power company bills you for kilowatt-hours of energy used. Another energy unit that is sometimes useful is the watt-second (joule).

Energy units are seldom used in amateur practice, but it is obvious that a small amount of power used for a long time can eventually result in a power bill that is just as large as if a large amount of power had been used for a very short time.

One practical application of energy units is to estimate how long a radio (such as a hand-held unit) will operate from a certain battery. For example, suppose a fully charged battery stores 900 mA hr of energy, and a radio draws 30 mA on receive. You might guess that the radio will receive 30 hrs with this battery, assuming 100% efficiency. You shouldn't expect to get the full 900 mA hr out of the battery, and you will probably spend some of the time transmitting, which will also reduce the time the battery will last. The **Real-World Component Characteristics** and **Power Supplies** chapters include additional information about batteries and their charge/discharge cycles.

# Circuits and Components

## SERIES AND PARALLEL CIRCUITS

Passive components (resistors for dc circuits) can be used to make voltage and current dividers and limiters to obtain a desired value. For instance, in **Fig 5.8A**, two resistors are connected in series to provide a voltage divider. As long as the device connected at point A has a much higher resistance than the resistors in the divider, the voltage will be approximately the ratio of the resistances. Thus, if  $E = 10\text{ V}$ ,  $R_1 = 5\ \Omega$  and  $R_2 = 5\ \Omega$ , the voltage at point A will be 5 V measured on a high-impedance voltmeter. A good rule of thumb is that the load at point A should be at least ten times the value of the highest resistor in the divider to get reasonably close to the voltage you want. As the load resistance gets closer to the value of the divider, the current drawn by the load affects the division and causes changes from the desired value. If you need precise voltage division from fixed resistors and know the value of the load resistance, you

can use Kirchhoff's Laws and Thevenin's Theorem (explained earlier) to calculate exact values.

Similarly, resistors can be used, as shown in **Fig 5.8B**, to make current dividers. Suppose you had two LEDs (light emitting diodes) and wanted one to glow twice as brightly as the other. You could use one resistor with twice the value of the other for the dimmer LED. Thus, approximately two-thirds of the current would flow through one LED and one-third through the other (neglecting any effect of the 0.7-V drop across the diode).

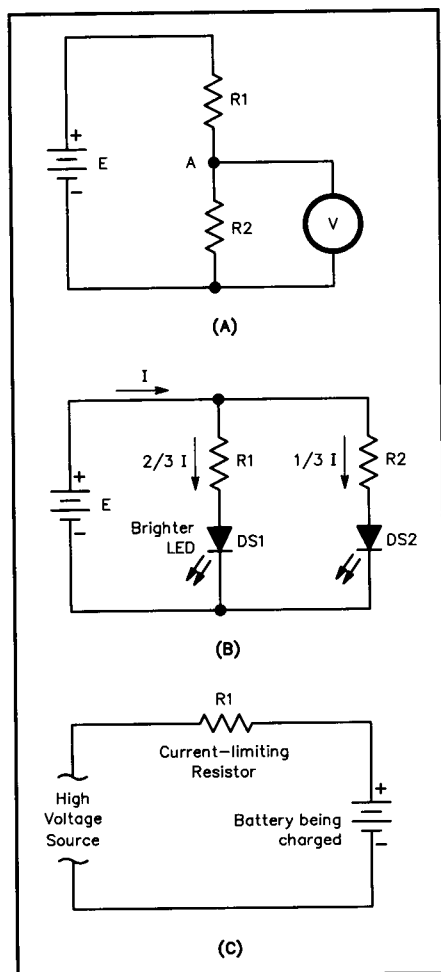

Resistors can also be used to limit the current through a device from a fixed voltage source. A typical example is shown in **Fig 5.8C**. Here a high-voltage source feeds a battery in a battery charger. This is typical of nickel cadmium chargers. The high resistor value limits the current that can possibly flow through the battery to a value that is low enough so it will not damage the battery.

nating current use. Because ac voltage goes through zero with each cycle, switches can successfully interrupt much more alternating current than direct current without arcing. A switch that has a 10-A ac current rating may arc and damage the contacts if used to turn off more than an ampere or two of dc.

Switches are normally designated by the number of *poles* (circuits controlled) and *positions* (circuit path choices). The simplest switch is the on-off switch, which is a single-pole, single-throw (SPST) switch as shown in **Fig 5.9A**. The off position does not direct the current to another circuit. The next step would be to change the current path to another path, and would be a single-pole, double-throw (SPDT) switch as shown in **Fig 5.9B**. Adding an off position would give a single-pole, double-throw, center-off switch as shown in **Fig 5.9C**.

Several such switches can be "ganged" to the same mechanical activator to provide double pole, triple pole or even more, separate control paths all activated at once. Switches can be activated in a variety of ways. The most common methods include lever, push button and rotary switches. Samples of these are shown in **Fig 5.10**. Most switches stay in the position set, but some are spring loaded so they only stay in the desired position while held there. These are called momentary switches.

Switches typically found in the home are usually rated for 125 V ac and 15 to 20 A. Switches in cars are usually rated for 12 V dc and several amperes. The breakdown voltage rating of a switch, which is usually higher than the interrupt rating, primarily depends on the insulating material surrounding the contacts and the separation between the contacts. Plastic or phenolic material normally provides both structural support and insulation. Ceramic material may be used to provide better insulation, particularly in rotary (wafer) switches.

**Fig 5.8** — This circuit shows a resistive voltage divider.

## SWITCHES

Switches are used to start or stop a signal (current) flowing in a particular circuit. Most switches are mechanical devices, although the same effect may be achieved with solid-state devices. Relays are switches that are controlled by another electrical signal rather than manual or mechanical means.

Switches come in many different forms and a wide variety of ratings. The most important ratings are the voltage and current handling capabilities. The voltage rating usually includes both the breakdown rating and the interrupt rating. Normally, the interrupt rating is the lower value, and therefore the one given on (for) the switch. The current rating includes both the current carrying capacity and the interrupt capability.

Most power switches are rated for alter-

**Fig 5.9** — Schematic diagrams of various types of switches. A is an SPST, B is an SPDT, C is an SPDT switch with a center-off position.

**Fig 5.10** — This photo shows examples of various styles of switches.

The current carrying capacity of the switch depends on the contact material and size and on the pressure between the contacts. It is primarily determined from the allowable contact temperature rise. On larger ac switches, or most dc switches, the interrupt capability may be lower than the current carrying value.

Rotary/wafer switches can provide very complex switching patterns. Several poles (separate circuits) can be included on each wafer. Many wafers may be stacked on the same shaft. Not only may many different circuits be controlled at once, but by wiring different poles/positions on different wafers together, a high degree of circuit switching logic can be developed. Such switches can select different paths as they are turned, and can also "short" together successive contacts to connect numbers of components or paths. They can also be designed to either break one contact before making another, or to short two contacts together before disconnecting the first one (make before break) to eliminate arcing or perform certain logic functions.

In choosing a switch for a particular task, consideration should be given to function, voltage and current ratings, ease of use, availability and cost. If a switch is to be operated frequently, a slightly higher cost for a better-quality switch is usually less costly over the long run. If signal noise or contact corrosion is a potential problem, (usually in low-current signal applications) it is best to get gold plated contacts. Gold does not oxidize or corrode, thus providing surer contact, which can be particularly important at very low signal levels. Gold plating will not hold up under high-current-interrupt applications, however.

## FUSES

Fuses self-destruct to protect circuit wiring or equipment. The fuse element that melts is a carefully shaped piece of soft metal, usually mounted in a cartridge of some kind. The element is designed to safely carry a given amount of current and to melt at a current value that is a certain percentage over the rated value. The melting value depends on the type of material, the shape of the element and the heat dissipation capability of the cartridge and holder, among other factors. Some fuses (Slo-blo) are designed to carry an overload for a short period of time. They typically are used in motor starting and power-supply circuits that have a large inrush current when first started. Other fuses are designed to blow very quickly to protect delicate instruments and solid-state circuits. A replacement fuse should have the same current rating and the same characteristics as the fuse it replaces. **Fig 5.11** shows a variety of fuse types and sizes.

The most important fuse rating is the nominal current rating that it will safely carry. Next most important are the timing characteristics, or how quickly it opens under a given current overload. A fuse also has a voltage rating, both a value in volts and whether it is expected to be used in ac or dc circuits. While you should never substitute a fuse with a higher current rating than the one it replaces, you can use a fuse with a higher voltage rating. There is no danger in replacing a 12-V, 2-A fuse with a 250-V, 2-A unit.

Fuses fail for several reasons. The most obvious reason is that a problem develops in the circuit, which causes too much current to flow. In this case, the circuit problem needs to be fixed. A fuse may just fail eventually, particularly when cycled on and off near its current rating. A kind of metal fatigue sets in, and eventually the fuse goes. A fuse can also blow because of a momentary power surge, or even turning something on and off several times quickly when there is a large inrush current. In these cases it is only necessary to replace the fuse with the same type and value. Never substitute a fuse with a larger current rating. You may cause permanent damage (maybe even a fire) to the wiring or circuit elements if/when there is an internal problem in the equipment

## RELAYS

Relays are switches that are driven by an electrical signal, usually through a magnetic coil. An armature that moves when current is applied pushes the switch contacts together, or pulls them apart. Many such contacts can be connected to the same armature, allowing many circuits to be controlled by a single signal. Usually, relays have only two positions (opening some contacts and closing others) although there are special cases.

Like switches, relays have specific voltage and current ratings for the contacts. These may be far different from the voltage and current of the coil that drives the relay. That means a small signal voltage might control very large values of voltage and/or current. Relay contacts (and housings) may be designed for ac, dc or RF signals. The control voltages are usually 12 V dc or 125 V ac for most amateur applications, but the coils may be designed to be "current sensing" and operate when the current through the coil exceeds a specific value. **Fig 5.12** shows some typical relays found in amateur equipment. Relays with 24- and 28-V coils are also common.

Coaxial relays are specially designed to handle RF signals and to maintain a characteristic impedance to match certain values of coaxial-cable impedance. They

**Fig 5.11** — This photo shows examples of various styles of fuses.

**Fig 5.12** — This photo shows examples of various styles of relays.

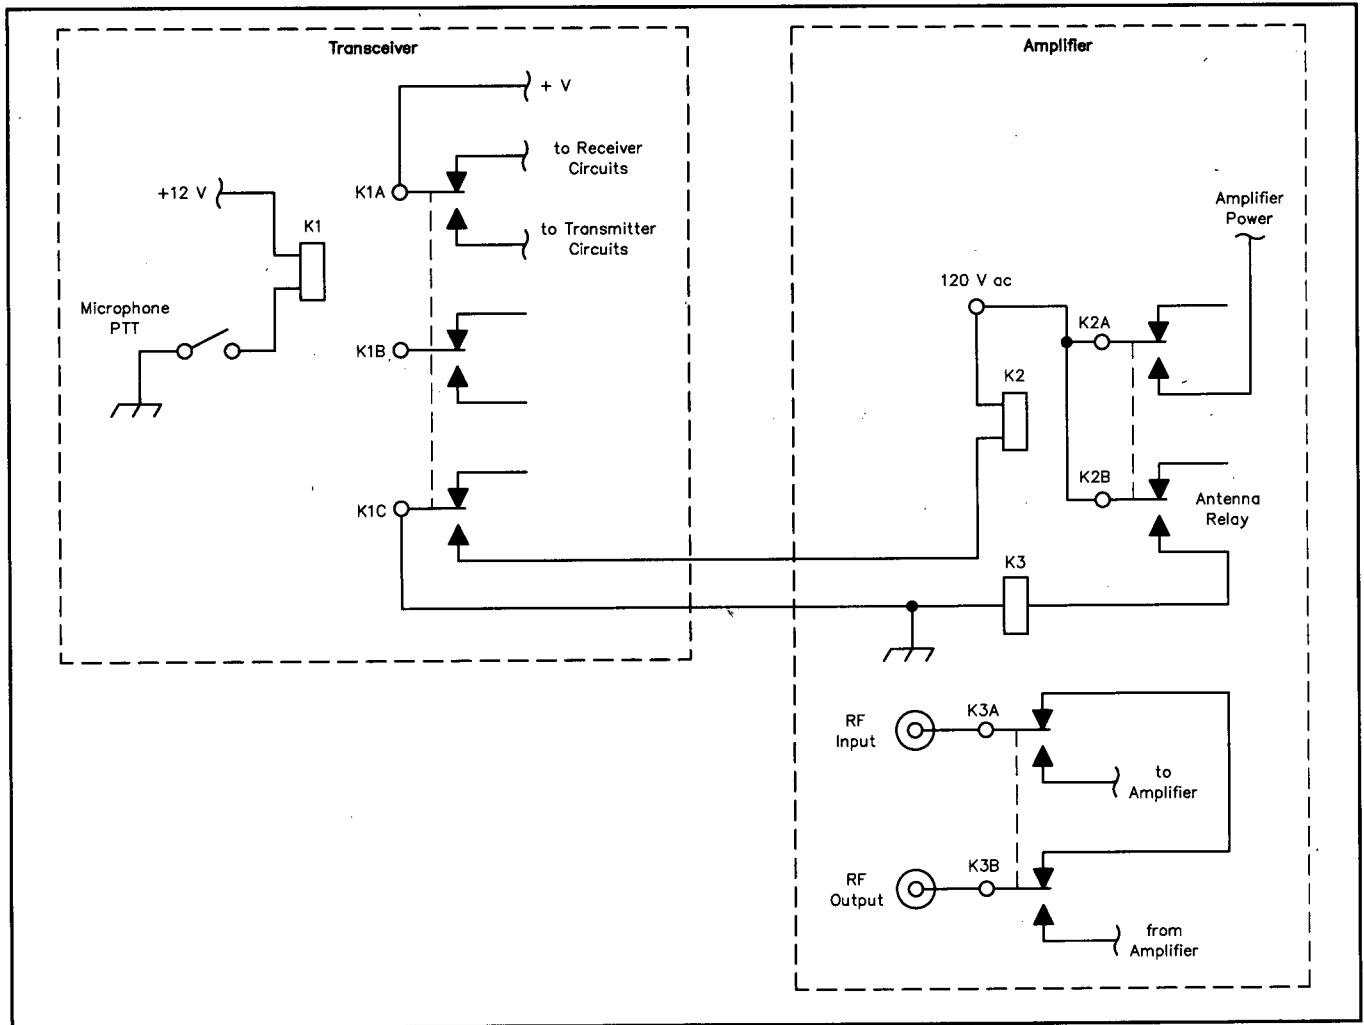

typically are used to switch an antenna between a receiver and transmitter or between a linear amplifier and a transceiver. **Fig 5.13** shows how several relays may be controlled by a microphone button to switch various functions in an amateur station. This simple system does not include control circuitry to provide proper sequencing of the relays.

## POTENTIOMETERS

Potentiometer is a big name for a variable resistor. They are commonly used as volume controls on radios, televisions and stereos. A typical potentiometer is a circular pattern of resistive material, usually a carbon compound, that has a wiper on a shaft moving across the material. For higher power applications, the resistive material may be wire, wound around a core. As the wiper moves along the material, more resistance is introduced between the wiper and one of the fixed contacts on the material. A potentiometer may be used primarily to control current, voltage or resistance in a circuit. **Fig 5.14** shows several circuits to demonstrate various uses. **Fig 5.15** shows several different types of potentiometers.

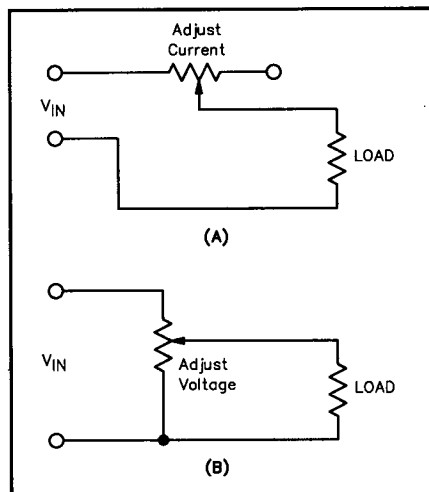

Typical specifications for a potentiometer include maximum resistance, power dissipation, voltage and current ratings, number of turns (or degrees) the shaft can rotate, type and size of shaft, mounting arrangements and resistance "taper."

Not all potentiometers have a *linear* taper. That is, the resistance may not be

**Fig 5.13 — A simple station control circuit. This example does not include control circuitry to provide proper sequencing of the relays.**

the same for a given number of degrees of shaft rotation along different portions of the resistive material. A typical use of a potentiometer with a nonlinear taper is as a volume control. Since the human ear has a logarithmic response to sound, a volume control may actually change the volume (resistance) much more near one end of the potentiometer than the other (for a given amount of rotation) so that the “perceived” change in volume is about the same for a similar change in the control. This is commonly called an “audio taper” as the change in resistance per degree of rotation attempts to match the response of the human ear. The taper can be designed to match almost any desired control function for a given application. Linear and audio tapers are the most common.

**Fig 5.14 — Various uses of potentiometers.**

# AC Theory and Reactive Components

## 6

### Glossary

**Admittance ( $Y$ )** — The reciprocal of impedance, measured in siemens (S).

**Capacitance ( $C$ )** — The ability to store electrical energy in an electrostatic field, measured in farads (F). A device with capacitance is a capacitor.

**Conductance ( $G$ )** — The reciprocal of resistance, measured in siemens (S).

**Current ( $I$ )** — The rate of electron flow through a conductor, measured in amperes (A).

**Flux density ( $B$ )** — The number of magnetic-force lines per unit area, measured in gauss.

**Frequency ( $f$ )** — The rate of change of an ac voltage or current, measured in cycles per second, or hertz (Hz).

**Impedance ( $Z$ )** — The complex combination of resistance and reactance, measured in ohms ( $\Omega$ ).

**Inductance ( $L$ )** — The ability to store electrical energy in a magnetic field, measured in henrys (H). A device, such as a coil, with inductance is an inductor.

**Peak (voltage or current)** — The maximum value relative to zero that an ac voltage or current attains during any cycle.

**Peak-to-peak (voltage or current)** — The value of the total swing of an ac voltage or current from its peak negative value to its peak positive value, ordinarily twice

the value of the peak voltage or current.

**Period ( $T$ )** — The duration of one ac voltage or current cycle, measured in seconds (s).

**Permeability ( $\mu$ )** — The ratio of the magnetic flux density of an iron, ferrite, or similar core in an electromagnet compared to the magnetic flux density of an air core, when the current through the electromagnet is held constant.

**Power ( $P$ )** — The rate of electrical-energy use, measured in watts (W).

**$Q$  (quality factor)** — The ratio of energy stored in a reactive component (capacitor or inductor) to the energy dissipated, equal to the reactance divided by the resistance.

**Reactance ( $X$ )** — Opposition to alternating current by storage in an electrical field (by a capacitor) or in a magnetic field (by an inductor), measured in ohms ( $\Omega$ ).

**Resistance ( $R$ )** — Opposition to current by conversion into other forms of energy, such as heat, measured in ohms ( $\Omega$ ).

**Resonance** — Ordinarily, the condition in an ac circuit containing both capacitive and inductive reactance in which the reactances are equal.

**RMS (voltage or current)** — Literally, "root mean square;" the square root of the average of the squares of the instantaneous

values for one cycle of a waveform. A dc voltage or current that will produce the same heating effect as the waveform. For a sine wave, the RMS value is equal to 0.707 times the peak value of ac voltage or current.

**Susceptance ( $B$ )** — The reciprocal of reactance, measured in siemens (S).

**Time constant ( $\tau$ )** — The time required for the voltage in an RC circuit or the current in an RL circuit to rise from zero to approximately 63.2% of its maximum value or to fall from its maximum value 63.2% toward zero.

**Toroid** — Literally, any donut-shaped solid; most commonly referring to ferrite or powdered-iron cores supporting inductors and transformers.

**Transducer** — Any device that converts one form of energy to another; for example an antenna, which converts electrical energy to electromagnetic energy or a speaker, which converts electrical energy to sonic energy.

**Transformer** — A device consisting of at least two coupled inductors capable of transferring energy through mutual inductance.

**Voltage ( $E$ )** — Electromotive force or electrical pressure, measured in volts (V).

### Alternating Current, Frequency and Wavelength

#### AC IN CIRCUITS

A circuit is a complete conductive route for electrons to follow from a source, through a load and back to the source. If the source permits the electrons to flow in only one direction, the current is *dc* or *direct current*. If the source permits the

current periodically to change direction, the current is *ac* or *alternating current*.

**Fig 6.1** illustrates the two types of circuits. Drawing A shows the source as a battery, a typical dc source. Drawing B shows a more abstract source symbol to indicate ac. In an ac circuit, not only does the cur-

rent change direction periodically; the voltage also periodically reverses. The rate of reversal may range from a few times per second to many billions per second.

Graphs of current or voltage, such as Fig 6.1, begin with a horizontal axis that represents time. The vertical axis represents

**Fig 6.1 — Basic circuits for direct and alternating currents. With each circuit is a graph of the current, constant for the dc circuit, but periodically changing direction in the ac circuit.**

**Fig 6.3 — Two ac waveforms of similar frequencies ( $f_1 = 1.5 f_2$ ) and amplitudes form a composite wave. Note the points where the positive peaks of the two waves combine to create high composite peaks: this is the phenomenon of beats. The beat note frequency is  $1.5f - f = 0.5f$  and is visible in the drawing.**

**Fig 6.5 — Some common ac waveforms: square, triangle, ramp and sine.**

**Fig 6.2 — A pulsating dc current (A) and its resolution into an ac component (B) and a dc component (C).**

**Fig 6.4 — Two ac waveforms of widely different frequencies and amplitudes form a composite wave in which one wave appears to ride upon the other.**

the amplitude of the current or the voltage, whichever is graphed. Distance above the zero line means a greater positive amplitude; distance below the zero line means a greater negative amplitude. Positive and negative simply designate the opposing directions in which current may flow in an alternating current circuit or the opposing directions of force of an ac voltage.

If the current and voltage never change direction, then from one perspective, we have a dc circuit, even if the level of dc constantly changes. **Fig 6.2** shows a current that is always positive with respect to

0. It varies periodically in amplitude, however. Whatever the shape of the variations, the current can be called *pulsating dc*. If the current periodically reaches 0, it can be called *intermittent dc*. From another perspective, we may look at intermittent and pulsating dc as a combination of an ac and a dc current. Special circuits can separate the two currents into ac and dc components for separate analysis or use. There are also circuits that combine ac and dc currents and voltages for many purposes.

We can combine ac and dc voltages and currents. Different ac voltages and currents also form combinations. Such combinations will result in complex waveforms. A *waveform* is the pattern of amplitudes reached by the voltage or current as measured over time. **Fig 6.3** shows two ac waveforms fairly close in frequency, and their resultant combination. **Fig 6.4** shows two ac waveforms dissimilar in both frequency and wavelength, along with the resultant combined waveform. Note the similarities (and the differences) between the resultant waveform in **Fig 6.4** and the combined ac-dc waveform in **Fig 6.2**.

Alternating currents may take on many useful wave shapes. **Fig 6.5** shows a few that are commonly used in practical circuits and in test equipment. The square wave is vital to digital electronics. The triangular and ramp waves — sometimes called “sawtooth” waves — are especially useful in timing circuits. The sine wave is both mathematically and practically the foundation of all other forms of ac; the other forms can usually be reduced to (and even constructed from) a particular collection of sine waves.

There are numerous ways to generate alternating currents: with an ac power generator (an *alternator*), with a transducer (for example, a microphone) or with an electronic circuit (for example, an RF oscillator). The basis of the sine wave is circular motion, which underlies the most usual methods of generating alternating current. The circular motion of the ac generator may be physical or mechanical, as in an alternator. Currents in the resonant circuit of an oscillator may also produce sine waves without mechanical motion.

**Fig 6.6** demonstrates the relationship of the current (and voltage) amplitude to relative positions of a circular rotation through one complete revolution of  $360^\circ$ . Note that the current is zero at point 1. It rises to its maximum value at a point  $90^\circ$  from point 1, which is point 3. At a point  $180^\circ$  from point 1, which is point 4, the current level falls back to zero. Then the current begins to rise again. The direction of the current after point 4 and prior to its return to point 1, however,

**Fig 6.6 — The relationship of circular motion and the resultant graph of ac current or voltage. The curve is sinusoidal, a sine wave.**

is opposite the direction of current from point 1 to point 4. Point 2 illustrates one of the innumerable intermediate values of current throughout the cycle.

Tracing the rise and fall of current over a linear time line produces the curve accompanying the circle in Fig 6.6. The curve is *sinusoidal* or a *sine wave*. The amplitude of the current varies as the sine of the angle made by the circular movement with respect to the zero point. The sine of  $90^\circ$  is 1, and  $90^\circ$  is also the point of maximum current (along with  $270^\circ$ ). The sine of  $45^\circ$  (point 2) is 0.707, and the value of current at the  $45^\circ$  point of rotation is 0.707 times the maximum current. Similar considerations apply to the variation of ac voltage over time.

## FREQUENCY AND PERIOD

With a continuously rotating generator, alternating current will pass through many equal cycles over time. Select an arbitrary point on any one cycle and use it as a marker. For this example, the positive peak will work as an unambiguous marker. The number of times per second that the current (or voltage) reaches this positive peak in any one second is called the *frequency* of the ac. In other words, frequency expresses the *rate* at which current (or voltage) cycles occur. The unit of frequency is *cycles per second*, or *hertz*—abbreviated Hz (after the 19th century radio-phenomena pioneer, Heinrich Hertz).

The length of any cycle in units of time is the *period* of the cycle, as measured from and to equivalent points on succeeding cycles. Mathematically, the period is simply the inverse of the frequency. That is,

$$\text{Frequency (f) in Hz} = \frac{1}{\text{Period (T) in seconds}} \quad (1)$$

and

$$\text{Period (T) in seconds} = \frac{1}{\text{Frequency (f) in Hz}} \quad (2)$$

Example: What is the period of a 400.-hertz ac current?

$$T = \frac{1}{f} = \frac{1}{400. \text{ Hz}} = 0.00250 \text{ s} = 2.5 \text{ ms}$$

The frequency of alternating currents

used in Amateur Radio circuits varies from a few hertz, or cycles per second, to thousands of millions of hertz. Likewise, the period of alternating currents amateurs use ranges from significant fractions of a second down to nanoseconds or smaller. In order to express units of frequency, time and almost everything else in electronics compactly, electronics uses a standard system of prefixes. In magnitudes of 1000 or  $10^3$ , frequency is measurable in hertz, in kilohertz (1000 hertz or kHz), in megahertz (1 million hertz or MHz), gigahertz (1 billion hertz or GHz) and even in terahertz (1 trillion hertz or THz). For units smaller than one, as in the measurement of period, the basic unit seconds can become milliseconds (1 thousandth of a second or ms), microseconds (1 millionth of a second or  $\mu\text{s}$ ), nanoseconds (1 billionth of a second or ns) and picoseconds (1 trillionth of a second or ps). See the **Mathematics for Amateur Radio** chapter for a complete list of prefixes and their relationship to basic units.

The uses of ac in Amateur Radio circuits are many and varied. Most can be cataloged by reference to ac frequency ranges used in circuits. For example, ac power used in the home, office and factory is ordinarily 60 Hz in the United States and Canada. In Great Britain and much of Europe, ac power is 50 Hz. For special purposes, ac power has been generated up to about 400 Hz.

Sonic and ultrasonic applications of ac run from about 20 Hz up to several MHz. Audio work makes use of the lower end of the sonic spectrum, with communications audio focusing on the range from about 300 to 3000 Hz. High-fidelity audio uses ac circuits capable of handling 20 Hz to at least 20 kHz. Ultrasonics — used in medicine and industry — makes use of ac circuits above 20 kHz.

Amateur Radio circuits include both power- and sonic-frequency-range circuits. Radio communication and other electronics work, however, require ac circuits capable of operation with frequencies up to the gigahertz range. Some of the applications include signal sources for

transmitters (and for circuits inside receivers); industrial induction heating; diathermy; microwaves for cooking, radar and communication; remote control of appliances, lighting, model planes and boats and other equipment; and radio direction finding and guidance.

## AC IN CIRCUITS AND TRANSDUCED ENERGY

Alternating currents are often loosely classified as audio frequency (AF) and radio frequency (RF). Although these designations are handy, they actually represent something other than the electrical energy of ac circuits: They designate special forms of energy that we find useful.

*Audio* or *sonic* energy is the energy imparted by the mechanical movement of a medium, which can be air, metal, water or even the human body. Sound that humans can hear normally requires the movement of air between 20 Hz and 20 kHz, although the human ear loses its ability to detect the extremes of this range as we age. Some animals, such as elephants, can apparently detect air vibrations well below 20 Hz, while others, such as dogs and cats, can detect air vibrations well above 20 kHz.

Electrical circuits do not directly produce air vibrations. Sound production requires a *transducer*, a device to transform one form of energy into another form of energy; in this case electrical energy into sonic energy. The speaker and the microphone are the most common audio transducers. There are numerous ultrasonic transducers for various applications.

Likewise, converting electrical energy into radio signals also requires a transducer, usually called an *antenna*. In contrast to RF alternating currents in circuits, RF *energy* is a form of electromagnetic energy. The frequencies of electromagnetic energy run from below 20 kHz to above  $10^{12}$  GHz. They include radio, infrared, visible light, ultraviolet and a number of energy forms of greatest interest to physicists and astronomers. **Table 6.1** provides a brief glimpse at the total spectrum of electromagnetic energy.

**Table 6.1**

### Key Regions of the Electromagnetic Energy Spectrum

Region Name	Frequency Range	
Radio frequencies	$1.0 \times 10^4$ Hz	to $3.0 \times 10^{11}$ Hz
Infrared	$3.0 \times 10^{11}$ Hz	to $4.3 \times 10^{14}$ Hz
Visible light	$4.3 \times 10^{14}$ Hz	to $1.0 \times 10^{15}$ Hz
Ultraviolet	$1.0 \times 10^{15}$ Hz	to $6.0 \times 10^{16}$ Hz
X-rays	$6.0 \times 10^{16}$ Hz	to $3.0 \times 10^{19}$ Hz
Gamma rays	$3.0 \times 10^{19}$ Hz	to $5.0 \times 10^{20}$ Hz
Cosmic rays	$5.0 \times 10^{20}$ Hz	to $8.0 \times 10^{21}$ Hz

**Table 6.2**
**Classification of the Radio Frequency Spectrum**

Abbreviation	Classification	Frequency Range
VLF	Very low frequencies	10 to 30 kHz
LF	Low frequencies	30 to 300 kHz
MF	Medium frequencies	300 to 3000 kHz
HF	High frequencies	3 to 30 MHz
VHF	Very high frequencies	30 to 300 MHz
UHF	Ultrahigh frequencies	300 to 3000 MHz
SHF	Superhigh frequencies	3 to 30 GHz
EHF	Extremely high frequencies	30 to 300 GHz

All electromagnetic energy has one thing in common: it travels, or *propagates*, at the speed of light. This speed is approximately 300,000,000 (or  $3.00 \times 10^8$ ) meters per second in a vacuum. Electromagnetic-energy waves have a length uniquely associated with each possible frequency. The wavelength ( $\lambda$ ) is simply the speed of propagation divided by the frequency ( $f$ ) in hertz.

$$f (\text{Hz}) = \frac{3.00 \times 10^8 \left( \frac{\text{m}}{\text{s}} \right)}{\lambda (\text{m})} \quad (3)$$

and

$$\lambda (\text{m}) = \frac{3.00 \times 10^8 \left( \frac{\text{m}}{\text{s}} \right)}{f (\text{Hz})} \quad (4)$$

Example: What is the frequency of an 80.0-m RF wave?

$$f (\text{Hz}) = \frac{3.00 \times 10^8 \left( \frac{\text{m}}{\text{s}} \right)}{\lambda (\text{m})}$$

$$= \frac{3.00 \times 10^8 \left( \frac{\text{m}}{\text{s}} \right)}{80.0 \text{ m}}$$

$$f (\text{Hz}) = 3.75 \times 10^6 \text{ Hz}$$

We could use a similar equation to calculate the wavelength of a sound wave in air, but we would have to use the speed of sound instead of the speed of light in the numerator of the equation. The speed of propagation of the mechanical movement of air that we call sound varies considerably with air temperature and altitude. The speed of sound at sea level is about 331 m/s at 0°C and 344 m/s at 20°C.

To calculate the frequency of an electromagnetic wave directly in kilohertz, change the speed constant to 300,000 ( $3.00 \times 10^5$ ) km/s.

$$f (\text{kHz}) = \frac{3.00 \times 10^5 \left( \frac{\text{km}}{\text{s}} \right)}{\lambda (\text{m})} \quad (5)$$

and

$$\lambda (\text{m}) = \frac{3.00 \times 10^5 \left( \frac{\text{km}}{\text{s}} \right)}{f (\text{kHz})} \quad (6)$$

For frequencies in megahertz, use:

$$f (\text{MHz}) = \frac{300. \left( \frac{\text{Mm}}{\text{s}} \right)}{\lambda (\text{m})} \quad (7)$$

and

$$\lambda (\text{m}) = \frac{300. \left( \frac{\text{Mm}}{\text{s}} \right)}{f (\text{MHz})} \quad (8)$$

You would normally just drop the units that go with the speed of light constant, to make the equation look simpler.

Example: What is the wavelength of an RF wave whose frequency is 4.0 MHz?

$$\lambda (\text{m}) = \frac{300.}{f (\text{MHz})} = \frac{300.}{4.0 \text{ MHz}} = 75 \text{ m}$$

At higher frequencies, circuit elements act like transducers. This property can be put to use, but it can also cause problems for some circuit operations. Therefore, wavelength calculations are of some importance in designing ac circuits for those frequencies.

Within the part of the electromagnetic-energy spectrum of most interest to radio applications, frequencies have been classified into groups and given names. **Table 6.2** provides a reference list of these classifications. To a significant degree, the frequencies within each group exhibit similar properties. For example, HF or high frequencies, from 3 to 30 MHz, all exhibit *skip* or ionospheric refraction that permits regular long-range radio communications. This property also applies occasionally both to MF (medium frequencies) and to VHF (very high frequencies).

Despite the close relationship between RF electromagnetic energy and RF ac circuits, it remains important to distinguish the two. To the ac circuit producing or amplifying a 15-kHz alternating current, the ultimate transformation and use of the electrical energy may make no difference to the circuit's operation. By choosing the right transducer, one can produce either an audio tone or a

**Fig 6.7 — An ac cycle is divided into 360° that are used as a measure of time or phase.**

**Fig 6.8 — When two waves of the same frequency start their cycles at slightly different times, the time difference or phase difference is measured in degrees. In this drawing, wave B starts 45° (one-eighth cycle) later than wave A, and so lags 45° behind A.**

radio signal — or both. Such was the accidental fate of many horizontal oscillators and amplifiers in early television sets; they found ways to vibrate parts audibly and to radiate electromagnetic energy.

## PHASE

When tracing a sine-wave curve of an ac voltage or current, the horizontal axis represents time. We call this the *time domain* of the sine wave. Events to the right take place later; events to the left occur earlier. Although time is measurable in parts of a second, it is more convenient to treat each cycle as a complete time unit that we divide into 360°. The conventional starting point for counting degrees is the zero point as the voltage or current begins the positive half cycle. The essential elements of an ac cycle appear in **Fig 6.7**.

The advantage of treating the ac cycle in this way is that many calculations and measurements can be taken and recorded in a manner that is independent of frequency. The positive peak voltage or current occurs at 90° along the cycle. Relative to the starting point, 90° is the *phase* of the ac at that point. Thus, a complete description of an ac voltage or current involves reference to three properties: frequency, amplitude and phase.

Phase relationships also permit the com-

comparison of two ac voltages or currents at the same frequency, as **Fig 6.8** demonstrates. Since B crosses the zero point in the positive direction after A has already done so, there is a *phase difference* between the two waves. In the example, B lags A by 45°, or A leads B by 45°. If A and B occur in the same circuit, their composite waveform will also be a sine wave at an intermediate phase angle relative to each. Adding any number of sine waves of the same frequency always results in a sine wave at that frequency.

Fig 6.8 might equally apply to a voltage and a current measured in the same ac circuit. Either A or B might represent the voltage; that is, in some instances voltage will lead the current and in others voltage will lag the current.

Two important special cases appear in **Fig 6.9**. In Part A, line B lags 90° behind line A. Its cycle begins exactly one quarter cycle later than the A cycle. When one wave is passing through zero, the other just reaches its maximum value.

In Part B, lines A and B are 180° out of phase. In this case, it does not matter which one is considered to lead or lag. Line B is always positive while line A is negative, and vice versa. If the two waveforms are of two voltages or two currents in the same circuit and if they have the same amplitude, they will cancel each other completely.

### MEASURING AC VOLTAGE, CURRENT AND POWER

Measuring the voltage or current in a dc circuit is straightforward, as **Fig 6.10A** demonstrates. Since the current flows in only one direction, for a resistive load, the voltage and current have constant values until the circuit components change.

Fig 6.10B illustrates a perplexing problem encountered when measuring voltages and currents in ac circuits. The current and voltage continuously change direction and value. Which values are meaningful? In fact, several values of constant sine-wave voltage and current in ac circuits are important to differing applications and concerns.

### Instantaneous Voltage and Current

**Fig 6.11** shows a sine wave of some arbitrary frequency and amplitude with respect to either voltage or current. The instantaneous voltage (or current) at point A on the curve is a function of three factors: the maximum value of voltage (or current) along the curve (point B), the frequency of the wave,

and the time elapsed in seconds or fractions of a second. Thus,

$$E_{\text{inst}} = E_{\text{max}} \sin (2\pi f t) \theta \quad (9)$$

Considering just one sine wave, independent of frequency, the instantaneous value of voltage (or current) becomes

$$E_{\text{inst}} = E_{\text{max}} \sin \theta \quad (10)$$

where  $\theta$  is the angle in degrees through which the voltage has moved over time after the beginning of the cycle.

Example: What is the instantaneous value of voltage at point D in Fig 6.11, if the maximum voltage value is 120. V and the angular travel is 60.0°?

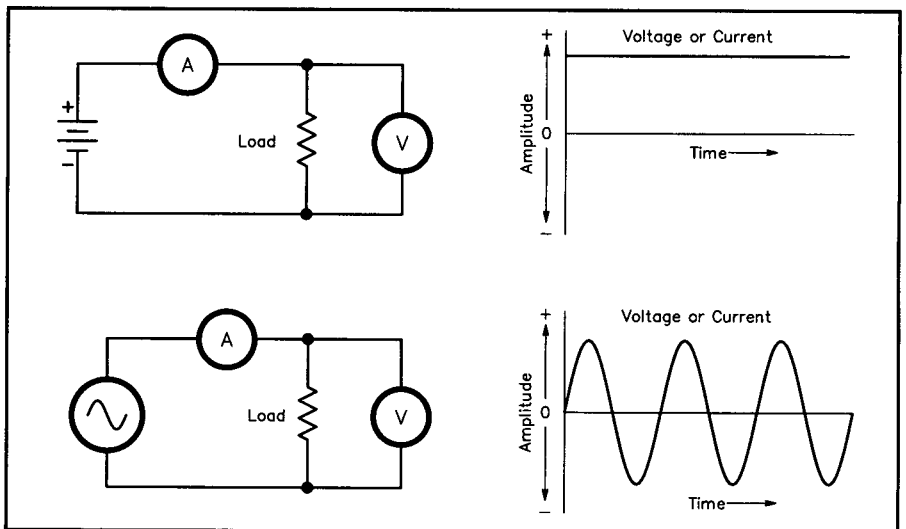

$$E_{\text{inst}} = 120. \text{ V} \times \sin 60.0^\circ = 120. \times 0.866 \\ = 104 \text{ V}$$

### Peak and Peak-to-Peak Voltage and Current

The most important instantaneous voltages and currents are the maximum or peak values reached on each positive and

**Fig 6.9 — Two important special cases of phase difference: In the upper drawing, the phase difference between A and B is 90°; in the lower drawing, the phase difference is 180°.**

**Fig 6.10 — Voltage and current measurements in dc and ac circuits.**

**Fig 6.11 — Two cycles of a sine wave to illustrate instantaneous, peak, and peak-to-peak ac voltage and current values.**

**Fig 6.12 — The relationships between RMS, average, peak, and peak-to-peak values of ac voltage and current.**

**Table 6.3**  
**Conversion Factors for AC Voltage or Current**

From	To	Multiply By
Peak	Peak-to-Peak	2
Peak-to-Peak	Peak	0.5
Peak	RMS	$1 / \sqrt{2}$ or 0.707
RMS	Peak	$\sqrt{2}$ or 1.414
Peak-to-Peak	RMS	$1 / (2 \times \sqrt{2})$ or 0.35355
RMS	Peak-to-Peak	$2 \times \sqrt{2}$ or 2.828
Peak	Average	$2 / \pi$ or 0.6366
Average	Peak	$\pi / 2$ or 1.5708
RMS	Average	$(2 \times \sqrt{2}) / \pi$ or 0.90
Average	RMS	$\pi / (2 \times \sqrt{2})$ or 1.11

Note: These conversion factors apply only to continuous pure sine waves.

negative half cycle of the sine wave. In Fig 6.11, points B and C represent the positive and negative peaks of voltage or current. Peak (pk) values are especially important with respect to component ratings, which the voltage or current in a circuit must not exceed without danger of component failure.

The peak power in an ac circuit is simply the product of the peak voltage and the peak current, or

$$P_{pk} = E_{pk} \times I_{pk} \quad (11)$$

The span from points B to C in Fig 6.11 represents the largest voltage or current swing of the sine wave. Designated the *peak-to-peak* (P-P) voltage (or current), this span is equal to twice the peak value of the voltage (or current). Thus,

$$E_{P-P} = 2E_{pk} \quad (12)$$

Amplifying devices often specify their input limits in terms of peak-to-peak volt-

ages. Operational amplifiers, which have almost unlimited gain potential, often require input-level limiting to prevent the output signals from distorting if they exceed the peak-to-peak output rating of the devices.

### RMS Voltages and Currents

The *root mean square* or *RMS* values of voltage and current are the most common values encountered in electronics. Sometimes called the *effective* values of ac voltage and current, they are based upon equating the values of ac and dc power required to heat a resistive element to exactly the same degree. The peak ac power required for this condition is twice the dc power needed. Therefore, the average ac power equivalent to a corresponding average dc power is half the peak ac power.

$$P_{ave} = \frac{P_{pk}}{2} \quad (13)$$

Since a circuit with a constant resistance is linear — that is, raising or lowering the voltage will raise or lower the current proportionally — the voltage and current values needed to arrive at average ac power are related to their peak values by the  $\sqrt{2}$ .

$$E_{RMS} = \frac{E_{pk}}{\sqrt{2}} = \frac{E_{pk}}{1.414} = E_{pk} \times 0.707 \quad (14)$$

$$I_{RMS} = \frac{I_{pk}}{\sqrt{2}} = \frac{I_{pk}}{1.414} = I_{pk} \times 0.707 \quad (15)$$

In the time domain of a sine wave, the RMS values of voltage and current occur at the 45°, 135°, 225° and 315° points along the cycle shown in Fig 6.12. (The sine of 45° is approximately 0.707.) The absolute instantaneous value of voltage or current is greater than the RMS value for half the cycle and less than the RMS value for half the cycle.

The RMS values of voltage and current get their name from the means used to derive their value relative to peak voltage and current. Square the individual values of all the instantaneous values of voltage or current in a single cycle of ac. Take the average of these squares and then find the square root of the average. This *root mean square* procedure produces the RMS value of voltage or current.

If the RMS voltage is the peak voltage divided by the  $\sqrt{2}$ , then the peak voltage must be the RMS voltage multiplied by the  $\sqrt{2}$ , or

$$E_{pk} = E_{RMS} \times 1.414 \quad (16)$$

$$I_{pk} = I_{RMS} \times 1.414 \quad (17)$$

Since circuit specifications will most commonly list only RMS voltage and current values, these relationships are important in finding the peak voltages or currents that will stress components.

Example: What is the peak voltage on a capacitor if the RMS voltage of a sinusoidal waveform signal across it is 300. V ac?

$$E_{pk} = 300. \text{ V} \times 1.414 = 424 \text{ V}$$

The capacitor must be able to withstand this higher voltage, plus a safety margin. The capacitor must also be rated for ac use. A capacitor rated for 1 kV dc may explode if used in this application. In power supplies that convert ac to dc and use capacitive input filters, the output voltage will approach the peak value of the ac voltage rather than the RMS value.

Example: What is the peak voltage and the peak-to-peak voltage at the usual

household ac outlet, if the RMS voltage is 120. V?

$$E_{pk} = 120. \text{ V} \times 1.414 = 170. \text{ V}$$

$$E_{p-p} = 2 \times 170. \text{ V} = 340. \text{ V}.$$

Unless otherwise specified, unlabeled ac voltage and current values found in most electronics literature are normally RMS values.

### Average Values of Voltage and Current

Certain kinds of circuits respond to the *average* value of an ac waveform. Among these circuits are electrodynamic meter movements and power supplies that convert ac to dc and use heavily inductive ("choke") input filters, both of which use the pulsating dc output of a full-wave rectifier. The average value of each ac half cycle is the *mean* of all the instantaneous values in that half cycle. Related to the peak values of voltage and current, average values are  $2/\pi$  (or 0.6366) times the peak value.

$$E_{ave} = 0.6366 E_{pk} \quad (18)$$

$$I_{ave} = 0.6366 I_{pk} \quad (19)$$

For convenience, **Table 6.3** summarizes the relationships between all of the common ac values. All of these relationships apply only to pure sine waves.

### Complex Waves and Peak-Envelope Values

Complex waves, as shown earlier in Fig 6.4, differ from pure sine waves. The amplitude of the peak voltage may vary significantly from one cycle to the next. Therefore, other amplitude measures are required, especially for accurate measurement of voltage and power with single sideband (SSB) waveforms. **Fig 6.13** illustrates a multitone composite waveform as the basis.

The RF ac waveform has a frequency many times that of the audio-frequency ac waveform with which it is usually combined in SSB operations. Therefore, the resultant waveform appears as an amplitude envelope superimposed upon the RF waveform. The *peak envelope voltage* (PEV), then, is the maximum or peak value of voltage achieved.

Peak envelope voltage permits the calculation of *peak envelope power* (PEP). The Federal Communications Commission

**Fig 6.13 — The peak envelope voltage (PEV) for a composite waveform.**

(FCC) uses the concept of peak envelope power to set the maximum power standards for amateur transmitters. PEP is the *average* power supplied to the antenna transmission line by a transmitter during one RF cycle at the crest of the modulation envelope, taken under normal operating conditions. Since calculation of PEP requires the average power of the cycle, multiply the PEV by 0.707 to obtain the RMS value. Then calculate power by using the square of the voltage divided by the load resistance.

$$PEP = \frac{(PEV \times 0.707)^2}{R} \quad (20)$$

## Capacitance and Capacitors

Without the ability to store electrical energy, radio would not be possible. One may build and hold an electrical charge in an *electrostatic field*. This phenomenon is called *capacitance*, and the devices that exhibit capacitance are called *capacitors*. **Fig 6.14** shows several schematic symbols for capacitors. Part A shows a fixed capacitor; one that has a single value of capacitance. Part B shows variable capacitors; these are adjustable over a range of values. Ordinarily, the straight line in each symbol connects to a positive voltage, while the curved line goes to a negative voltage or to ground. Some capacitor designs require rigorous adherence to polarity markings; other designs are symmetrical and nonpolarized.

### CHARGE AND ELECTROSTATIC ENERGY STORAGE

Suppose two flat metal plates are placed close to each other (but not touching) and are connected to a battery through a switch, as illustrated in **Fig 6.15A**. At the instant the switch is closed, electrons are attracted from the upper plate to the positive terminal of the battery, and the same number are repelled

**Fig 6.14 — Schematic symbol for a fixed capacitor is shown at A. The symbols for a variable capacitor are shown at B.**

**Fig 6.15 — A simple capacitor showing the basic charging arrangement at A, and the retention of the charge due to the electrostatic field at B.**

into the lower plate from the negative battery terminal. Enough electrons move into one plate and out of the other to make the

voltage between the plates the same as the battery voltage.

If the switch is opened after the plates

**Fig 6.16 — The flow of current during the charge and discharge of a capacitor. The charge graphs assume that the charge switch is closed and the discharge switch is open. The discharge graphs assume just the opposite.**

have been charged in this way, the top plate is left with a deficiency of electrons and the bottom plate with an excess. Since there is no current path between the two, the plates remain charged despite the fact that the battery no longer is connected. The charge remains due to the electrostatic field between the plates. The large number of opposite charges exert an attractive force across the small distance between plates, as illustrated in Fig 6.15B.

If a wire is touched between the two plates (short-circuiting them), the excess electrons on the bottom plate flow through the wire to the upper plate, restoring electrical neutrality. The plates are discharged.

These two plates represent an electrical capacitor, a device possessing the property of storing electrical energy in the electric field between its plates. During the time the electrons are moving — that is, while the capacitor is being charged or discharged — a current flows in the circuit

even though the circuit apparently is broken by the gap between the capacitor plates. The current flows only during the time of charge and discharge, however, and this time is usually very short. There can be no continuous flow of direct current through a capacitor.

**Fig 6.16** demonstrates the voltage and current in the circuit, first, at the moment the switch is closed to charge the capacitor and, second, at the moment the shorting switch is closed to discharge the unit. Note that the periods of charge and discharge are very short, but that they are not zero. This finite charging and discharging time can be lengthened and will prove useful later in timing circuits.

Although dc cannot pass through a capacitor, alternating current can. As fast as one plate is charged positively by the positive excursion of the alternating current, the other plate is being charged negatively. Positive charges flowing into one plate causes a cur-

rent to flow out of the other plate during one half of the cycle, resulting in a negative charge on that plate. The reverse occurs during the second half of the cycle.

The charge or quantity of electricity that can be held on the capacitor plates is proportional to the applied voltage and to the capacitance of the capacitor:

$$Q = CE \quad (21)$$

where:

$Q$  = charge in coulombs,  
 $C$  = capacitance in farads, and  
 $E$  = electrical potential in volts.

The energy stored in a capacitor is also a function of electrical potential and capacitance:

$$W = \frac{E^2 C}{2} \quad (22)$$

where:

$W$  = energy in joules (watt-seconds),  
 $E$  = electrical potential in volts (some texts use  $V$  instead of  $E$ ), and  
 $C$  = capacitance in farads.

The numerator of this expression can be derived easily from the definitions for charge, capacitance, current, power and energy. The denominator is not so obvious, however. It arises because the voltage across a capacitor is not constant, but is a function of time. The average voltage over the time interval determines the energy stored. The time dependence of the capacitor voltage is a very useful property; see the section on time constants.

## UNITS OF CAPACITANCE AND CAPACITOR CONSTRUCTION

A capacitor consists, fundamentally, of two plates separated by an insulator or *dielectric*. The *larger* the plate area and the *smaller* the spacing between the plates, the *greater* the capacitance. The capacitance also depends on the kind of insulating material between the plates: it is smallest with air insulation or a vacuum. Substituting other insulating materials for air may greatly increase the capacitance.

The ratio of the capacitance with a material other than a vacuum or air between the plates to the capacitance of the same capacitor with air insulation is called the dielectric constant, or  $K$ , of that particular insulating material. The dielectric constants of a number of materials commonly used as dielectrics in capacitors are given in **Table 6.4**. For example, if a sheet of polystyrene is substituted for air between the plates of a capacitor, the capacitance will be 2.6 times greater.

The basic unit of capacitance, the ability to store electrical energy in an elec-

trostatic field, is the farad. This unit is generally too large for practical radio work, however. Capacitance is usually measured in microfarads (abbreviated  $\mu\text{F}$ ), nanofarads (abbreviated nF) or picofarads (pF). The microfarad is one millionth of a farad ( $10^{-6}$  F), the nanofarad is one thousandth of a microfarad ( $10^{-9}$  F) and the picofarad is one millionth of a microfarad ( $10^{-12}$  F).

In practice, capacitors often have more than two plates, the alternate plates being connected to form two sets, as shown in Fig 6.17. This practice makes it possible to obtain a fairly large capacitance in a small space, since several plates of smaller individual area can be stacked to form the equivalent of a single large plate of the same total area. Also, all plates except the two on the ends are exposed to plates of the other group on both sides, and so are twice as effective in increasing the capacitance.

The formula for calculating capacitance from these physical properties is:

$$C = \frac{0.2248 \text{ K A (n - 1)}}{d} \tag{C3}$$

where:

- C = capacitance in pF,
- K = dielectric constant of material between plates,
- A = area of one side of one plate in square inches,
- d = separation of plate surfaces in inches, and
- n = number of plates.

If the area (A) is in square centimeters and the separation (d) is in centimeters, then the formula for capacitance becomes

$$C = \frac{0.0885 \text{ K A (n - 1)}}{d} \tag{C4}$$

If the plates in one group do not have the same area as the plates in the other, use the area of the smaller plates.

Example: What is the capacitance of 2 copper plates, each 1.50 square inches in area, separated by a distance of 0.00500 inches, if the dielectric is air?

$$\begin{aligned} C &= \frac{0.2248 \text{ K A (n - 1)}}{d} \\ &= \frac{0.2248 \times 1 \times 1.50 (2 - 1)}{0.00500} \end{aligned}$$

$$C = 67.4 \text{ pF}$$

### KINDS OF CAPACITORS AND THEIR USES

The capacitors used in radio work differ considerably in physical size, construction and capacitance. Representative kinds are shown in Fig 6.18. In variable capacitors, which are almost always constructed with

**Table 6.4**  
**Relative Dielectric Constants of Common Capacitor Dielectric Materials**

Material	Dielectric Constant (k)	(O)rganic or (I)norganic
Vacuum	1 (by definition)	
Air	1.0006	
Ruby mica	6.5 - 8.7	
Glass (flint)	10	
Barium titanate (class I)	5 - 450	
Barium titanate (class II)	200 - 12000	
Kraft paper	≈ 2.6	O
Mineral Oil	≈ 2.23	O
Castor Oil	≈ 4.7	O
Halowax	≈ 5.2	O
Chlorinated diphenyl	≈ 5.3	O
Polyisobutylene	≈ 2.2	O
Polytetrafluoroethylene	≈ 2.1	O
Polyethylene terephthalate	≈ 3	O
Polystyrene	≈ 2.6	O
Polycarbonate	≈ 3.1	O
Aluminum oxide	≈ 8.4	
Tantalum pentoxide	≈ 28	
Niobium oxide	≈ 40	
Titanium dioxide	≈ 80	

(Adapted from: Charles A. Harper, *Handbook of Components for Electronics*, p 8-7.)

air for the dielectric, one set of plates is made movable with respect to the other set so the capacitance can be varied. Fixed capacitors — those having a single, non-adjustable value of capacitance — can also be made with metal plates and with air as the dielectric.

Fixed capacitors are usually constructed from plates of metal foil with a thin solid or liquid dielectric sandwiched between, so a relatively large capacitance can be obtained in a small unit. The solid dielectrics commonly used are mica, paper and special ceramics. An example of a liquid dielectric is mineral oil. Electrolytic capacitors use aluminum-foil plates with a semiliquid conducting chemical compound between them. The actual dielectric is a very thin film of insulating material that forms on one set of plates through electrochemical action when a dc voltage is applied to the capacitor. The capacitance obtained with a given plate area in an electrolytic capacitor is very large compared to capacitors having other dielectrics, because the film is so thin — much less than any thickness practical with a solid dielectric.

The use of electrolytic and oil-filled capacitors is confined to power-supply filtering and audio-bypass applications because their dielectrics have high losses at higher frequencies. Mica and ceramic capacitors are used throughout the frequency range from audio to several hundred megahertz.

New dielectric materials appear from

**Fig 6.17 — A multiple-plate capacitor. Alternate plates are connected to each other.**

time to time and represent improvements in capacitor performance. Silvered-mica capacitors, formed by spraying thin coats of silver on each side of the mica insulating sheet, improved the stability of mica capacitors in circuits sensitive to temperature changes. Polystyrene and other synthetic dielectrics, along with tantalum electrolytics, have permitted the size of capacitors to shrink per unit of capacitance.

### VOLTAGE RATINGS AND BREAKDOWN

When high voltage is applied to the plates of a capacitor, considerable force is exerted on the electrons and nuclei of the dielectric. The dielectric is an insulator; its electrons do not become detached from atoms the way they do in conductors. If the force is great enough,

**Fig 6.18 —** Fixed-value capacitors are shown at A. A large computer-grade unit is at the upper left. The 40-μF unit is an electrolytic capacitor. The smaller pieces are silvered-mica, disc-ceramic, tantalum, polystyrene and ceramic-chip capacitors. The small black cylindrical unit is a PC-board-mount electrolytic. Variable capacitors are shown at B. A vacuum variable is at the upper left. The units with visible plates are air-variable capacitors. Some tiny variable capacitors use a thin piece of mica as a dielectric.

however, the dielectric will break down. Failed dielectrics usually puncture and offer a low-resistance current path between the two plates.

The *breakdown voltage* a dielectric can withstand depends on the chemical composition and thickness of the dielectric. Breakdown voltage is not directly proportional to the thickness; doubling the thickness does not quite double the breakdown voltage. Gas dielectrics also break down, as evidenced by a spark or arc between the plates. Spark voltages are generally given with the units *kilovolts per centimeter*. For air, the spark voltage or  $V_s$  may range from more than 120 kV/cm for gaps as narrow as 0.006 cm down to 28 kV/cm for gaps as wide as 10 cm. In addition, a large number of variables enter into the actual breakdown voltage in a real situation. Among the variables are the electrode shape, the gap distance, the air pressure or density, the voltage, impurities in the air (or any other dielectric material) and the nature of the external circuit (with air, for instance, the humidity affecting conduction on the surface of the capacitor plate).

Dielectric breakdown occurs at a lower voltage between pointed or sharp-edged surfaces than between rounded and polished surfaces. Consequently, the breakdown voltage between metal plates of any given spacing in air can be increased by buffing the edges of the plates. With most gas dielectrics such as air, once the voltage is removed, the arc ceases and the capacitor is ready for use again. If the plates are damaged so they are no longer smooth and polished,

they may have to be polished or the capacitor replaced. In contrast, solid dielectrics are permanently damaged by dielectric breakdown, and often will totally short out and melt or explode.

A thick dielectric must be used to withstand high voltages. Since the capacitance is inversely proportional to dielectric thickness (plate spacing) for a given plate area, a high-voltage capacitor must have more plate area than a low-voltage one of the same capacitance. High-voltage, high-capacitance capacitors are therefore physically large.

Dielectric strength is specified in terms of a dielectric withstanding voltage (DWV), given in volts per mil (0.001 inch) at a specified temperature. Taking into account the design temperature range of a capacitor and a safety margin, manufacturers specify *dc working voltage* (dcwv) to express the maximum safe limits of dc voltage across a capacitor to prevent dielectric breakdown.

It is not safe to connect capacitors across an ac power line unless they are rated for such use. Capacitors with dc ratings may short the line. Several manufacturers make capacitors specifically rated for use across the ac power line.

For use with other ac signals, the peak value of ac voltage should not exceed the dc working voltage, unless otherwise specified in component ratings. In other words, the RMS value of ac should be 0.707 times the dcwv value or lower. With many types of capacitors, further derating is required as the operating frequency increases. An additional safety margin is good practice.

Any two surfaces having different electrical potentials, and which are close enough to exhibit a significant electrostatic field, constitute a capacitor. The arrangement of circuit components and leads sometimes results in the creation of unintended capacitors. This is called *stray capacitance*: It often results in the passage of signals in ways that disrupt the normal operation of a circuit. Good design minimizes stray capacitance.

Stray capacitance may have a greater affect in a high-impedance circuit because the capacitive reactance may be a greater percentage of the circuit impedance. Also, because stray capacitance often appears in parallel with the circuit, the stray capacitor may bypass more of the desired signal at higher frequencies. Stray capacitance can often adversely affect sensitive circuits.

For further information of the physical and electrical characteristics of various types of capacitors in actual use, see the **Real-World Component Characteristics** chapter.

## CAPACITORS IN SERIES AND PARALLEL

When a number of capacitors are connected in parallel, as in Fig 6.19A, the total capacitance of the group is equal to the sum of the individual capacitances:

$$C_{\text{total}} = C_1 + C_2 + C_3 + C_4 + \dots + C_n \quad (25)$$

When two or more capacitors are connected in series, as in Fig 6.19B, the total

capacitance is less than that of the smallest capacitor in the group. The rule for finding the capacitance of a number of series-connected capacitors is the same as that for finding the resistance of a number of parallel-connected resistors.

$$C_{\text{total}} = \frac{1}{\frac{1}{C_1} + \frac{1}{C_2} + \frac{1}{C_3} + \dots + \frac{1}{C_n}} \quad (26)$$

For only two capacitors in series, the formula becomes:

$$C_{\text{total}} = \frac{C_1 \times C_2}{C_1 + C_2} \quad (27)$$

The same units must be used throughout; that is, all capacitances must be expressed in either  $\mu\text{F}$ ,  $\text{nF}$  or  $\text{pF}$ . Different units cannot be used in the same equation.

Capacitors are usually connected in parallel to obtain a larger total capacitance than is available in one unit. The largest voltage that can be applied safely to a parallel-connected group of capacitors is the voltage that can be applied safely to the one having the lowest voltage rating.

When capacitors are connected in series, the applied voltage is divided between them according to Kirchhoff's Voltage Law: The situation is much the same as when resistors are in series and there is a voltage drop across each. The voltage that appears across each series-connected capacitor is inversely proportional to its capacitance, as compared with the capacitance of the whole group. (This assumes ideal capacitors.)

Example: Three capacitors having capacitances of 1, 2 and 4  $\mu\text{F}$ , respectively, are connected in series as shown in Fig 6.20. The voltage across the entire series is 2000 V. What is the total capacitance? (Since this is a calculation using theoretical values to illustrate a technique, we will not follow the rules of significant figures for the calculations.)

$$C_{\text{total}} = \frac{1}{\frac{1}{C_1} + \frac{1}{C_2} + \frac{1}{C_3}}$$

$$= \frac{1}{\frac{1}{1 \mu\text{F}} + \frac{1}{2 \mu\text{F}} + \frac{1}{4 \mu\text{F}}}$$

$$C_{\text{total}} = \frac{1}{\frac{7}{4 \mu\text{F}}} = \frac{4 \mu\text{F}}{7} = 0.5714 \mu\text{F}$$

The voltage across each capacitor is proportional to the total capacitance divided by the capacitance of the capacitor in question. So the voltage across  $C_1$  is:

$$E_1 = \frac{0.5714 \mu\text{F}}{1 \mu\text{F}} \times 2000 \text{ V} = 1143 \text{ V}$$

Similarly, the voltages across  $C_2$  and  $C_3$  are:

$$E_2 = \frac{0.5714 \mu\text{F}}{2 \mu\text{F}} \times 2000 \text{ V} = 571 \text{ V}$$

and

$$E_3 = \frac{0.5714 \mu\text{F}}{4 \mu\text{F}} \times 2000 \text{ V} = 286 \text{ V}$$

The sum of these three voltages equals 2000 V, the applied voltage.

Capacitors may be connected in series to enable the group to withstand a larger voltage than any individual capacitor is rated to withstand. The trade-off is a decrease in the total capacitance. As shown by the previous example, the applied voltage does not divide equally between the capacitors except when all the capacitances are precisely the same. Use care to ensure that the voltage rating of any capacitor in the group is not exceeded. If you use capacitors in series to withstand a higher voltage, you should also connect an "equalizing resistor" across each capacitor. Use resistors with about 100  $\Omega$  per volt of supply voltage, and be sure they have sufficient power-handling capability for the circuit. With real capacitors, the leakage resistance of the capacitors may have more effect on the voltage division than does the capacitance. A capacitor with a high parallel resistance will have the highest voltage across it. Adding equalizing resistors reduces this effect.

## RC TIME CONSTANT

Connecting a dc voltage source directly to the terminals of a capacitor charges the capacitor to the full source voltage almost instantaneously. Any resistance added to the circuit as in Fig 6.21A limits the current, lengthening the time required for the voltage between the capacitor plates to build up to the source-voltage value. During this charging period, the current flowing from the source into the capacitor gradually decreases from its initial value. The increasing voltage stored in the capacitor's electric field offers increasing opposition to the steady source voltage.

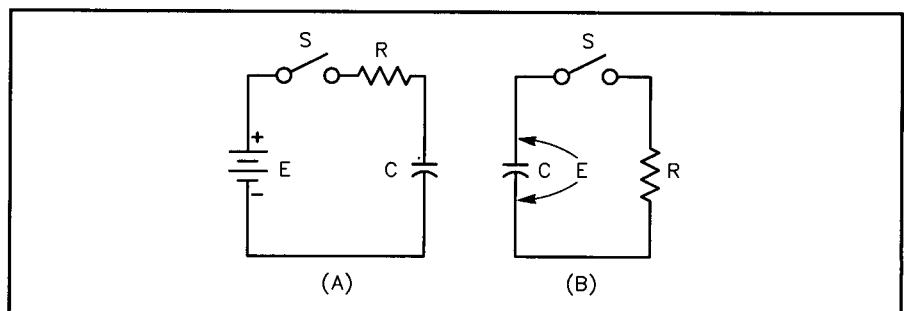

Fig 6.21 — An illustration of the time constant in an RC circuit.

While it is being charged, the voltage between the capacitor terminals is an exponential function of time, and is given by:

$$V(t) = E \left( 1 - e^{-\frac{t}{RC}} \right) \quad (28)$$

where:

$V(t)$  = capacitor voltage in volts at time  $t$ ;

$E$  = potential of charging source in volts;

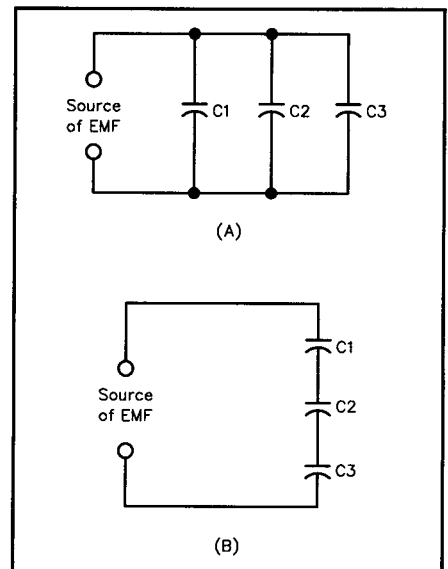

Fig 6.19 — Capacitors in parallel are shown at A, and in series at B.

Fig 6.20 — An example of capacitors connected in series. The text shows how to find the voltage drops,  $E_1$  through  $E_3$ .

$t$  = time in seconds after initiation of charging current;  
 $e$  = natural logarithmic base = 2.718;  
 $R$  = circuit resistance in ohms; and  
 $C$  = capacitance in farads.

Theoretically, the charging process is never really finished, but eventually the charging current drops to an unmeasurable value. For many purposes, it is convenient to let  $t = RC$ . Under this condition, the above equation becomes:

$$V(RC) = E(1 - e^{-1}) \approx 0.632 E \quad (29)$$

The product of  $R$  in ohms times  $C$  in farads is called the *time constant* of the circuit and is the time in seconds required to charge the capacitor to 63.2% of the supply voltage. (The lower-case Greek letter tau [ $\tau$ ] is often used to represent the time constant in electronics circuits.) After two time constants ( $t = 2\tau$ ) the capacitor charges another 63.2% of the difference between the capacitor voltage at one time constant and the supply voltage, for a total charge of 86.5%. After three time constants the capacitor reaches 95% of the supply voltage, and so on, as illustrated in the curve of Fig 6.22A. After 5

**Fig 6.22** — At A, the curve shows how the voltage across a capacitor rises, with time, when charged through a resistor. The curve at B shows the way in which the voltage decreases across a capacitor when discharging through the same resistance. For practical purposes, a capacitor may be considered charged or discharged after 5 RC periods.

RC time periods, a capacitor is considered fully charged, having reached 99.24% of the source voltage.

If a charged capacitor is discharged through a resistor, as indicated in Fig 6.21B, the same time constant applies for the decay of the capacitor voltage. A direct short circuit applied between the capacitor terminals would discharge the capacitor almost instantly. The resistor,  $R$ , limits the current, so the capacitor voltage decreases only as rapidly as the capacitor can discharge itself through  $R$ . A capacitor discharging through a resistance exhibits the same time-constant characteristics (calculated in the same way as above) as a charging capacitor. The voltage, as a function of time while the capacitor is being discharged, is given by:

$$V(t) = E \left( e^{-\frac{t}{RC}} \right) \quad (30)$$

where  $t$  = time in seconds after initiation of discharge.

Again, by letting  $t = RC$ , the time constant of a discharging capacitor represents a decrease in the voltage across the capacitor of about 63.2%. After 5 time-constant periods, the capacitor is considered fully discharged, since the voltage has dropped to less than 1% of the full-charge voltage.

Time constant calculations have many uses in radio work. The following examples are all derived from practical-circuit applications.

**Example 1:** A 100.- $\mu\text{F}$  capacitor in a high-voltage power supply is shunted by a 100.-k $\Omega$  resistor. What is the minimum time before the capacitor may be considered fully discharged? Since full discharge is approximately 5 RC periods,

$$t = 5 \times RC = 5 \times 100. \times 10^3 \Omega \times 100. \times 10^{-6} \text{ F} = 50000 \times 10^{-3} \text{ seconds}$$

$$t = 50.0 \text{ s}$$

(Look at the table of metric-system units in the **Mathematics for Amateur Radio** chapter to prove that *ohms* times *farads* gives units of *seconds*.)

**Note:** Although waiting almost a minute for the capacitor to discharge seems safe in this high-voltage circuit, never rely solely on capacitor-discharging resistors (often called *bleeder resistors*). Be certain the power source is removed and the capacitors are totally discharged before touching any circuit components.

**Example 2:** Smooth CW keying with-

out clicks requires approximately 5 ms (0.005 s) of delay in both the make and break edges of the waveform, relative to full charging and discharging of a capacitor in the circuit. What typical values might a builder choose for an RC delay circuit in a keyed voltage line? Since full charge and discharge require 5 RC periods,

$$RC = \frac{t}{5} = \frac{0.005 \text{ s}}{5} = 0.001 \text{ s}$$

Any combination of resistor and capacitor whose values, multiplied together, equaled 0.001 would do the job. A typical capacitor might be 0.05  $\mu\text{F}$ . In that case, the necessary resistor would be:

$$R = \frac{0.001 \text{ s}}{0.05 \times 10^{-6} \text{ F}} = 0.02 \times 10^6 \Omega = 20000 \Omega \text{ or } 20 \text{ k}\Omega.$$

In practice, a builder would likely either experiment with values or use a variable resistor. The final value would be selected after monitoring the waveform on an oscilloscope.

**Example 3:** Many modern integrated circuit (IC) devices use RC circuits to control their timing. To match their internal circuitry, they may use a specified threshold voltage as the trigger level. For example, a certain IC uses a trigger level of 0.667 of the supply voltage. What value of capacitor and resistor would be required for a 4.5-second timing period?

First we will solve equation 28 for the time constant, TC. The threshold voltage is 0.667 times the supply voltage, so we use this value for  $V(t)$ .

$$V(t) = E \left( 1 - e^{-\frac{t}{RC}} \right)$$

$$0.667 E = E \left( 1 - e^{-\frac{t}{RC}} \right)$$

$$e^{-\frac{t}{RC}} = 1 - 0.667$$

$$\ln \left( e^{-\frac{t}{RC}} \right) = \ln (0.333)$$

$$-\frac{t}{RC} = -1.10$$

We want to find a capacitor and resistor combination that will produce a 4.5 s timing period, so we substitute that value for  $t$ .

$$RC = \frac{4.5 \text{ s}}{1.10} = 4.1 \text{ s}$$

If we select a value of  $10. \mu\text{F}$ , we can solve for  $R$ .

$$R = \frac{4.1 \text{ s}}{10. \times 10^{-6} \text{ F}} = 0.41 \times 10^6 \Omega = 410 \text{ k}\Omega$$

A 1% tolerance resistor and capacitor will give good precision. You could also use a variable resistor and an accurate method to measure the time to set the circuit to a 4.5 s period.

As the examples suggest, RC circuits have numerous applications in electronics. The number of applications is growing steadily, especially with the introduction of integrated circuits controlled by part or all of a capacitor charge or discharge cycle.

## ALTERNATING CURRENT IN CAPACITANCE

Everything said about capacitance and capacitors in a dc circuit applies to capacitance in an ac circuit with one major exception. Whereas a capacitor in a dc circuit will appear as an open circuit except for the brief charge and discharge periods, the same capacitor in an ac circuit will both pass and limit current. A capacitor in an ac circuit does not handle electrical energy like a resistor, however. Instead of converting the energy to heat and dissipating it, capacitors store electrical energy and return it to the circuit.

In Fig 6.23 a sine-wave ac voltage having a maximum value of 100 is applied to a capacitor. In the period OA, the applied voltage increases from 0 to 38; at the end of this period the capacitor is charged to that voltage. In interval AB the voltage increases to 71; that is, 33 V additional. During this interval a smaller quantity of charge has been added than in OA, because the voltage rise during interval AB is smaller. Consequently the average current during interval AB is smaller than during OA. In the third interval, BC, the voltage rises from 71 to 92, an increase of 21 V. This is less than the voltage increase during AB, so the quantity of electricity added is less; in other words, the average current during interval BC is still smaller. In the fourth interval, CD, the voltage increases only 8 V; the charge added is smaller than in any preceding interval and therefore the current also is smaller.

By dividing the first quarter cycle into a very large number of intervals, it could be shown that the current charging the capacitor has the shape of a sine wave, just as the applied voltage does. The current is largest at the beginning of the cycle and becomes zero at the maximum value of the voltage, so there is a phase difference of  $90^\circ$  between the voltage

Fig 6.23 — Voltage and current phase relationships when an alternating current is applied to a capacitor.

and the current. During the first quarter cycle the current is flowing in the normal direction through the circuit, since the capacitor is being charged. Hence the current is positive, as indicated by the dashed line in Fig 6.23.

In the second quarter cycle — that is, in the time from D to H — the voltage applied to the capacitor decreases. During this time the capacitor loses its charge. Applying the same reasoning, it is evident that the current is small in interval DE and continues to increase during each succeeding interval. The current is flowing against the applied voltage, however, because the capacitor is discharging into the circuit. The current flows in the negative direction during this quarter cycle.

The third and fourth quarter cycles repeat the events of the first and second, respectively, with this difference: the polarity of the applied voltage has reversed, and the current changes to correspond. In other words, an alternating current flows in the circuit because of the alternate charging and discharging of the capacitance. As shown in Fig 6.23, the current starts its cycle  $90^\circ$  before the voltage, so the current in a capacitor *leads* the applied voltage by  $90^\circ$ . You might find it helpful to remember the word “ICE” as a mnemonic because the current (I) in a capacitor (C) comes before voltage (E). We can also turn this statement around, to say the voltage in a capacitor *lags* the current by  $90^\circ$ .

## CAPACITIVE REACTANCE

The quantity of electric charge that can be placed on a capacitor is proportional to the applied voltage and the

capacitance. This amount of charge moves back and forth in the circuit once each cycle, and so the rate of movement of charge (the current) is proportional to voltage, capacitance and frequency. When the effects of capacitance and frequency are considered together, they form a quantity that plays a part similar to that of resistance in Ohm's Law. This quantity is called *reactance*. The unit for reactance is the ohm, just as in the case of resistance. The formula for calculating the reactance of a capacitor at a given frequency is:

$$X_C = \frac{1}{2 \pi f C} \quad (31)$$

where:

$X_C$  = capacitive reactance in ohms,  
 $f$  = frequency in hertz,  
 $C$  = capacitance in farads  
 $\pi = 3.1416$

Note: In many references and texts, the symbol  $\omega$  is used to represent  $2 \pi f$ . In such references, equation 31 would read

$$X_C = \frac{1}{\omega C}$$

Although the unit of reactance is the ohm, there is no power dissipated in reactance. The energy stored in the capacitor during one portion of the cycle is simply returned to the circuit in the next.

The fundamental units for frequency and capacitance (hertz and farads) are too cumbersome for practical use in radio circuits. If the capacitance is specified in microfarads ( $\mu\text{F}$ ) and the frequency is in megahertz (MHz), however, the reactance calculated from the previous formula retains the unit ohms.

Example: What is the reactance of a capacitor of 470. pF (0.000470  $\mu$ F) at a frequency of 7.15 MHz?

$$\begin{aligned} X_C &= \frac{1}{2 \pi f C} \\ &= \frac{1}{2 \pi \times 7.15 \text{ MHz} \times 0.000470 \mu\text{F}} \\ &= \frac{1 \Omega}{0.0211} = 47.4 \Omega \end{aligned}$$

Fig 6.24 — A graph showing the general relationship of reactance to frequency for a fixed value of capacitance.

Example: What is the reactance of the same capacitor, 470. pF (0.000470  $\mu$ F), at a frequency of 14.30 MHz?

$$\begin{aligned} X_C &= \frac{1}{2 \pi f C} \\ &= \frac{1}{2 \pi \times 14.30 \text{ MHz} \times 0.000470 \mu\text{F}} \\ &= \frac{1 \Omega}{0.0422} = 23.7 \Omega \end{aligned}$$

The rate of change of voltage in a sine wave increases directly with the frequency. Therefore, the current into the capacitor also increases directly with frequency. Since, for a given voltage, an increase in current is equivalent to a decrease in reactance, the reactance of any capacitor decreases proportionally as the frequency increases. Fig 6.24 traces the decrease in reactance of an arbitrary-value capacitor with respect to increasing frequency. The only limitation on the application of the graph is the physical make-up of the capacitor, which may favor low-frequency uses or high-frequency applications.

Among other things, reactance is a measure of the ability of a capacitor to limit the flow of ac in a circuit. For some purposes, it is important to know the ability of a capacitor to pass current. This ability is called *susceptance*, and it corresponds to conductance in resistive circuit elements. In an ideal capacitor with no resistive losses — that is, no energy lost as heat — susceptance is simply the reciprocal of reactance. Hence,

$$B = \frac{1}{X_C} \quad (32)$$

where:

$X_C$  is the reactance, and  
 $B$  is the susceptance.

The unit of susceptance (and conductance and admittance) is the *siemens* (abbreviated S). In literature only a few years old, the term *mho* is also sometimes given as the unit of susceptance (as well as of conductance and admittance). The role of reactance and susceptance in current and other Ohm's Law calculations will appear in a later section of this chapter.

## Inductance and Inductors

A second way to store electrical energy is in a *magnetic field*. This phenomenon is called *inductance*, and the devices that exhibit inductance are called *inductors*. Inductance depends upon some basic underlying magnetic properties.

### MAGNETISM

#### Magnetic Fields, Flux and Flux Density

Magnetic fields are closed fields that surround a magnet, as illustrated in Fig 6.25. The field consists of lines of magnetic force or *flux*. It exhibits polarity, which is conventionally indicated as north-seeking and south-seeking poles, or *north* and *south poles* for short. Magnetic flux is measured in the SI unit of the weber, which is a volt second ( $\text{Wb} = \text{V s}$ ). In the *centimeter gram second (cgs)* metric system units, we measure magnetic flux in maxwells ( $1 \text{ Mx} = 10^{-8} \text{ Wb}$ ).

The field intensity, known as the *flux density*, decreases with the square of the

distance from the source. Flux density ( $B$ ) is represented in gauss (G), where one gauss is equivalent to one line of force per square centimeter of area across the field ( $G = \text{Mx} / \text{m}^2$ ). The gauss is a *cgs* unit. In SI units, flux density is represented by the tesla (T), which is one weber per square meter ( $T = \text{Wb} / \text{m}^2$ ).

Magnetic fields exist around two types of materials. First, certain ferromagnetic materials contain molecules aligned so as to produce a magnetic field. Lodestone, Alnico and other materials with high *retentivity* form *permanent magnets* because they retain their magnetic properties for long periods. Other materials, such as soft iron, yield temporary magnets that lose their magnetic properties rapidly.

The second type of magnetic material is an electrical conductor with a current through it. As shown in Fig 6.26, moving electrons are surrounded by a closed magnetic field lying in a plane perpendicular to their motion. The needle of a compass placed near a wire carrying direct current

will be deflected by the magnetic field around the wire. This phenomenon is one aspect of a two-way relationship: a moving magnetic field whose lines cut across a wire will induce an electrical current in the wire, and an electrical current will produce a magnetic field.

If the wire is coiled into a solenoid, the

Fig 6.25 — The magnetic field and poles of a permanent magnet. The magnetic field direction is from the North to the South Pole.

**Fig 6.26 — The magnetic field around a conductor carrying an electrical current. If the thumb of your right hand points in the direction of the conventional current, your fingers curl in the direction of the magnetic field around the wire.**

magnetic field greatly intensifies as the individual flux lines add together. **Fig 6.27** illustrates the principle by showing a coil section. Note that the resulting *electromagnet* has magnetic properties identical in principle to those of a permanent magnet, including poles and lines of force or flux. The strength of the magnetic field depends on several factors: the number of turns of the coil, the magnetic properties of the materials surrounding the coil (both inside and out), the length of the magnetic path and the amplitude of the current.

The magnetizing or *magnetomotive force* that produces a flux or total magnetic field is measured in gilberts (Gb). The force in gilberts equals  $0.4\pi$  (approximately 1.257) times the number of turns in the coil times the current in amperes. (The SI unit of magnetomotive force is the ampere turn, abbreviated A, just like the ampere.) The magnetic field strength,  $H$ , measured in oersteds (Oe) produced by any particular magnetomotive force (measured in gilberts) is given by:

$$H = \frac{0.4 \pi N I}{\ell} \quad (33)$$

where:

$H$  = magnetic field strength in oersteds,  
 $N$  = number of turns,  
 $I$  = dc current in amperes,  
 $\pi$  = 3.1416, and  
 $\ell$  = mean magnetic path length in centimeters.

The gilbert and oersted are *cgs* units. These are given here because most amateur calculations will use these units. You may also see the preferred SI units in some literature. The SI unit of magnetic field strength is the ampere (turn) per meter.

A force is required to produce a given

magnetic field strength. This implies that there is a resistance, called *reluctance*, to be overcome.

### Core Properties: Permeability, Saturation, Reluctance, Hysteresis

The nature of the material within the coil of an electromagnet, where the lines of force are most concentrated, has the greatest effect upon the magnetic field established by the coil. All materials are compared to air. The ratio of flux density produced by a given material compared to the flux density produced by an air core is the *permeability* of the material. Suppose the coil in **Fig 6.28** is wound on an iron core having a cross-sectional area of 2 square inches. When a certain current is sent through the coil, it is found that there are 80000 lines of force in the core. Since the area is 2 square inches, the magnetic flux density is 40000 lines per square inch. Now suppose that the iron core is removed and the same current is main-

**Fig 6.27 — Cross section of an inductor showing its flux lines and overall magnetic field.**

tained in the coil. Also suppose the flux density without the iron core is found to be 50 lines per square inch. The ratio of these flux densities, iron core to air, is  $40000 / 50$  or 800, the core's permeability.

Permeabilities as high as  $10^6$  have been attained. The three most common types of materials used in magnetic cores are these:

- A. stacks of laminated steel sheets (for power and audio applications);
- B. various ferrite compounds (for cores shaped as rods, toroids, beads and numerous other forms); and
- C. powdered iron (shaped as slugs, toroids and other forms for RF inductors).

Brass has a permeability less than 1. A brass core inserted into a coil will decrease the inductance compared to an air core.

The permeability of silicon-steel power-transformer cores approaches 5000 in high-quality units. Powdered-iron cores used in RF tuned circuits range in permeability from 3 to about 35, while ferrites of nickel-zinc and manganese-zinc range from 20 to 15000. **Table 6.5** lists some common magnetic materials, their composition and their permeabilities. Core materials are often fre-

**Fig 6.28 — A coil of wire wound around a laminated iron core.**

**Table 6.5**  
**Properties of Some High-Permeability Materials**

Material	Approximate Percent Composition					Maximum Permeability
	Fe	Ni	Co	Mo	Other	
Iron	99.91	—	—	—	—	5000

 (Reference: L. Ridenour, ed., *Modern Physics for the Engineer*, p 119.)

quency sensitive, exhibiting excessive losses outside the frequency band of intended use.

As a measure of the ease with which a magnetic field may be established in a material as compared with air, permeability ( $\mu$ ) corresponds roughly to electrical conductivity. Permeability is given as:

$$\mu = \frac{B}{H} \quad (34)$$

where:

$B$  is the flux density in gauss, and

$H$  is the magnetomotive force in oersted.

Unlike electrical conductivity, which is independent of other electrical parameters, the permeability of a magnetic material varies with the flux density. At low flux densities (or with an air core), increasing the current through the coil will cause a proportionate increase in flux. But at very high flux densities, increasing the

current beyond a certain point may cause no appreciable change in the flux. At this point, the core is said to be *saturated*. Saturation causes a rapid decrease in permeability, because it decreases the ratio of flux lines to those obtainable with the same current using an air core. **Fig 6.29** displays a typical permeability curve, showing the region of saturation. The saturation point varies with the make-up of different magnetic materials. Air and other nonmagnetic materials do not saturate and have a permeability of one. *Reluctance*, which is the reciprocal of permeability and corresponds roughly to resistance in an electrical circuit, is also one for air and other nonmagnetic cores.

The retentivity of magnetic core materials creates another potential set of losses caused by *hysteresis*. **Fig 6.30** illustrates the change of flux density ( $B$ ) with a changing magnetizing force ( $H$ ). From starting point A, with no residual flux, the flux reaches point B at the maximum mag-

netizing force. As the force decreases, so too does the flux, but it does not reach zero simultaneously with the force at point D. As the force continues in the opposite direction, it brings the flux density to point C. As the force decreases to zero, the flux once more lags behind. In effect, a reverse force is necessary to overcome the residual magnetism retained by the core material, a *coercive force*. The result is a power loss to the magnetic circuit, which appears as heat in the core material. Air cores are immune to hysteresis effects and losses.

## INDUCTANCE AND DIRECT CURRENT

In an electrical circuit, any element having a magnetic field is called an *inductor*. **Fig 6.31** shows schematic-diagram symbols and photographs of a few representative inductors: an air-core inductor, a slug-tuned variable inductor with a nonmagnetic core and an inductor with a magnetic (iron) core.

The transfer of energy to the magnetic field of an inductor represents work performed by the source of the voltage. Power is required for doing work, and since power is equal to current multiplied by voltage, there must be a voltage drop in the circuit while energy is being stored in the field. This voltage drop, exclusive of any voltage drop caused by resistance in the circuit, is the result of an opposing voltage induced in the circuit while the field is building up to its final value. Once the field becomes constant, the *induced voltage* or back-voltage disappears, because no further energy is being stored. The induced voltage opposes the voltage of the source and tends to prevent the current from rising rapidly when the circuit is closed. **Fig 6.32A** illustrates the situation of energizing an inductor or magnetic circuit, showing the relative amplitudes of induced voltage and the delayed rise in current to its full value.

The amplitude of the induced voltage is proportional to the rate at which the current changes (and consequently, the rate at which the magnetic field changes) and to a constant associated with the circuit itself: the *inductance* (or *self-inductance*) of the circuit. Inductance depends on the physical configuration of the inductor. Coiling a conductor increases its inductance. In effect, the growing (or shrinking) magnetic field of each turn produces magnetic lines of force that — in their expansion (or contraction) — cut across the other turns of the coil, inducing a voltage in every other turn. The mutuality of the effect multiplies the ability of the coiled conductor to store electrical energy.

A coil of many turns will have more

**Fig 6.29** — A typical permeability curve for a magnetic core, showing the point where saturation begins.

**Fig 6.30** — A typical hysteresis curve for a magnetic core, showing the additional energy needed to overcome residual flux.

**Fig 6.31** — Schematic symbols for representative inductors, including (from left to right) an air-core inductor, a variable inductor with a nonmagnetic slug, and an inductor with a magnetic core.

inductance than one of few turns, if both coils are otherwise physically similar. Furthermore, if an inductor is placed around a magnetic core, its inductance will increase in proportion to the permeability of that core, if the circuit current is below the point at which the core saturates.

The polarity of an induced voltage is always such as to oppose any change in the circuit current. This means that when the current in the circuit is increasing, work is being done against the induced voltage by storing energy in the magnetic field. Likewise, if the current in the circuit tends to decrease, the stored energy of the field returns to the circuit, and adds to the energy being supplied by the voltage source. Inductors try to maintain a constant current through the circuit. This phenomenon tends to keep the current flowing even though the applied voltage may be decreasing or be removed entirely. Fig 6.32B illustrates the decreasing but continuing flow of current caused by the induced voltage after the source voltage is removed from the circuit.

The energy stored in the magnetic field of an inductor is given by the formula:

$$W = \frac{I^2 L}{2} \quad (35)$$

where:

$W$  = energy in joules,

$I$  = current in amperes, and

$L$  = inductance in henrys.

This formula corresponds to the energy-storage formula for capacitors: energy storage is a function of current squared over time. As with capacitors, the time dependence of inductor current is a significant property; see the section on time constants.

The basic unit of inductance is the *henry* (abbreviated H), which equals an induced voltage of one volt when the inducing current is varying at a rate of one ampere per second. In various aspects of radio work, inductors may take values ranging from a fraction of a nanohenry (nH) through millihenrys (mH) up to about 20 H.

## MUTUAL INDUCTANCE AND MAGNETIC COUPLING

### Mutual Inductance

When two coils are arranged with their axes on the same line, as shown in Fig 6.33, current sent through coil 1 creates a magnetic field that cuts coil 2. Consequently, a voltage will be induced in coil 2 whenever the field strength of coil 1 is changing. This induced voltage is similar to the voltage of self-induction, but since it appears in the second coil because of

Fig 6.32 — Inductive circuit showing and graphing the generation of induced voltage and the rise of current in an inductor at A, and the decay of current as power is removed and the coil shorted at B.

current flowing in the first, it is a mutual effect and results from the *mutual inductance* between the two coils.

When all the flux set up by one coil cuts all the turns of the other coil, the mutual inductance has its maximum possible value. If only a small part of the flux set up by one coil cuts the turns of the other, the mutual inductance is relatively small. Two coils having mutual inductance are said to be *coupled*.

The ratio of actual mutual inductance to the maximum possible value that could theoretically be obtained with two given coils is called the *coefficient of coupling* between the coils. It is frequently expressed as a percentage. Coils that have nearly the maximum possible mutual inductance (coefficient = 1 or 100%) are said to be closely, or tightly, coupled. If the mutual inductance is relatively small the coils are said to be loosely coupled. The degree of coupling depends upon the physical spacing between the coils and how they are placed with respect to each other. Maximum coupling exists when they have a common axis and are as close together as possible (for example, one

Fig 6.33 — Mutual inductance: When S is closed, current flows through coil number 1, setting up a magnetic field that induces a voltage in the turns of coil number 2.

wound over the other). The coupling is least when the coils are far apart or are placed so their axes are at right angles.

The maximum possible coefficient of coupling is closely approached when the two coils are wound on a closed iron core. The coefficient with air-core coils may

run as high as 0.6 or 0.7 if one coil is wound over the other, but will be much less if the two coils are separated. Although unity coupling is suggested by Fig 6.33, such coupling is possible only when the coils are wound on a closed magnetic core.

### Unwanted Couplings: Spikes, Lightning and Other Pulses

Every conductor passing current has a magnetic field associated with it — and therefore inductance — even though the conductor is not formed into a coil. The inductance of a short length of straight wire is small, but it may not be negligible. If the current through it changes rapidly, the induced voltage may be appreciable. This is the case in even a few inches of wire with an alternating current having a frequency on the order of 100 MHz or higher. At much lower frequencies or at dc, the inductance of the same wire might be ignored because the induced voltage would seemingly be negligible.

There are many phenomena, however, both natural and man-made, which create sufficiently strong magnetic fields to induce voltages into straight wires. Many of them are brief but intense pulses of energy that act like the turning on of the switch in a circuit containing self-inductance. Because the fields created grow to very high levels rapidly, they cut across wires leading into and out of — and wires wholly within — electronic equipment, inducing unwanted voltages by mutual coupling.

Short-duration, high-level voltage spikes occur on ac and dc power lines. Because the field intensity is great, these spikes may induce voltages upon conducting elements in sensitive circuits, disrupting them and even injuring components. Lightning in the vicinity of the equipment can induce voltages on power lines and other conductive paths (even ground conductors) that lead to the equipment location. Lightning that seems a safe distance away can induce

large spikes on power lines that ultimately lead to the equipment. Closer at hand, heavy equipment with electrical motors can induce significant spikes into power lines within the equipment location. Even though the power lines are straight, the powerful magnetic field of a spike source can induce damaging voltages on equipment left “plugged in” during electrical storms or during the operation of heavy equipment that inadequately filters its spikes.

Parallel-wire cables linking elements of electronic equipment consist of long wires in close proximity to each other. Signal pulses can couple both magnetically and capacitively from one wire to another. Since the magnetic field of a changing current decreases as the square of distance, separating the signal-carrying lines diminishes inductive coupling. Placing a grounded wire between signal-carrying lines reduces capacitive coupling. Unless they are well-shielded and filtered, however, the lines are still susceptible to the inductive coupling of pulses from other sources.

### INDUCTORS IN RADIO WORK

Various facets of radio work make use of inductors ranging from the tiny up to the massive. Small values of inductance, as illustrated by Fig 6.34A, serve mostly in RF circuits. They may be self-supporting air-core or air-wound coils or the winding may be supported by nonmagnetic strips or a form. Phenolic, certain plastics and ceramics are the most common coil forms for air-core inductors. These inductors range in value from a few hundred  $\mu\text{H}$  for medium- and high-frequency circuits down to tenths of a  $\mu\text{H}$  for VHF and UHF work. The smallest values of inductance in radio work result from component leads. For VHF work and higher frequencies, component lead length is often critical. Circuits may fail to operate properly because leads are a little too short or too long.

It is possible to make these solenoid coils variable by inserting a slug in the center of the coil. (Slug-tuned coils normally have a ceramic, plastic or phenolic insulating form between the conductive slug and the coil winding.) If the slug material is magnetic, such as powdered iron, the inductance increases as the slug is centered along the length of the coil. If the slug is brass or some other conductive but nonmagnetic material, centering the slug will reduce the coil's inductance. This effect stems from the fact that brass has low electrical resistance and acts as an effective short-circuited one-turn secondary for the coil. (See more on transformer effects later in this chapter.)

An alternative to air-core inductors for RF work are toroidal coils wound on cores composed of powdered iron mixed with a binder to hold the material together. The availability of many types and sizes of powdered-iron cores has made these inductors popular for low-power fixed-value service. The toroidal shape concentrates the inductor's field tightly about the coil, eliminating the need in many cases for other forms of shielding to limit the interaction of the inductor's magnetic field with the fields of other inductors.

Fig 6.34B shows samples of inductors in the millihenry range. Among these inductors are multisection RF chokes designed to keep RF currents from passing beyond them to other parts of circuits. Low-frequency radio work may also use inductors in this range of values, sometimes wound with *litz* wire. Litz wire is a special version of stranded wire, with each strand insulated from the others. For audio filters, toroidal coils with values below 100 mH are useful. Resembling powdered-iron-core RF toroids, these coils are wound on ferrite or molybdenum-permalloy cores having much higher permeabilities.

Audio and power-supply inductors appear in Fig 6.34C. Lower values of these iron-core coils, in the range of a few henrys, are useful as audio-frequency chokes. Larger values up to about 20 H may be found in power supplies, as choke filters, to suppress 120-Hz ripple. Although some of these inductors are open frame, most have iron covers to confine the powerful magnetic fields they produce.

### INDUCTANCES IN SERIES AND PARALLEL

When two or more inductors are connected in series (Fig 6.35A), the total inductance is equal to the sum of the individual inductances, provided that the coils

Fig 6.34 — Part A shows small-value air-wound inductors, B shows some inductors with values in the range of a few millihenrys and C shows large inductors as might be used in audio circuits or as power-supply chokes.

are sufficiently separated so that coils are not in the magnetic field of one another. That is:

$$L_{\text{total}} = L_1 + L_2 + L_3 \dots + L_n \quad (36)$$

If inductors are connected in parallel (Fig 6.35B), and if the coils are separated sufficiently, the total inductance is given by:

$$L_{\text{total}} = \frac{1}{\frac{1}{L_1} + \frac{1}{L_2} + \frac{1}{L_3} + \dots + \frac{1}{L_n}} \quad (37)$$

For only two inductors in parallel, the formula becomes:

$$L_{\text{total}} = \frac{L_1 \times L_2}{L_1 + L_2} \quad (38)$$

Thus, the rules for combining inductances in series and parallel are the same as those for resistances, assuming that the coils are far enough apart so that each is unaffected by another's magnetic field. When this is not so, the formulas given above will not yield correct results.

### RL TIME CONSTANT

A comparable situation to an RC circuit exists when resistance and inductance are connected in series. In Fig 6.36, first consider  $L$  to have no resistance and also consider that  $R$  is zero. Closing  $S_1$  sends a current through the circuit. The instantaneous transition from no current to a finite value, however small, represents a rapid change in current, and a reverse voltage is developed by the self-inductance of  $L$ . The value of reverse voltage is almost equal and opposite to the applied voltage. The resulting initial current is very small.

The reverse voltage depends on the change in the value of the current and would cease to offer opposition if the current did not continue to increase. With no resistance in the circuit (which, by Ohm's Law, would lead to an infinitely large current), the current would increase forever, always growing just fast enough to keep the self-induced voltage equal to the applied voltage.

When resistance in the circuit limits the current, Ohm's Law defines the value that the current can reach. The reverse voltage generated in  $L$  must only equal the difference between  $E$  and the drop across  $R$ , because the difference is the voltage actually applied to  $L$ . This difference becomes smaller as the current approaches the final Ohm's Law value. Theoretically, the reverse voltage never quite disappears, and so the current never quite reaches the Ohm's Law value. In practical terms, the differences become unmeasurable after a time.

The current at any time after the switch in Fig 6.36 has been closed, can be found from:

$$I(t) = \frac{E \left( 1 - e^{-\frac{tR}{L}} \right)}{R} \quad (39)$$

where:

$I(t)$  = current in amperes at time  $t$ ,  
 $E$  = power supply potential in volts,  
 $t$  = time in seconds after initiation of current,  
 $e$  = natural logarithmic base = 2.718,  
 $R$  = circuit resistance in ohms, and  
 $L$  = inductance in henrys.

The time in seconds required for the current to build up to 63.2% of the maximum value is called the time constant, and is equal to  $L/R$ , where  $L$  is in henrys and  $R$  is in ohms. After each time interval equal to this constant, the circuit conducts an additional 63.2% of the remaining current. This behavior is graphed in Fig 6.36. As is the case with capacitors, after 5 time constants the current is considered to have reached its maximum value. As with capacitors, we often use the lower-case Greek tau ( $\tau$ ) to represent the time constant.

Example: If a circuit has an inductor of 5.0 mH in series with a resistor of 10.  $\Omega$ , how long will it take for the current in the circuit to reach full value after power is applied? Since achieving maximum current takes approximately five time constants,

$$t = 5 L / R = (5 \times 5.0 \times 10^{-3} \text{ H}) / 10. \Omega \\ = 2.5 \times 10^{-3} \text{ seconds or } 2.5 \text{ ms}$$

(Look at the table of metric-system units in the **Mathematics for Amateur Radio** chapter to prove that *henrys* divided by *ohms* gives units of *seconds*.)

Note that if the inductance is increased to 5.0 H, the required time increases by a factor of 1000 to 2.5 seconds. Since the circuit resistance didn't change, the final current is the same for both cases in this example. Increasing inductance increases the time required to reach full current.

Zero resistance would prevent the circuit from ever achieving full current. All inductive circuits have some resistance, however, if only the resistance of the wire making up the inductor.

An inductor cannot be discharged in the simple circuit of Fig 6.36 because the magnetic field collapses as soon as the current ceases. Opening  $S_1$  does not leave the inductor charged in the way that a capacitor would remain charged. The energy stored in the magnetic field returns instantly to the circuit when  $S_1$  is opened. The rapid collapse of the field causes a very large voltage to be induced in the coil. Usually the induced

voltage is many times larger than the applied voltage, because the induced voltage is proportional to the rate at which the field changes. The common result of opening the switch in such a circuit is that a spark or arc forms at the switch contacts during the instant the switch opens. When the inductance is large and the current in the circuit is high, large amounts of energy are released in a very short time. It is not at all unusual for the switch contacts to burn or melt under such circumstances. The spark or arc at the opened switch can be reduced or suppressed by connecting a suitable capacitor and resistor in series across the contacts. Such an RC combination is called a *snubber network*.

Transistor switches connected to and controlling coils, such as relay solenoids,

Fig 6.35 — Part A shows inductances in series, and Part B shows inductances in parallel.

Fig 6.36 — Time constant of an RL circuit being energized.

also require protection. In most cases, a small power diode connected in reverse across the relay coil will prevent field-collapse currents from harming the transistor.

If the excitation is removed without breaking the circuit, as theoretically diagrammed in Fig 6.37, the current will decay according to the formula:

$$I(t) = \left( \frac{E}{R} \right) e^{\left( \frac{-tR}{L} \right)} \quad (40)$$

where  $t$  = time in seconds after removal of the source voltage.

**Fig 6.37 — Time constant of an RL circuit being deenergized. This is a theoretical model only, since a mechanical switch cannot change state instantaneously.**

After one time constant the current will lose 63.2% of its steady-state value. (It will decay to 36.8% of the steady-state value.) The graph in Fig 6.37 shows the current-decay waveform to be identical to the voltage-discharge waveform of a capacitor. Be careful about applying the terms *charge* and *discharge* to an inductive circuit, however. These terms refer to energy storage in an electric field. An inductor stores energy in a magnetic field.

## ALTERNATING CURRENT IN INDUCTORS

When an alternating voltage is applied to an ideal inductance (one with no resistance — all practical inductors have some resistance), the current is 90° out of phase with the applied voltage. In this case the current *lags* 90° behind the voltage; the opposite of the capacitor current-voltage relationship, as shown in Fig 6.38. (Here again, we can also say the voltage across an inductor *leads* the current by 90°.)

If you have difficulty remembering the phase relationships between voltage and current with inductors and capacitors, you may find it helpful to think of the mnemonic, “ELI the ICE man.” This little phrase will remind you that voltage leads current through an inductor, because the E comes before the I, with an L between them, as you read from left to right. (The letter L represents inductance.) It will also help you remember the capacitor conditions because I comes before E with a C between them.

Interpreting Fig 6.38 begins with understanding that the primary cause for current lag in an inductor is the reverse voltage generated in the inductance. The amplitude of the reverse voltage is proportional

to the rate at which the current changes. In time segment OA, when the applied voltage is at its positive maximum, the reverse or induced voltage is also maximum, allowing the least current to flow. The rate at which the current is changing is the highest, a 38% change in the time period OA. In the segment AB, the current changes by only 33%, yielding a reduced level of induced voltage, which is in step with the decrease in the applied voltage. The process continues in time segments BC and CD, the latter producing only an 8% rise in current as the applied and induced voltage approach zero.

In segment DE, the applied voltage changes direction. The induced voltage also changes direction, which returns current to the circuit from storage in the magnetic field. The direction of this current is now opposite to the applied voltage, which sustains the current in the positive direction. As the applied voltage continues to increase negatively, the current — although positive — decreases in value, reaching zero as the applied voltage reaches its negative maximum. The negative half-cycle continues just as did the positive half-cycle.

Compare Fig 6.38 with Fig 6.23. Whereas in a pure capacitive circuit, the current *leads* the voltage by 90°, in a pure inductive circuit, the current *lags* the voltage by 90°. These phenomena are especially important in circuits that combine inductors and capacitors.

## INDUCTIVE REACTANCE

The amplitude of alternating current in an inductor is inversely proportional to the applied frequency. Since the reverse voltage is directly proportional to inductance for a given rate of current change, the current is inversely proportional to inductance for a given applied voltage and frequency.

The combined effect of inductance and frequency is called inductive reactance, which — like capacitive reactance — is expressed in ohms. The formula for inductive reactance is:

$$X_L = 2 \pi f L \quad (41)$$

where:

$X_L$  = inductive reactance,

$f$  = frequency in hertz,

$L$  = inductance in henrys, and

$\pi = 3.1416$ .

(If  $\omega = 2 \pi f$ , then  $X_L = \omega L$ .)

Example: What is the reactance of a coil having an inductance of 8.00 H at a frequency of 120. Hz?

$$\begin{aligned} X_L &= 2 \pi f L \\ &= 6.2832 \times 120. \text{ Hz} \times 8.00 \text{ H} \\ &= 6030 \Omega \end{aligned}$$

**Fig 6.38 — Phase relationships between voltage and current when an alternating current is applied to an inductance.**

In RF circuits the inductance values are usually small and the frequencies are large. When the inductance is expressed in millihenrys and the frequency in kilohertz, the conversion factors for the two units cancel, and the formula for reactance may be used without first converting to fundamental units. Similarly, no conversion is necessary if the inductance is expressed in microhenrys and the frequency in megahertz.

Example: What is the reactance of a 15.0-microhenry coil at a frequency of 14.0 MHz?

$$\begin{aligned}X_L &= 2 \pi f L \\&= 6.2832 \times 14.0 \text{ MHz} \times 15.0 \mu\text{H} \\&= 1320 \Omega\end{aligned}$$

The resistance of the wire used to wind the coil has no effect on the reactance, but simply acts as a separate resistor con-

nected in series with the coil.

Example: What is the reactance of the same coil at a frequency of 7.0 MHz?

$$\begin{aligned}X_L &= 2 \pi f L \\&= 6.2832 \times 7.0 \text{ MHz} \times 15.0 \mu\text{H} \\&= 660 \Omega\end{aligned}$$

Comparing the two examples suggests correctly that inductive reactance varies directly with frequency. The rate of change of the current varies directly with the frequency, and this rate of change also determines the amplitude of the induced or reverse voltage. Hence, the opposition to the flow of current increases proportionally to frequency. This opposition is called *inductive reactance*. The direct relationship between frequency and reactance in inductors, combined with the inverse relationship between reactance and frequency in the case of capacitors, will be

of fundamental importance in creating resonant circuits.

As a measure of the ability of an inductor to limit the flow of ac in a circuit, inductive reactance is similar to capacitive reactance in having a corresponding *susceptance*, or ability to pass ac current in a circuit. In an ideal inductor with no resistive losses — that is, no energy lost as heat — susceptance is simply the reciprocal of reactance.

$$B = \frac{1}{X_L} \quad (42)$$

where:

$X_L$  = reactance, and

$B$  = susceptance.

The unit of susceptance for both inductors and capacitors is the *siemens*, abbreviated S.

## Quality Factor, or Q of Components

Components that store energy, like capacitors and inductors, may be compared in terms of quality or Q. The Q of any such component is the ratio of its ability to store energy to the sum total of all energy losses within the component. In practical terms, this ratio reduces to the formula:

$$Q = \frac{X}{R} \quad (43)$$

where:

Q = figure of merit or quality (no units),  
X =  $X_L$  (inductive reactance) for inductors and  $X_C$  (capacitive reactance) for capacitors (in ohms), and

R = the sum of all resistances associated with the energy losses in the component (in ohms).

The Q of capacitors is ordinarily high.

Good quality ceramic capacitors and mica capacitors may have Q values of 1200 or more. Small ceramic trimmer capacitors may have Q values too small to ignore in some applications. Microwave capacitors can have poor Q values; 10 or less at 10 GHz and higher frequencies.

Inductors are subject to many types of electrical energy losses, however: wire resistance, core losses and skin effect. All electrical conductors have some resistance through which electrical energy is lost as heat. Moreover, inductor wire must be sized to handle the anticipated current through the coil. Wire conductors suffer additional ac losses because alternating current tends to flow on the conductor surface. As the frequency increases, the current is confined to a thinner layer of the

conductor surface. This property is called *skin effect*. If the inductor's core is a conductive material, such as iron, ferrite, or brass, the core will introduce additional losses of energy. The specific details of these losses are discussed in connection with each type of core material.

The sum of all core losses may be depicted by showing a resistor in series with the inductor (as in Figs 6.36 and 6.37), although there is no separate component represented by the symbol. As a result of inherent energy losses, inductor Q rarely, if ever, approaches capacitor Q in a circuit where both components work together. Although many circuits call for the highest Q inductor obtainable, other circuits may call for a specific Q, even a very low one.

# Calculating Practical Inductors

Although builders and experimenters rarely construct their own capacitors, inductor fabrication is common. In fact, it is often necessary, since commercially available units may be unavailable or expensive. Even if available, they may consist of coil stock to be trimmed to the required value. Core materials and wire for winding both solenoid and toroidal inductors are readily available. The following information includes fundamental formulas and design examples for calculating prac-

tical inductors, along with additional data on the theoretical limits in the use of some materials.

## AIR-CORE INDUCTORS

Many circuits require air-core inductors using just one layer of wire. The approximate inductance of a single-layer air-core coil may be calculated from the simplified formula:

$$L (\mu\text{H}) = \frac{d^2 n^2}{18 d + 40 \ell} \quad (44)$$

where:

$L$  = inductance in microhenrys,  
 $d$  = coil diameter in inches (from wire center to wire center),  
 $\ell$  = coil length in inches, and  
 $n$  = number of turns.

The notation is explained in Fig 6.39. This formula is a close approximation for coils having a length equal to or greater than  $0.4 d$ . (Note: Inductance varies as the square of the turns. If the number of turns is doubled, the inductance is quadrupled. This relationship is inherent in the equa-

tion, but is often overlooked. For example, if you want to double the inductance, put on additional turns equal to 1.4 times the original number of turns, or 40% more turns.)

Example: What is the inductance of a coil if the coil has 48 turns wound at 32 turns per inch and a diameter of  $\frac{3}{4}$  inch? In this case,  $d = 0.75$ ,  $\ell = \frac{48}{32} = 1.5$  and  $n = 48$ .

$$L = \frac{0.75^2 \times 48^2}{(18 \times 0.75) + (40 \times 1.5)} \\ = \frac{1300}{74} = 18 \mu\text{H}$$

To calculate the number of turns of a single-layer coil for a required value of inductance, the formula becomes:

$$n = \frac{\sqrt{L (18 d + 40 \ell)}}{d} \quad (45)$$

Example: Suppose an inductance of  $10.0 \mu\text{H}$  is required. The form on which the coil is to be wound has a diameter of one inch and is long enough to accommodate a coil of  $1\frac{1}{4}$  inches. Then  $d = 1.00$  inch,  $\ell = 1.25$  inches and  $L = 10.0$ . Substituting:

$$n = \frac{\sqrt{10.0 [(18 \times 1.00) + (40 \times 1.25)]}}{1} \\ = \sqrt{680} = 26.1 \text{ turns}$$

A 26-turn coil would be close enough in practical work. Since the coil will be 1.25 inches long, the number of turns per inch will be  $26.1 / 1.25 = 20.9$ . Consulting the wire table in the **References** chapter, we find that #17 enameled wire (or anything smaller) can be used. The proper inductance is obtained by winding the required number of turns on the form and then adjusting the spacing between the turns to make a uniformly spaced coil 1.25 inches long.

Most inductance formulas lose accuracy when applied to small coils (such as are used in VHF work and in low-pass filters built for reducing harmonic interference to televisions) because the conductor thickness is no longer negligible in comparison with the size of the coil. Fig 6.40 shows the measured inductance of VHF coils and may be used as a basis for circuit design. Two curves are given; curve A is for coils wound to an inside diameter of  $\frac{1}{2}$  inch; curve B is for coils of  $\frac{3}{4}$ -inch inside diameter. In both curves, the wire size is #12, and the winding pitch is eight turns to the inch ( $\frac{1}{8}$  inch center-to-center turn spacing). The inductance values given include leads  $\frac{1}{2}$ -inch long.

Machine-wound coils with the preset di-

Fig 6.39 — Coil dimensions used in the inductance formula for air-core inductors.

Fig 6.40 — Measured inductance of coils wound with #12 bare wire, eight turns to the inch. The values include half-inch leads.

ameters and turns per inch are available in many radio stores, under the trade names of B&W Miniductor, Airdux and Polycoil. The **References** chapter provides information on using such coil stock to simplify the process of designing high-quality inductors for most HF applications. Forming a wire into a solenoid increases its inductance, and also introduces distributed capacitance. Since each turn is at a slightly different ac potential, each pair of turns effectively forms a parasitic capacitor. See the **Real-World Components** chapter for information on the effects of these complications to the "ideal" inductors under discussion in this chapter. Moreover, the  $Q$  of air-core inductors is, in part, a function of the coil shape, specifically its ratio of length to diameter.  $Q$  tends to be highest when these dimensions are nearly equal. With wire properly sized to the current carried by the coil, and with high-caliber construction, air-core inductors can achieve  $Q$ s above 200. Air-core inductors with  $Q$ s as high as 400 are possible.

### STRAIGHT-WIRE INDUCTANCE

At low frequencies the inductance of a straight, round, nonmagnetic wire in free space is given by:

$$L = 0.00508 b \left\{ \left[ \ln \left( \frac{2b}{a} \right) \right] - 0.75 \right\} \quad (46)$$

where:

$L$  = inductance in  $\mu\text{H}$ ,

$a$  = wire radius in inches,

$b$  = wire length in inches, and

$\ln$  = natural logarithm =  $2.303 \times$  common logarithm (base 10).

If the dimensions are expressed in millimeters instead of inches, the equation may still be used, except replace the 0.00508 value with 0.0002.

Skin effect reduces the inductance at VHF and above. As the frequency approaches infinity, the 0.75 constant within the brackets approaches unity. As a practical matter, skin effect will not reduce the inductance by more than a few percent.

Example: What is the inductance of a wire that is 0.1575 inch in diameter and 3.9370 inches long? For the calculations,  $a = 0.0787$  inch (radius) and  $b = 3.9370$  inch.

$$L = 0.00508 b \left\{ \left[ \ln \left( \frac{2b}{a} \right) \right] - 0.75 \right\}$$

$$= 0.00508 (3.9370) \times$$

$$\left\{ \left[ \ln \left( \frac{2 \times 3.9370}{0.0787} \right) \right] - 0.75 \right\}$$

$$L = 0.0200 [\ln(100.) - 0.75]$$

$$= 0.0200 (4.60 - 0.75)$$

$$= 0.0200 \times 3.85 = 0.077 \mu\text{H}$$

Fig 6.41 — Inductance of various conductor sizes as straight wires.

Fig 6.42 — Equation for determining the inductance of a wire parallel to a ground plane, with one end grounded. If the dimensions are in millimeters, the numerical coefficients become 0.0004605 for the first term and 0.0002 for the second term.

Fig 6.43 — Equation for determining the inductance of a flat strip inductor.

**Fig 6.41** is a graph of the inductance for wires of various radii as a function of length.

A VHF or UHF tank circuit can be fabricated from a wire parallel to a ground plane, with one end grounded. A formula for the inductance of such an arrangement is given in **Fig 6.42**.

Example: What is the inductance of a wire 3.9370 inches long and 0.0787 inch in radius, suspended 1.5748 inch above a ground plane? (The inductance is measured between the free end and the ground plane, and the formula includes the inductance of the 1.5748-inch grounding link.) To demonstrate the use of the formula in **Fig 6.42**, begin by evaluating these quantities:

$$b + \sqrt{b^2 + a^2}$$

$$= 3.9370 + \sqrt{3.9370^2 + 0.0787^2}$$

$$= 3.9370 + 3.94 = 7.88$$

$$b + \sqrt{b^2 + 4(h^2)}$$

$$= 3.9370 + \sqrt{3.9370^2 + 4(1.5748^2)}$$

$$= 3.9370 + \sqrt{15.500 + 4(2.4800)}$$

$$= 3.9370 + \sqrt{15.500 + 9.9200}$$

$$= 3.9370 + 5.0418 = 8.9788$$

$$\frac{2h}{a} = \frac{2 \times 1.5748}{0.0787} = 40.0$$

$$\frac{b}{4} = \frac{3.9370}{4} = 0.98425$$

**Fig 6.44** — Typical construction of an iron-core inductor. The small air gap prevents magnetic saturation of the iron and thus maintains the inductance at high currents.

Substituting these values into the formula yields:

$$L = 0.0117 \times 3.9370 \left\{ \log_{10} \left[ 40.0 \times \left( \frac{7.88}{8.9788} \right) \right] \right\}$$

$$+ 0.00508 \times$$

$$(5.0418 - 3.94 + 0.98425 - 3.1496 + 0.0787)$$

$$L = 0.0662 \mu\text{H}$$

Another conductor configuration that is frequently used is a flat strip over a ground plane. This arrangement has lower skin-effect loss at high frequencies than round wire because it has a higher surface-area to volume ratio. The inductance of such a strip can be found from the formula in **Fig 6.43**. For a large collection of formulas useful in constructing air-core inductors of many configurations, see the "Circuit Elements" section in Terman's *Radio Engineers' Handbook* or the "Design Techniques" chapter of *The ARRL UHF/Microwave Experimenter's Manual*.

## IRON-CORE INDUCTORS

If the permeability of an iron core in an inductor is 800, then the inductance of any given air-wound coil is increased 800 times by inserting the iron core. The inductance will be proportional to the magnetic flux through the coil, other things being equal. The inductance of an iron-core inductor is highly dependent on the current flowing in the coil, in contrast to an air-core coil, where the inductance is independent of current because air does not saturate.

Iron-core coils such as the one sketched in **Fig 6.44** are used chiefly in power-supply equipment. They usually have direct current flowing through the winding, and any variation in inductance with current is usually undesirable. Inductance variations may be overcome by keeping the flux density below the saturation point of the iron. Opening the core so there is a small air gap, indicated by the dashed lines in **Fig 6.44**, will achieve this goal. The reluctance or magnetic resistance introduced by such a gap is very large compared with that of the iron, even though the gap is only a small fraction of an inch. Therefore, the gap — rather than the iron — controls the flux density. Air gaps in iron cores reduce the inductance, but they hold the value practically constant regardless of the current magnitude.

When alternating current flows through a coil wound on an iron core, a voltage is induced. Since iron is a conductor, a current also flows in the core. Such currents are called *eddy currents*. Eddy currents represent lost power because they flow through the resistance of the iron and gen-

erate heat. Losses caused by eddy currents can be reduced by laminating the core (cutting the core into thin strips). These strips or laminations are then insulated from each other by painting them with some insulating material such as varnish or shellac. These losses add to hysteresis losses, which are also significant in iron-core inductors.

Eddy-current and hysteresis losses in iron increase rapidly as the frequency of the alternating current increases. For this reason, ordinary iron cores can be used only at power-line and audio frequencies — up to approximately 15000 Hz. Even then, a very good grade of iron or steel is necessary for the core to perform well at the higher audio frequencies. Laminated iron cores become completely useless at radio frequencies.

## SLUG-TUNED INDUCTORS

For RF work, the losses in iron cores can be reduced to a more useful level by grinding the iron into a powder and then mixing it with a "binder" of insulating material in such a way that the individual iron particles are insulated from each other. Using this approach, cores can be made that function satisfactorily even into the VHF range.

Because a large part of the magnetic path is through a nonmagnetic material (the "binder"), the permeability of the iron is low compared with the values obtained at power-line frequencies. The core is usually shaped in the form of a slug or cylinder for fit inside the insulating form on which the coil is wound. Despite the fact that the major portion of the magnetic path for the flux is in air, the slug is quite effective in increasing the coil inductance. By pushing (or screwing) the slug in and out of the coil, the inductance can be varied over a considerable range. See *The ARRL Electronics Data Book* for information on a wide variety of representative slug-tuned coils available commercially.

## POWDERED-IRON TOROIDAL INDUCTORS

For fixed-value inductors intended for use at HF and VHF, the powdered-iron toroidal core has become almost the standard core and material in low power circuits. **Fig 6.45** shows the general outlines of a toroidal coil on a magnetic core. Manufacturers offer a wide variety of core materials, or mixes, to provide units that will perform over a desired frequency range with a reasonable permeability. Initial permeabilities for powdered-iron cores fall in the range of 3 to 35 for various mixes. In addition, core sizes are available in the range of 0.125-inch outside diam-

**Fig 6.45 — A typical toroidal inductor wound on a powdered-iron or ferrite core. Some key physical dimensions are noted. Equally important are the core material, its permeability, its intended range of operating frequencies, and its  $A_L$  value. This is an 11-turn toroid.**

eter (OD) up to 1.06-inch OD, with larger sizes to 5-inch OD available in certain mixes. The range of sizes permits the builder to construct single-layer inductors for almost any value using wire sized to meet the circuit current demands. While powdered-iron toroids are often painted various colors, you must know the manufacturer to identify the mix. There seems to be no set standard between manufacturers. Iron-powder toroids usually have rounded edges.

The use of powdered iron in a binder reduces core losses usually associated with iron, while the permeability of the core permits a reduction in the wire length and associated resistance in forming a coil of a given inductance. Therefore, powdered-iron-core toroidal inductors can achieve Qs well above 100, often approaching or exceeding 200 within the frequency range specified for a given core. Moreover, these coils are considered self-shielding since most of the flux lines are within the core, a fact that simplifies circuit design and construction.

Each powdered-iron core has a value of  $A_L$  determined and published by the core manufacturer. For powdered-iron cores,  $A_L$  represents the *inductance index*, that is, the inductance in  $\mu\text{H}$  per 100 turns of wire on the core, arranged in a single layer. The builder must select a core size capable of holding the calculated number of turns, of the required wire size, for the desired inductance. Otherwise, the coil calculation

is straightforward. To calculate the inductance of a powdered-iron toroidal coil, when the number of turns and the core material are known, use the formula:

$$L = \frac{A_L \times N^2}{10000} \quad (47)$$

where:

- $L$  = the inductance in  $\mu\text{H}$ ,
- $A_L$  = the inductance index in  $\mu\text{H}$  per 100 turns, and
- $N$  = the number of turns.

Example: What is the inductance of a 60-turn coil on a core with an  $A_L$  of 55? This  $A_L$  value was selected from manufacturer's information about a 0.8-inch OD core with an initial permeability of 10. This particular core is intended for use in the range of 2 to 30 MHz. See the **Component Data** chapter for more detailed data on the range of available cores.

$$\begin{aligned} L &= \frac{A_L \times N^2}{10000} = \frac{55 \times 60^2}{10000} \\ &= \frac{198000}{10000} = 19.8 \mu\text{H} \end{aligned}$$

To calculate the number of turns needed for a particular inductance, use the formula:

$$N = 100 \sqrt{\frac{L}{A_L}} \quad (48)$$

Example: How many turns are needed for a 12.0- $\mu\text{H}$  coil if the  $A_L$  for the selected core is 49?

$$\begin{aligned} N &= 100 \sqrt{\frac{L}{A_L}} = 100 \sqrt{\frac{12.0}{49}} \\ &= 100 \sqrt{0.245} = 100 \times 0.495 = 49.5 \text{ turns} \end{aligned}$$

If the value is critical, experimenting with 49-turn and 50-turn coils is in order, especially since core characteristics may vary slightly from batch to batch. Count turns by each pass of the wire through the center of the core. (A straight wire through a toroidal core amounts to a one-turn coil.) Fine adjustment of the inductance may be possible by spreading or squeezing inductor turns.

The power-handling ability of toroidal cores depends on many variables, which include the cross-sectional area through the core, the core material, the numbers of turns in the coil, the applied voltage and the operating frequency. Although powdered-iron cores can withstand dc flux densities up to 5000 gauss without saturating, ac flux densities from sine waves above certain limits can overheat cores. Manufacturers provide guideline limits for ac flux densities to avoid overheating. The limits range from 150 gauss at 1 MHz to 30 gauss at 28 MHz,

although the curve is not linear. To calculate the maximum anticipated flux density for a particular coil, use the formula:

$$B_{\text{max}} = \frac{E_{\text{RMS}} \times 10^8}{4.44 \times A_e \times N \times f} \quad (49)$$

where:

- $B_{\text{max}}$  = the maximum flux density in gauss,
- $E_{\text{RMS}}$  = the voltage across the coil,
- $A_e$  = the cross-sectional area of the core in square centimeters,
- $N$  = the number of turns in the coil, and
- $f$  = the operating frequency in Hz.

Example: What is the maximum ac flux density for a coil of 15 turns if the frequency is 7.0 MHz, the RMS voltage is 25 V and the cross-sectional area of the core is 0.133  $\text{cm}^2$ ?

$$\begin{aligned} B_{\text{max}} &= \frac{E_{\text{RMS}} \times 10^8}{4.44 \times A_e \times N \times f} \\ &= \frac{25 \times 10^8}{4.44 \times 0.133 \times 15 \times 7.0 \times 10^6} \\ &= \frac{25 \times 10^8}{62 \times 10^6} = 40. \text{ gauss} \end{aligned}$$

Since the recommended limit for cores operated at 7 MHz is 57 gauss, this coil is well within guidelines.

## FERRITE TOROIDAL INDUCTORS

Although nearly identical in general appearance to powdered-iron cores, ferrite cores differ in a number of important characteristics. They are often unpainted, unlike powdered-iron toroids. Ferrite toroids often have sharp edges, while powdered-iron toroids usually have rounded edges. Composed of nickel-zinc ferrites for lower permeability ranges and of manganese-zinc ferrites for higher permeabilities, these cores span the permeability range from 20 to above 10000. Nickel-zinc cores with permeabilities from 20 to 800 are useful in high-Q applications, but function more commonly in amateur applications as RF chokes. They are also useful in wide-band transformers (discussed later in this chapter).

Because of their higher permeabilities, the formulas for calculating inductance and turns require slight modification. Manufacturers list ferrite  $A_L$  values in mH per 1000 turns. Thus, to calculate inductance, the formula is

$$L = \frac{A_L \times N^2}{1000000} \quad (50)$$

where:

- $L$  = the inductance in mH,
- $A_L$  = the inductance index in mH per 1000 turns, and
- $N$  = the number of turns.

Example: What is the inductance of a 60-turn coil on a core with an  $A_L$  of 523? (See the **Component Data** chapter for more detailed data on the range of available cores.)

$$L = \frac{A_L \times N^2}{1000000} = \frac{523 \times 60^2}{1000000}$$

$$= \frac{1.88 \times 10^6}{1 \times 10^6} = 1.88 \text{ mH}$$

To calculate the number of turns needed for a particular inductance, use the formula:

$$N = 1000 \sqrt{\frac{L}{A_L}} \quad (51)$$

Example: How many turns are needed for a 1.2-mH coil if the  $A_L$  for the selected core is 150?

$$N = 1000 \sqrt{\frac{L}{A_L}} = 1000 \sqrt{\frac{1.2}{150}}$$

$$= 1000 \sqrt{0.008} = 1000 \times 0.089 = 89 \text{ turns}$$

For inductors carrying both dc and ac currents, the upper saturation limit for most ferrites is a flux density of 2000 gauss, with power calculations identical to those used for powdered-iron cores. For detailed information on available cores and their characteristics, see *Iron-Powder and Ferrite Coil Forms*, a combination catalog and information book from Amidon Associates, Inc. (See the Address List in the **References** chapter for information about contacting Amidon.)

## Ohm's Law for Reactance

Only ac circuits containing capacitance or inductance (or both) have reactance. Despite the fact that the voltage in such circuits is  $90^\circ$  out of phase with the current, circuit reactance does limit current in a manner that corresponds to resistance. Therefore, the Ohm's Law equations relating voltage, current and resistance apply to purely reactive circuits:

$$E = I X \quad (52)$$

$$I = \frac{E}{X} \quad (53)$$

$$X = \frac{E}{I} \quad (54)$$

where:

$E$  = ac voltage in RMS,

$I$  = ac current in amperes, and

$X$  = inductive or capacitive reactance.

Example: What is the voltage across a capacitor of 200. pF at 7.15 MHz, if the current through the capacitor is 50. mA?

Since the reactance of the capacitor is a function of both frequency and capacitance, first calculate the reactance:

$$X_C = \frac{1}{2 \pi f C}$$

$$= \frac{1}{2 \times 3.1416 \times 7.15 \times 10^6 \text{ Hz} \times 200. \times 10^{-12} \text{ F}}$$

$$= \frac{10^6 \Omega}{8980} = 111 \Omega$$

Next, use Ohm's Law:

$$E = I \times X_C = 0.050 \text{ A} \times 111 \Omega = 5.6 \text{ V}$$

Example: What is the current through an 8.00-H inductor at 120. Hz, if 420. V is applied?

$$X_L = 2 \pi f L = 2 \times 3.1416 \times 120. \text{ Hz} \times 8.00 \text{ H} = 6030 \Omega$$

$$I = \frac{E}{X_L} = \frac{420. \text{ V}}{6030 \Omega} = 0.0697 \text{ A} = 69.7 \text{ mA}$$

**Fig 6.46** charts the reactances of capacitors from 1 pF to 100  $\mu\text{F}$ , and the reactances of inductors from 0.1  $\mu\text{H}$  to 10 H, for frequencies between 100 Hz and 100 MHz. Approximate values of reactance can be read or interpolated from the chart. The formulas will produce more exact values, however.

Although both inductive and capacitive reactance limit current, the two types of reactance differ. With capacitive reactance, the current *leads* the voltage by  $90^\circ$ , whereas with inductive reactance, the current *lags* the voltage by  $90^\circ$ . The convention for charting the two types of reactance appears in **Fig 6.47**. On this graph, inductive reactance is plotted along the  $+90^\circ$  vertical line, while capacitive reactance is plotted along the  $-90^\circ$  vertical line. This convention of assigning a positive value to inductive reactance and a negative value to capacitive reactance results from the mathematics involved in impedance calculations.

### REACTANCES IN SERIES AND PARALLEL

If a circuit contains two reactances of the same type, whether in series or in parallel, the resultant reactance can be determined by applying the same rules

as for resistances in series and in parallel. Series reactance is given by the formula

$$X_{\text{total}} = X_1 + X_2 + X_3 + \dots + X_n \quad (55)$$

**Fig 6.47** — The conventional method of plotting reactances on the vertical axis of a graph, using the upward or "plus" direction for inductive reactance and the downward or "minus" direction for capacitive reactance. The horizontal axis will be used for resistance in later examples.

Fig 6.46 — Inductive and capacitive reactance vs frequency. Heavy lines represent multiples of 10, intermediate lines multiples of 5. For example, the light line between 10  $\mu\text{H}$  and 100  $\mu\text{H}$  represents 50  $\mu\text{H}$ ; the light line between 0.1  $\mu\text{F}$  and 1  $\mu\text{F}$  represents 0.5  $\mu\text{F}$ , and so on. Other values can be extrapolated from the chart. For example, the reactance of 10 H at 60 Hz can be found by taking the reactance of 10 H at 600 Hz and dividing by 10 for the 10 times decrease in frequency.

Example: Two noninteracting inductances are in series. Each has a value of 4.0  $\mu\text{H}$ , and the operating frequency is 3.8 MHz. What is the resulting reactance?

The reactance of each inductor is:

$$X_L = 2\pi fL = 2 \times 3.1416 \times 3.8 \times 10^6 \text{ Hz} \times 4 \times 10^{-6} \text{ H} = 96 \Omega$$

$$X_{\text{total}} = X_1 + X_2 = 96 \Omega + 96 \Omega = 192 \Omega$$

We might also calculate the total reactance by first adding the inductances:

$$L_{\text{total}} = L_1 + L_2 = 4.0 \mu\text{H} + 4.0 \mu\text{H} \\ L_{\text{total}} = 8.0 \mu\text{H}$$

$$X_{\text{total}} = 2\pi fL = 2 \times 3.1416 \times 3.8 \times 10^6 \text{ Hz} \times 8.0 \times 10^{-6} \text{ H}$$

$$X_{\text{total}} = 191 \Omega$$

(The fact that the last digit differs by one illustrates the uncertainty of the calculation caused by the uncertainty of the measured values in the problem, and differences caused by rounding off the calculated values. This also shows why it is important to follow the rules for significant figures discussed in the **Mathematics for Amateur Radio** chapter.)

Example: Two noninteracting capacitors are in series. One has a value of 10.0 pF, the other of 20.0 pF. What is the resulting reac-

tance in a circuit operating at 28.0 MHz?

$$X_{C1} = \frac{1}{2\pi fC}$$

$$= \frac{1}{2 \times 3.1416 \times 28.0 \times 10^6 \text{ Hz} \times 10.0 \times 10^{-12} \text{ F}} \\ = \frac{10^6 \Omega}{1760} = 568 \Omega$$

$$X_{C2} = \frac{1}{2\pi fC}$$

$$= \frac{1}{2 \times 3.1416 \times 28.0 \times 10^6 \text{ Hz} \times 20.0 \times 10^{-12} \text{ F}} \\ = \frac{10^6 \Omega}{3520} = 284 \Omega$$

$$X_{\text{total}} = X_{C1} + X_{C2} = 568 \Omega + 284 \Omega = 852 \Omega$$

Alternatively, for series capacitors, the total capacitance is  $6.67 \times 10^{-12} \text{ F}$  or  $6.67 \text{ pF}$ . Then:

$$\begin{aligned} X_{\text{total}} &= \frac{1}{2 \pi f C} \\ &= \frac{1}{2 \times 3.1416 \times 28.0 \times 10^6 \text{ Hz} \times 6.67 \times 10^{-12} \text{ F}} \\ &= \frac{10^6 \Omega}{1170} = 855 \Omega \end{aligned}$$

(Within the uncertainty of the measured values and the rounding of values in the calculations, this is the same result as we obtained with the first method.)

This example serves to remind us that *series capacitance* is not calculated in the manner used by other series resistance and inductance, but *series capacitive reactance* does follow the simple addition formula.

For reactances of the same type in parallel, the general formula is:

$$X_{\text{total}} = \frac{1}{\frac{1}{X_1} + \frac{1}{X_2} + \frac{1}{X_3} + \dots + \frac{1}{X_n}} \quad (56)$$

or, for exactly two reactances in parallel

$$X_{\text{total}} = \frac{X_1 \times X_2}{X_1 + X_2} \quad (57)$$

Example: Place the capacitors in the last example ( $10.0 \text{ pF}$  and  $20.0 \text{ pF}$ ) in parallel in the  $28.0 \text{ MHz}$  circuit. What is the resultant reactance?

$$\begin{aligned} X_{\text{total}} &= \frac{X_1 \times X_2}{X_1 + X_2} \\ &= \frac{568 \Omega \times 284 \Omega}{568 \Omega + 284 \Omega} = 189 \Omega \end{aligned}$$

Alternatively, two capacitors in parallel add their capacitances.

$$\begin{aligned} C_{\text{total}} &= C_1 + C_2 = 10.0 \text{ pF} + 20.0 \text{ pF} \\ &= 30.0 \text{ pF} \end{aligned}$$

$$\begin{aligned} X_C &= \frac{1}{2 \pi f C} \\ &= \frac{1}{2 \times 3.1416 \times 28.0 \times 10^6 \text{ Hz} \times 30.0 \times 10^{-12} \text{ F}} \\ &= \frac{10^6 \Omega}{5280} = 189 \Omega \end{aligned}$$

Example: Place the series inductors above ( $4.0 \mu\text{H}$  each) in parallel in a  $3.8\text{-MHz}$  circuit. What is the resultant reactance?

$$\begin{aligned} X_{\text{total}} &= \frac{X_{L1} \times X_{L2}}{X_{L1} + X_{L2}} \\ &= \frac{96 \Omega \times 96 \Omega}{96 \Omega + 96 \Omega} = 48 \Omega \end{aligned}$$

Of course, equal reactances (or resistances) in parallel yield a reactance that is the value of one of them divided by the number ( $n$ ) of equal reactances, or:

$$X_{\text{total}} = \frac{X}{n} = \frac{96 \Omega}{2} = 48 \Omega$$

All of these calculations apply only to reactances of the same type; that is, all capacitive or all inductive. Mixing types

of reactances requires a different approach.

## UNLIKE REACTANCES IN SERIES

When combining unlike reactances — that is, combinations of inductive and capacitive reactance — in series, it is necessary to take into account that the voltage-to-current phase relationships differ for the different types of reactance. **Fig 6.48** shows a series circuit with both types of reactance. Since the reactances are in series, the current must be the same in both. The voltage across each circuit element differs in phase, however. The voltage  $E_L$  *leads* the current by  $90^\circ$ , and the voltage  $E_C$  *lags* the current by  $90^\circ$ . Therefore,  $E_L$  and  $E_C$  have opposite polarities and cancel each other in whole or in part. The dotted line in Fig 6.48 approximates the resulting voltage  $E$ , which is the *difference* between  $E_L$  and  $E_C$ .

Since, for a constant current, the reactance is directly proportional to the voltage, the net reactance must be the difference between the inductive and the capacitive reactances, or:

$$X_{\text{total}} = X_L - X_C \quad (58)$$

For this and subsequent calculations in which there is a mixture of inductive and capacitive reactance, use the absolute value of each reactance. The convention of recording inductive reactances as positive and capacitive reactances as negative is built into the mathematical operators in the formulas.

Example: Using Fig 6.48 as a visual aid, let  $X_C = 20.0 \Omega$  and  $X_L = 80.0 \Omega$ . What is the resulting reactance?

$$\begin{aligned} X_{\text{total}} &= X_L - X_C = 80.0 \Omega - 20.0 \Omega \\ &= +60.0 \Omega \end{aligned}$$

Since the result is a positive value, reactance is inductive. Had the result been a negative number, the reactance would have been capacitive.

When reactance types are mixed in a series circuit, the resulting reactance is always smaller than the larger of the two reactances. Likewise, the resulting voltage across the series combination of reactances is always smaller than the larger of the two voltages across individual reactances.

Every series circuit of mixed reactance types with more than two circuit elements can be reduced to the type of circuit covered here. If the circuit has more than one capacitor or more than one inductor in the overall series string, first use the formulas given earlier to determine the total series inductance alone and the total series capacitance alone (or their respective reactances).

**Fig 6.48** — A series circuit containing both inductive and capacitive components, together with representative voltage and current relationships.

Then combine the resulting single capacitive reactance and single inductive reactance as shown in this section.

### UNLIKE REACTANCES IN PARALLEL

The situation of parallel reactances of mixed type appears in **Fig 6.49**. Since the elements are in parallel, the voltage is common to both reactive components. The current through the capacitor,  $I_C$ , leads the voltage by  $90^\circ$ , and the current through the inductor,  $I_L$ , lags the voltage by  $90^\circ$ . The two currents are  $180^\circ$  out of phase and thus cancel each other in whole or in part. The total current is the difference between the individual currents, as indicated by the solid, heavy line in **Fig 6.49**.

Since reactance is the ratio of voltage to current, the total reactance in the circuit is:

$$X_{\text{total}} = \frac{E}{I_L - I_C} \quad (59)$$

In the drawing,  $I_C$  is larger than  $I_L$ , and the resulting differential current retains the phase of  $I_C$ . Therefore, the overall reactance,  $X_{\text{total}}$ , is capacitive in this case. The total reactance of the circuit will be larger than the smaller of the individual reactances, because the total current is smaller than the larger of the two individual currents.

In parallel circuits of this type, reactance and current are inversely proportional to each other for a constant voltage. Therefore, to calculate the total reactance directly from the individual reactances, use the formula:

$$X_{\text{total}} = \frac{-X_L \times X_C}{X_L - X_C} \quad (60)$$

As with the series formula for mixed reactances, use the absolute values of the reactances, since the minus signs in the formula take into account the convention of treating capacitive reactances as negative numbers. If the solution yields a negative number, the resulting reactance is capacitive, and if the solution is positive, then the reactance is inductive.

Example: Using **Fig 6.49** as a visual aid, place a capacitive reactance of  $10.0 \Omega$  in parallel with an inductive reactance of  $40.0 \Omega$ . What is the resulting reactance?

$$\begin{aligned} X_{\text{total}} &= \frac{-X_L \times X_C}{X_L - X_C} \\ &= \frac{-40.0 \Omega \times 10.0 \Omega}{40.0 \Omega - 10.0 \Omega} \\ &= \frac{-400.0 \Omega}{30.0} = -13.3 \Omega \end{aligned}$$

**Fig 6.49 — A parallel circuit containing both inductive and capacitive components, together with representative voltage and current relationships.**

The reactance is capacitive, as indicated by the negative solution. Moreover, the resultant reactance is always smaller than the larger of the two individual reactances.

As with the case of series reactances, if each leg of a parallel circuit contains more than one reactance, first simplify each leg to a single reactance. If the reactances are of the same type in each leg, the series reactance formulas for reactances of the same type will apply. If the reactances are of different types, then use the formulas shown above for mixed series reactances to simplify the leg to a single value and type of reactance.

### APPROACHING RESONANCE

When two unlike reactances have the same numerical value, any series or parallel circuit in which they occur is said to be *resonant*. For any given inductance or capacitance, it is theoretically possible to find a value of the opposite reactance type to produce a resonant circuit for any desired frequency.

When a series circuit like the one shown in **Fig 6.48** is resonant, the voltage  $E_C$  and  $E_L$  are equal and cancel; their sum is zero. Since the reactance of the circuit is proportional to the sum of these voltages, the total reactance also goes to zero. Theoretically, the current, as shown in **Fig 6.50**, can rise without limit. In fact, it is limited only by power losses in the components and other resistances that would be in a real circuit

**Fig 6.50 — The relative generator current with a fixed voltage in a series circuit containing inductive and capacitive reactances as the frequency approaches and departs from resonance.**

of this type. As the frequency of operation moves slightly off resonance, the reactance climbs rapidly and then begins to level off. Similarly, the current drops rapidly off resonance and then levels.

In a parallel-resonant circuit of the type in **Fig 6.49**, the current  $I_L$  and  $I_C$  are equal and cancel to zero. Since the reactance is inversely proportional to the current, as the current approaches

**Fig 6.51** — The relative generator current with a fixed voltage in a parallel circuit containing inductive and capacitive reactances as the frequency approaches and departs from resonance. (The circulating current through the parallel inductor and capacitor is a maximum at resonance.)

**Fig 6.52** — The transition from capacitive to inductive reactance in a series-resonant circuit as the frequency passes resonance.

zero, the reactance rises without limit. As with series circuits, component power losses and other resistances in the circuit limit the current drop to some point above zero. **Fig 6.51** shows the theoretical current curve near and at resonance for a purely reactive parallel-resonant circuit. Note that in both **Fig 6.50** and **Fig 6.51**, the departure of current from the resonance value is close to, but not quite, symmetrical above and below the resonant frequency.

Example: What is the reactance of a series L-C circuit consisting of a 56.04-pF capacitor and an 8.967-μH inductor at 7.00, 7.10 and 7.20 MHz? Using the formulas from earlier in this chapter, we calculate a table of values:

**Fig 6.53** — The transition from inductive to capacitive reactance in a parallel-resonant circuit as the frequency passes resonance.

Frequency (MHz)	$X_L (\Omega)$	$X_C (\Omega)$	$X_{total} (\Omega)$
7.000	394.4	405.7	-11.3
7.100	400.0	400.0	0
7.200	405.7	394.4	11.3

The exercise shows the manner in which the reactance rises rapidly as the frequency moves above and below resonance. Note that in a series-resonant circuit, the reactance at frequencies below resonance is capacitive, and above resonance, it is inductive. **Fig 6.52** displays this fact graphically. In a parallel-resonant circuit, where the reactance increases without limit at resonance, the opposite condition exists: above resonance, the reactance is capacitive and below resonance it is inductive, as shown in **Fig 6.53**. Of course, all graphs and calculations in this section are theoretical and presume a purely reactive circuit. Real circuits are never purely reactive; they contain some resistance that modifies their performance considerably. Real resonant circuits will be discussed later in this chapter.

## REACTIVE POWER

Although purely reactive circuits, whether simple or complex, show a measurable ac voltage and current, we cannot simply multiply the two together to arrive at power. Power is the rate at which energy is consumed by a circuit, and purely reactive circuits do not consume power. The charge placed on a capacitor during part of an ac cycle is returned to the circuit during the next part of a cycle. Likewise, the energy stored in the magnetic field of an inductor returns to the circuit as the field collapses later in the ac cycle. A reactive circuit simply cycles and recycles energy into and out of the reactive components. If a purely reactive circuit were possible in reality, it would consume no

power at all.

In reactive circuits, circulation of energy accounts for seemingly odd phenomena. For example, in a series circuit with capacitance and inductance, the voltages across the components may exceed the supply voltage. That condition can exist because, while energy is being stored by the inductor, the capacitor is returning energy to the circuit from its previously charged state, and vice versa. In a parallel circuit with inductive and capacitive branches, the current circulating through the components may exceed the current drawn from the source. Again, the phenomenon occurs because the inductor's collapsing field supplies current to the capacitor, and the discharging capacitor provides current to the inductor.

To distinguish between the nondissipated power in a purely reactive circuit and the dissipated power of a resistive circuit, the unit of reactive power is called the *volt-ampere reactive*, or VAR. The term watt is not used; sometimes reactive power is called wattless power. Formulas similar to those for resistive power are used to calculate VAR:

$$\text{VAR} = I E \quad (61)$$

$$\text{VAR} = I^2 X \quad (62)$$

$$\text{VAR} = \frac{E^2}{X} \quad (63)$$

These formulas have only limited use in radio work.

## REACTANCE AND COMPLEX WAVEFORMS

All of the formulas and relationships shown in this section apply to alternating current in the form of regular sine waves. Complex wave shapes complicate the reactive situation considerably. A complex or nonsinusoidal wave can be resolved into a fundamental frequency and a series of harmonic frequencies whose amplitudes depend on the original wave shape. When such a complex wave — or collection of sine waves — is applied to a reactive circuit, the current through the circuit will not have the same wave shape as the applied voltage. The difference results because the reactance of an inductor and capacitor depend in part on the applied frequency.

For the second-harmonic component of the complex wave, the reactance of the inductor is twice and the reactance of the capacitor is half their respective values at the fundamental frequency. A third-har-

monic component produces inductive reactances that are triple and capacitive reactances that are one-third those at the fundamental frequency. Thus, the overall circuit reactance is different for each harmonic component.

The frequency sensitivity of a reactive circuit to various components of a complex wave shape creates both difficulties and opportunities. On the one hand, calculating the circuit reactance in the presence of highly variable as well as complex waveforms, such as speech, is difficult at best. On the other hand, the frequency sensitivity of reactive components and circuits lays the

foundation for filtering, that is, for separating signals of different frequencies and passing them into different circuits. For example, suppose a coil is in the series path of a signal and a capacitor is connected from the signal line to ground, as represented in **Fig 6.54**. The reactance of the coil to the second harmonic of the signal will be twice that at the fundamental frequency and oppose more effectively the flow of harmonic current. Likewise, the reactance of the capacitor to the harmonic will be half that to the fundamental, allowing the harmonic an easier current path away from the signal line toward ground. See

the **Filters** chapter for detailed information on filter theory and construction.

**Fig 6.54** — A signal path with a series inductor and a shunt capacitor. The circuit presents different reactances to an ac signal and to its harmonics.

# Impedance

When a circuit contains both resistance and reactance, the combined opposition to current is called *impedance*. Symbolized by the letter  $Z$ , impedance is a more general term than either resistance or reactance. Frequently, the term is used even for circuits containing only resistance or reactance. Qualifications such as “resistive impedance” are sometimes added to indicate that a circuit has only resistance, however.

The reactance and resistance comprising an impedance may be connected either in series or in parallel, as shown in **Fig 6.55**. In these circuits, the reactance is shown as a box to indicate that it may be either inductive or capacitive. In the series circuit at A, the current is the same in both elements, with (generally) different voltages appearing across the resistance and reactance. In the parallel circuit at B, the same voltage is applied to both elements, but different currents may flow in the two branches.

In a resistance, the current is in phase with the applied voltage, while in a reactance it is  $90^\circ$  out of phase with the voltage. Thus, the phase relationship between current and voltage in the circuit as a whole may be anything between zero and  $90^\circ$ , depending on the relative amounts of resistance and reactance.

As shown in **Fig 6.47** in the preceding section, reactance is graphed on the vertical (Y) axis to record the phase difference between the voltage and the current. **Fig 6.56** adds resistance to the graph. Since the voltage is in phase with the current, resistance is recorded on the horizontal axis, using the positive or right side of the scale.

## CALCULATING $Z$ FROM $R$ AND $X$ IN SERIES CIRCUITS

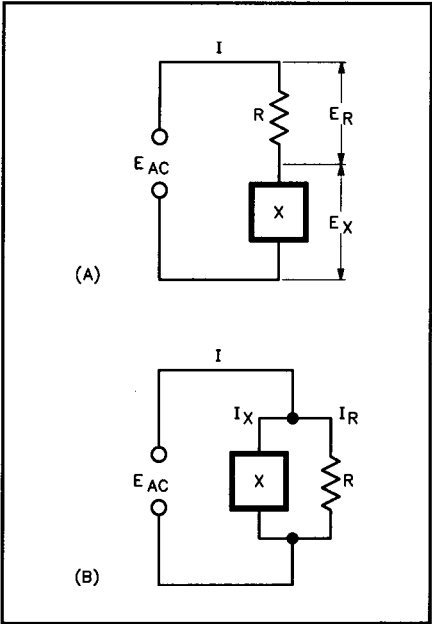

Impedance is the complex combination

of resistance and reactance. Since there is a  $90^\circ$  phase difference between resistance and reactance (whether inductive or capacitive), simply adding the two values will not yield what actually happens in a circuit. Therefore, expressions like “ $Z = R \pm X$ ” can be misleading, because they suggest simple addition. As a result, impedance is often expressed “ $Z = R \pm jX$ .”

In pure mathematics, “ $i$ ” indicates an imaginary number. Because  $i$  represents current in electronics, we use the letter “ $j$ ” for the same mathematical operator, although there is nothing imaginary about what it represents in electronics. With re-

spect to resistance and reactance, the letter  $j$  is normally assigned to those figures on the vertical scale,  $90^\circ$  out of phase with the horizontal scale. The actual function of  $j$  is to indicate that calculating impedance from resistance and reactance requires *vector addition*. In vector addition, the result of combining two values at a  $90^\circ$  phase difference results in a new quantity for the combination, and also in a new combined phase angle relative to the base line.

Consider **Fig 6.57**, a series circuit consisting of an inductive reactance and a resistance. As given, the inductive reactance is  $100. \Omega$  and the resistance is  $50. \Omega$ . Using

**Fig 6.55** — Series and parallel circuits containing resistance and reactance.

**Fig 6.56** — The conventional method of charting impedances on a graph, using the vertical axis for reactance (the upward or “plus” direction for inductive reactance and the downward or “minus” direction for capacitive reactance), and using the horizontal axis for resistance.

**Fig 6.57 — A series circuit consisting of an inductive reactance of 100 Ω and a resistance of 50 Ω. At B, the graph plots the resistance, reactance, and impedance.**

rectangular coordinates, the impedance becomes

$$Z = R + jX \quad (64)$$

where:

$Z$  = the impedance in ohms,  
 $R$  = the resistance in ohms, and  
 $X$  = the reactance in ohms.

In the present example, \*

$$Z = 50. + j100. \Omega$$

As the graph shows, the combined opposition to current (or impedance) is represented by a line triangulating the two given values. The graph will provide an estimate of the value. A more exact way to calculate the resultant impedance involves the formula for right triangles, where the square of the hypotenuse equals the sum of the squares of the two sides. Since impedance is the hypotenuse:

$$Z = \sqrt{R^2 + X^2} \quad (65)$$

In this example:

$$\begin{aligned} Z &= \sqrt{(50. \Omega)^2 + (100. \Omega)^2} \\ &= \sqrt{2500 \Omega^2 + 10000 \Omega^2} \\ &= \sqrt{12500 \Omega^2} = 112 \Omega \end{aligned}$$

**Fig 6.58 — A series circuit consisting of a capacitive reactance and a resistance: the impedance is given as 12.0 Ω ∠-42.0°. At B, the graph plots the resistance, reactance, and impedance.**

The impedance that results from combining 50. Ω of resistance with 100. Ω of inductive reactance is 112 Ω. The phase angle of the resultant is neither 0° nor +90°. Instead, it lies somewhere between the two. Let  $\theta$  be the angle between the horizontal axis and the line representing the impedance. From trigonometry, the tangent of the angle is the side-opposite the angle divided by the side adjacent to the angle, or

$$\tan \theta = \frac{X}{R} \quad (66)$$

where:

$X$  = the reactance, and  
 $R$  = the resistance.

Find the angle by taking the inverse tangent, or arctan:

$$\theta = \arctan \frac{X}{R} \quad (67)$$

In the example shown in Fig 6.57,

$$\theta = \arctan \frac{100. \Omega}{50. \Omega} = \arctan 2.0 = 63.4^\circ$$

Combining the resultant impedance with the angle provides the impedance in polar coordinate form:

$$Z \angle \theta \quad (68)$$

Using the information just calculated, the impedance is:

$$Z = 112 \Omega \angle 63.4^\circ$$

The expressions  $R \pm jX$  and  $Z \angle \theta$  both provide the same information, but in two different forms. The procedure just given permits conversion from rectangular coordinates into polar coordinates. The reverse procedure is also important. Fig 6.58 shows an impedance composed of a capacitive reactance and a resistance. Since capacitive reactance appears as a negative value, the impedance will be at a negative phase angle, in this case, 12.0 Ω at a phase angle of -42.0° or  $Z = 12.0 \Omega \angle -42.0^\circ$ .

Think of the impedance as forming a triangle with the values of  $X$  and  $R$  from the rectangular coordinates. The reactance axis forms the side opposite the angle  $\theta$ .

$$\sin \theta = \frac{\text{side opposite}}{\text{hypotenuse}} = \frac{X}{Y} \quad (69)$$

Solving this equation for reactance, we have:

$$X = Z \times \sin \theta \text{ (ohms)} \quad (70)$$

Likewise, the resistance forms the side adjacent to the angle.

$$\cos \theta = \frac{\text{side adjacent}}{\text{hypotenuse}} = \frac{R}{Z}$$

Solving for resistance, we have:

$$R = Z \times \cos \theta \text{ (ohms)} \quad (71)$$

Then from our example:

$$\begin{aligned} X &= 12.0 \Omega \times \sin (-42.0^\circ) \\ &= 12.0 \Omega \times -0.669 = -8.03 \Omega \end{aligned}$$

$$\begin{aligned} R &= 12.0 \Omega \times \cos (-42.0^\circ) \\ &= 12.0 \Omega \times 0.743 = 8.92 \Omega \end{aligned}$$

Since  $X$  is a negative value, it plots on the lower vertical axis, as shown in Fig 6.58, indicating capacitive reactance. In rectangular form,  $Z = 8.92 \Omega - j8.03 \Omega$ .

In performing impedance and related calculations with complex circuits, rectangular coordinates are most useful when formulas require the addition or subtraction of values. Polar notation is most useful for multiplying and dividing complex numbers. The **Mathematics for Amateur Radio** chapter has information about performing addition, subtraction, multiplication and division with complex numbers.

All of the examples shown so far in this section have presumed values of reactance that contribute to the circuit impedance. Reactance is a function of frequency, however, and many impedance calculations may begin with a value of capacitance or inductance and

an operating frequency. In terms of these values, the series impedance formula (Eq 65) becomes two formulas:

$$Z = \sqrt{R^2 + (2\pi f L)^2} \quad (72)$$

$$Z = \sqrt{R^2 + \left(\frac{1}{2\pi f C}\right)^2} \quad (73)$$

Example: What is the impedance of a circuit like Fig 6.57 with a resistance of  $100. \Omega$  and a  $7.00\text{-}\mu\text{H}$  inductor operating at a frequency of  $7.00 \text{ MHz}$ ? Using equation 72,

$$Z = \sqrt{R^2 + (2\pi f L)^2} \\ = \sqrt{(100. \Omega)^2 + (2\pi \times 7.00 \times 10^{-6} \mu\text{H} \times 7.00 \times 10^6 \text{ Hz})^2}$$

$$Z = \sqrt{10000 \Omega^2 + (308 \Omega)^2} \\ = \sqrt{10000 \Omega^2 + 94900 \Omega^2} \\ = \sqrt{104900 \Omega^2} = 323.9 \Omega$$

Since  $308 \Omega$  is the value of inductive reactance of the  $7.00\text{-}\mu\text{H}$  coil at  $7.00 \text{ MHz}$ , the phase angle calculation proceeds as given in the earlier example (equation 67):

$$\theta = \arctan\left(\frac{X}{R}\right) = \arctan\left(\frac{308 \Omega}{100. \Omega}\right) \\ = \arctan(3.08) = 72.0^\circ$$

Since the reactance is inductive, the phase angle is positive.

### CALCULATING Z FROM R AND X IN PARALLEL CIRCUITS

In a parallel circuit containing reactance and resistance, such as shown in Fig 6.59, calculation of the resultant impedance from the values of  $R$  and  $X$  does not proceed by direct triangulation. The general formula for such parallel circuits is:

$$Z = \frac{RX}{\sqrt{R^2 + X^2}} \quad (74)$$

where the formula uses the absolute (unsigned) reactance value. The phase angle for the parallel circuit is given by:

$$\theta = \arctan\left(\frac{R}{X}\right) \quad (75)$$

If the parallel reactance is capacitive, then  $\theta$  is a negative angle, and if the parallel reactance is inductive, then  $\theta$  is a positive angle.

Example: An inductor with a reactance of  $30.0 \Omega$  is in parallel with a resistor of  $40.0 \Omega$ . What is the resulting impedance and phase angle?

$$Z = \frac{RX}{\sqrt{R^2 + X^2}} = \frac{30.0 \Omega \times 40.0 \Omega}{\sqrt{(30.0 \Omega)^2 + (40.0 \Omega)^2}} \\ = \frac{1200 \Omega^2}{\sqrt{900. \Omega^2 + 1600 \Omega^2}} = \frac{1200 \Omega^2}{\sqrt{2500 \Omega^2}} \\ = \frac{1200 \Omega^2}{50.0 \Omega}$$

$$Z = 24.0 \Omega$$

$$\theta = \arctan\left(\frac{R}{X}\right) = \arctan\left(\frac{40.0 \Omega}{30.0 \Omega}\right) \\ = \arctan(1.33) = 53.1^\circ$$

Since the parallel reactance is inductive, the resultant angle is positive.

Example: A capacitor with a reactance of  $16.0 \Omega$  is in parallel with a resistor of  $12.0 \Omega$ . What is the resulting impedance and phase angle?

$$Z = \frac{RX}{\sqrt{R^2 + X^2}} = \frac{16.0 \Omega \times 12.0 \Omega}{\sqrt{(16.0 \Omega)^2 + (12.0 \Omega)^2}} \\ = \frac{192 \Omega^2}{\sqrt{256 \Omega^2 + 144 \Omega^2}} = \frac{192 \Omega^2}{\sqrt{400. \Omega^2}}$$

$$Z = \frac{192 \Omega^2}{20.0 \Omega} = 9.60 \Omega$$

$$\theta = \arctan\left(\frac{R}{X}\right) = \arctan\left(\frac{12.0 \Omega}{16.0 \Omega}\right)$$

$$\theta = \arctan(0.750) = -36.9^\circ$$

Because the parallel reactance is capacitive, the resultant phase angle is negative.

### ADMITTANCE

Just as the inverse of resistance is conductance ( $G$ ) and the inverse of reactance is susceptance ( $B$ ), so too impedance has an inverse: admittance ( $Y$ ), measured in siemens (S). Thus,

$$Y = \frac{1}{Z} \quad (76)$$

Since resistance, reactance and impedance are inversely proportional to the current ( $Z = E / I$ ), conductance, susceptance and admittance are directly proportional to current. That is,

$$Y = \frac{I}{E} \quad (77)$$

One handy use for admittance is in simplifying parallel circuit impedance calculations. A parallel combination of reactance and resistance reduces to a vector addition of susceptance and conductance, if admittance is the desired outcome. In other words, for parallel circuits:

$$Y = \sqrt{G^2 + B^2} \quad (78)$$

where:

$Y$  = admittance,

Fig 6.59 — A parallel circuit containing an inductive reactance of  $30.0 \Omega$  and a resistor of  $40.0 \Omega$ . No graph is given, since parallel impedances do not triangulate in the simple way of series impedances.

$G$  = conductance or  $1 / R$ , and  
 $B$  = susceptance or  $1 / X$ .

Example: An inductor with a reactance of  $30.0 \Omega$  is in parallel with a resistor of  $40.0 \Omega$ . What is the resulting impedance and phase angle? The susceptance is  $1 / 30.0 \Omega = 0.0333 \text{ S}$  and the conductance is  $1 / 40.0 \Omega = 0.0250 \text{ S}$ .

$$Y = \sqrt{(0.0333 \text{ S})^2 + (0.0250 \text{ S})^2} \\ = \sqrt{0.00173 \text{ S}^2} = 0.0417 \text{ S}$$

$$Z = \frac{1}{Y} = \frac{1}{0.0417 \text{ S}} = 24.0 \Omega$$

The phase angle in terms of conductance and susceptance is:

$$\theta = \arctan\left(\frac{B}{G}\right) \quad (79)$$

In this example,

$$\theta = \arctan\left(\frac{0.0333 \text{ S}}{0.0250 \text{ S}}\right) = \arctan(1.33) = 53.1^\circ$$

Again, since the reactive component is inductive, the phase angle is positive. For a capacitively reactive parallel circuit, the phase angle would have been negative. Compare these results with the direct calculation earlier in the section.

Conversion from resistance, reactance and impedance to conductance, susceptance and admittance is perhaps most useful in complex-parallel-circuit calculations. Many advanced facets of active-circuit analysis will demand familiarity both with the concepts and with the calculation strategies introduced here, however.

### More than Two Elements in Series or Parallel

When a circuit contains several resistances or several reactances in series, simplify the circuit before attempting to calculate the impedance. Resistances in

series add, just as in a purely resistive circuit. Series reactances of the same kind — that is, all capacitive or all inductive — also add, just as in a purely reactive circuit. The goal is to produce a single value of resistance and a single value of reactance for the impedance calculation.

**Fig 6.60** illustrates a more difficult case in which a circuit contains two different reactive elements in series, along with a further series resistance. The series combination of  $X_C$  and  $X_L$  reduce to a single value using the same rules of combination discussed in the section on purely reactive components. As Fig 6.60B demonstrates,

**Fig 6.60 — A series impedance containing mixed capacitive and inductive reactances can be reduced to a single reactance plus resistance by combining the reactances algebraically.**

**Fig 6.61 — A parallel impedance containing mixed capacitive and inductive reactances can be reduced to a single reactance plus resistance using formulas shown earlier in the chapter. By converting reactances to susceptances, as shown in A, you can combine the susceptances algebraically into a single susceptance, as shown in B.**

the resultant reactance is the difference between the two series reactances.

For parallel circuits with multiple resistances or multiple reactances of the same type, use the rules of parallel combination to reduce the resistive and reactive components to single elements. Where two or more reactive components of different types appear in the same circuit, they can be combined using formulas shown earlier for pure reactances. As **Fig 6.61** suggests, however, they can also be combined as susceptances. Parallel susceptances of different types add, with attention to their differing signs. The resulting single susceptance can then be combined with the conductance to arrive at the overall circuit admittance. The inverse of the admittance is the final circuit impedance.

### Equivalent Series and Parallel Circuits

The two circuits shown in Fig 6.55 are equivalent if the same current flows when a given voltage of the same frequency is applied, and if the phase angle between voltage and current is the same in both cases. It is possible, in fact, to transform any given series circuit into an equivalent parallel circuit, and vice versa.

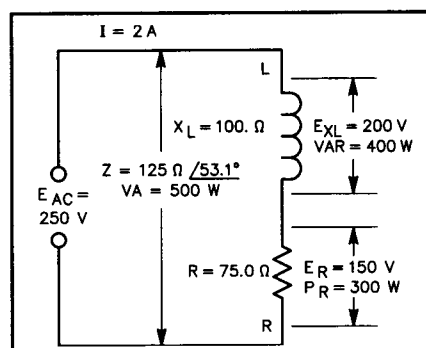

A series RX circuit can be converted into its parallel equivalent by means of the formulas:

$$R_P = \frac{R_S^2 + X_S^2}{R_S} \quad (80)$$

$$X_P = \frac{R_S^2 + X_S^2}{X_S} \quad (81)$$

where the subscripts P and S represent the parallel- and series-equivalent values, respectively. If the parallel values are known, the equivalent series circuit can be found from:

$$R_S = \frac{R_P X_P^2}{R_P^2 + X_P^2} \quad (82)$$

**Fig 6.62 — A series circuit consisting of an inductive reactance of 100. Ω and a resistance of 75.0 Ω. Also shown is the applied voltage, voltage drops across the circuit elements, and the current.**

and

$$X_S = \frac{R_P^2 X_P}{R_P^2 + X_P^2} \quad (83)$$

Example: Let the series circuit in Fig 6.55 have a series reactance of  $-50.0 \Omega$  (indicating a capacitive reactance) and a resistance of  $50.0 \Omega$ . What are the values of the equivalent parallel circuit?

$$R_P = \frac{R_S^2 + X_S^2}{R_S} = \frac{(50.0 \Omega)^2 + (-50.0 \Omega)^2}{50.0 \Omega} \\ = \frac{2500 \Omega^2 + 2500 \Omega^2}{50.0 \Omega} = \frac{5000 \Omega^2}{50.0 \Omega} = 100. \Omega$$

$$X_P = \frac{R_S^2 + X_S^2}{X_S} = \frac{(50.0 \Omega)^2 + (-50.0 \Omega)^2}{-50.0 \Omega} \\ = \frac{2500 \Omega^2 + 2500 \Omega^2}{-50.0 \Omega} = \frac{5000 \Omega^2}{-50.0 \Omega} = -100. \Omega$$

The parallel circuit in Fig 6.55 calls for a capacitive reactance of  $100. \Omega$  and a resistance of  $100. \Omega$  to be equivalent to the series circuit.

### OHM'S LAW FOR IMPEDANCE

Ohm's Law applies to circuits containing impedance just as readily as to circuits having resistance or reactance only. The formulas are:

$$E = I Z \quad (84)$$

$$I = \frac{E}{Z} \quad (85)$$

$$Z = \frac{E}{I} \quad (86)$$

where:

$E$  = voltage in volts,  
 $I$  = current in amperes, and  
 $Z$  = impedance in ohms.

**Fig 6.62** shows a simple circuit consisting of a resistance of  $75.0 \Omega$  and a reactance of  $100. \Omega$  in series. From the series-impedance formula previously given, the impedance is

$$Z = \sqrt{R^2 + X_L^2} = \sqrt{(75.0 \Omega)^2 + (100. \Omega)^2} \\ = \sqrt{5630 \Omega^2 + 10000 \Omega^2} = \sqrt{15600 \Omega^2} \\ = 125 \Omega$$

If the applied voltage is 250. V, then

$$I = \frac{E}{Z} = \frac{250. \text{ V}}{125 \Omega} = 2.00 \text{ A}$$

This current flows through both the resistance and reactance, so the voltage drops are:

$$E_R = I R = 2.00 \text{ A} \times 75.0 \Omega = 150. \text{ V}$$

$$E_{XL} = I X_L = 2.00 \text{ A} \times 100. \Omega = 200. \text{ V}$$

The simple arithmetical sum of these two drops, 350. V, is greater than the applied voltage because the two voltages are 90° out of phase. Their actual resultant, when phase is taken into account, is:

$$\begin{aligned} E &= \sqrt{(150. \text{ V})^2 + (200. \text{ V})^2} \\ &= \sqrt{22500 \text{ V}^2 + 40000 \text{ V}^2} = \sqrt{62500 \text{ V}^2} \\ &= 250. \text{ V} \end{aligned}$$

## POWER FACTOR

In the circuit of Fig 6.62, an applied voltage of 250. V results in a current of 2.00 A, giving an apparent power of 250. V × 2.00 A = 500. W. Only the resistance actually consumes power, however. The power in the resistance is:

$$P = I^2 R = (2.00 \text{ A})^2 \times 75.0 \Omega = 300. \text{ W}$$

The ratio of the consumed power to the apparent power is called the power factor

of the circuit.

$$PF = \frac{P_{\text{consumed}}}{P_{\text{apparent}}} = \frac{R}{Z} \quad (87)$$

In this example the power factor would be 300. W / 500. W = 0.600. Power factor is frequently expressed as a percentage; in this case, 60%. An equivalent definition of power factor is:

$$PF = \cos \theta$$

Where  $\theta$  is the phase angle. Since the phase angle equals:

$$\theta = \arctan \left( \frac{X}{R} \right) = \arctan \left( \frac{100. \Omega}{75.0 \Omega} \right)$$

$$= \arctan (1.33) = 53.1^\circ$$

Then the power factor is:

$$PF = \cos 53.1^\circ = 0.600$$

as the earlier calculation confirms.

Real, or dissipated, power is measured in watts. Apparent power, to distinguish it from real power, is measured in volt-

amperes (VA). It is simply the product of the voltage across and the current through an overall impedance. It has no direct relationship to the power actually dissipated unless the power factor of the circuit is known. The power factor of a purely resistive circuit is 100% or 1, while the power factor of a pure reactance is zero. In this illustration, the reactive power is:

$$\begin{aligned} VAR &= I^2 X_L = (2.00 \text{ A})^2 \times 100. \Omega \\ &= 400. \text{ VA} \end{aligned}$$

Since power factor is always rendered as a positive number, the value must be followed by the words "leading" or "lagging" to identify the phase of the voltage with respect to the current. Specifying the numerical power factor is not always sufficient. For example, many dc-to-ac power inverters can safely operate loads having a large net reactance of one sign but only a small reactance of the opposite sign. Hence, the final calculation of the power factor in this example yields the value 0.600, leading.

# Resonant Circuits

A circuit containing both an inductor and a capacitor — and therefore, both inductive and capacitive reactance — is often called a *tuned circuit*. There is a particular frequency at which the inductive and capacitive reactances are the same, that is,  $X_L = X_C$ . For most purposes, this is the *resonant frequency* of the circuit. (Special considerations apply to parallel circuits; they will emerge in the section devoted to such circuits.) At the resonant frequency — or at resonance, for short:

$$X_L = 2 \pi f L = X_C = \frac{1}{2 \pi f C}$$

By solving for  $f$ , we can find the resonant frequency of any combination of inductor and capacitor from the formula:

$$f = \frac{1}{2 \pi \sqrt{LC}} \quad (88)$$

where:

$f$  = frequency in hertz (Hz),  
 $L$  = inductance in henrys (H),  
 $C$  = capacitance in farads (F), and  
 $\pi = 3.1416$ .

For most high-frequency (HF) radio work, smaller units of inductance and capacitance and larger units of frequency are more convenient. The basic formula becomes:

$$f = \frac{10^3}{2 \pi \sqrt{LC}} \quad (89)$$

where:

$f$  = frequency in megahertz (MHz),  
 $L$  = inductance in microhenrys ( $\mu\text{H}$ ),  
 $C$  = capacitance in picofarads (pF), and  
 $\pi = 3.1416$ .

Example: What is the resonant frequency of a circuit containing an inductor of 5.0  $\mu\text{H}$  and a capacitor of 35 pF?

$$\begin{aligned} f &= \frac{10^3}{2 \pi \sqrt{LC}} = \frac{10^3}{6.2832 \times \sqrt{5.0 \times 35}} \\ &= \frac{10^3}{83} = 12 \text{ MHz} \end{aligned}$$

To find the matching component (inductor or capacitor) when the frequency and one component is known (capacitor or inductor) for general HF work, use the formula:

$$f^2 = \frac{1}{4 \pi^2 LC} \quad (90)$$

where  $F$ ,  $L$  and  $C$  are in basic units. For HF work in terms of MHz,  $\mu\text{H}$  and pF, the basic relationship rearranges to these handy formulas:

$$L = \frac{25330}{f^2 C} \quad (91)$$

$$C = \frac{25330}{f^2 L} \quad (92)$$

where:

$f$  = frequency in MHz,  
 $L$  = inductance in  $\mu\text{H}$ , and  
 $C$  = capacitance in pF.

Example: What value of capacitance is needed to create a resonant circuit at 21.1 MHz, if the inductor is 2.00  $\mu\text{H}$ ?

$$\begin{aligned} C &= \frac{25330}{f^2 L} = \frac{25330}{(21.1^2 \times 2.00)} \\ &= \frac{25330}{890} = 28.5 \text{ pF} \end{aligned}$$

For most radio work, these formulas will permit calculations of frequency and component values well within the limits of component tolerances. Resonant circuits have other properties of importance, in addition to the resonant frequency, however. These include impedance, voltage drop across components in series-resonant circuits, circulating current in parallel-resonant circuits, and bandwidth. These properties determine such factors as the selectivity of a tuned circuit and the component ratings for circuits handling considerable power. Although the basic determination of the tuned-circuit resonant frequency ignored any resistance in the

circuit, that resistance will play a vital role in the circuit's other characteristics.

## SERIES-RESONANT CIRCUITS

Fig 6.63 presents a basic schematic diagram of a *series-resonant circuit*. Although most schematic diagrams of radio circuits would show only the inductor and the capacitor, resistance is always present in such circuits. The most notable resistance is associated with losses in the inductor at HF; resistive losses in the capacitor are low enough at those frequencies to be ignored. The current meter shown in the circuit is a reminder that in series circuits, the same current flows through all elements.

At resonance, the reactance of the capacitor cancels the reactance of the inductor. The voltage and current are in phase with each other, and the impedance of the circuit is determined solely by the resistance. The actual current through the circuit at resonance, and for frequencies near resonance, is determined by the formula:

$$I = \frac{E}{Z} = \frac{E}{\sqrt{R^2 + \left[ 2\pi f L - \frac{1}{(2\pi f C)} \right]^2}} \quad (93)$$

where all values are in basic units.

At resonance, the reactive factor in the formula is zero. As the frequency is shifted above or below the resonant frequency without altering component values, however, the reactive factor becomes significant, and the value of the current becomes smaller than at resonance. At frequencies far from resonance, the reactive components become dominant, and the resistance no longer significantly affects the current amplitude.

The exact curve created by recording the current as the frequency changes depends on the ratio of reactance to resistance. When the reactance of either the coil or capacitor is of the same order of magnitude as the resistance, the current decreases rather slowly as the frequency is moved in either direction away from resonance. Such a curve is said to be *broad*. Conversely, when the reactance is considerably larger than the resistance, the current decreases rapidly as the frequency moves away from resonance, and the circuit is said to be *sharp*. A sharp circuit will respond a great deal more readily to the resonant frequency than to frequencies quite close to resonance; a broad circuit will respond almost equally well to a group or band of frequencies centered around the resonant frequency.

Both types of resonance curves are useful. A sharp circuit gives good selectivity — the ability to respond strongly (in terms of current amplitude) at one desired frequency and to discriminate against others. A broad circuit is used when the apparatus must give

Fig 6.63 — A series circuit containing L, C, and R is resonant at the applied frequency when the reactance of C is equal to the reactance of L. The I in the circle is the schematic symbol for an ammeter.

about the same response over a band of frequencies, rather than at a single frequency alone.

Fig 6.64 presents a family of curves, showing the decrease in current as the frequency deviates from resonance. In each case, the reactance is assumed to be 1000 Ω. The maximum current, shown as a relative value on the graph, occurs with the lowest resistance, while the lowest peak current occurs with the highest resistance. Equally important, the rate at which the current decreases from its maximum value also changes with the ratio of reactance to resistance. It decreases most rapidly when the ratio is high and most slowly when the ratio is low.

### Q

As noted in earlier sections of this chapter, the ratio of reactance or stored energy to resistance or consumed energy is Q. Since both terms of the ratio are measured in ohms, Q has no units and is variously known as the *quality factor*, the *figure of merit* or the *multiplying factor*. Since the resistive losses of the coil dominate the energy consumption in HF series-resonant circuits, the inductor Q largely determines the resonant-circuit Q. Since this value of Q is independent of any external load to which the circuit might transfer power, it is called the *unloaded Q* or  $Q_U$  of the circuit.

Example: What is the unloaded Q of a series-resonant circuit with a loss resistance of 5 Ω and inductive and capacitive components having a reactance of 500 Ω each? With a reactance of 50 Ω each?

$$Q_{U1} = \frac{X_L}{R} = \frac{500 \Omega}{5 \Omega} = 100$$

$$Q_{U2} = \frac{X_L}{R} = \frac{50 \Omega}{5 \Omega} = 10$$

Fig 6.64 — Current in series-resonant circuits with various values of series resistance and Q. The current values are relative to an arbitrary maximum of 1.0. The reactance for all curves is 1000 Ω. Note that the current is hardly affected by the resistance in the circuit at frequencies more than 10% away from the resonant frequency.

Fig 6.65 — Current in series-resonant circuits having different values of  $Q_U$ . The current at resonance is set at the same level for all curves in order to show the rate of change of decrease in current for each value of  $Q_U$ . The half-power points are shown to indicate relative bandwidth of the response for each curve. The bandwidth is indicated for a circuit with a  $Q_U$  of 10.

### Bandwidth

Fig 6.65 is an alternative way of drawing the family of curves that relate current to frequency for a series-resonant circuit. By assuming that the peak current of each curve

**Table 6.6****The Selectivity of Resonant Circuits**

Approximate percentage of current at resonance <sup>1</sup> or of impedance at resonance <sup>2</sup>	Bandwidth (between half-power or -3 dB points on response curve)	Series circuit current phase angle (degrees)
95	$f / 3Q$	18.5
90	$f / 2Q$	26.5
70.7	$f / Q$	45
44.7	$2f / Q$	63.5
24.2	$4f / Q$	76
12.4	$8f / Q$	83

<sup>1</sup>For a series resonant circuit<sup>2</sup>For a parallel resonant circuit(Reference: F. E. Terman, *Radio Engineers' Handbook*, Table 1, p 138, modified.)

is the same, the rate of change of current for various values of  $Q_U$  and the associated ratios of reactance to resistance are more easily compared. From the curves, it is evident that the lower  $Q_U$  circuits pass frequencies over a greater *bandwidth* of frequencies than the circuits with a higher  $Q_U$ . For the purpose of comparing tuned circuits, bandwidth is often defined as the frequency spread between the two frequencies at which the current amplitude decreases to 0.707 (or  $1/\sqrt{2}$ ) times the maximum value. Since the power consumed by the resistance,  $R$ , is proportional to the square of the current, the power at these points is half the maximum power at resonance, assuming that  $R$  is constant for the calculations. The half-power, or -3 dB, points are marked on Fig 6.65.

For  $Q$  values of 10 or greater, the curves shown in Fig 6.65 are approximately symmetrical. On this assumption, bandwidth (BW) can be easily calculated:

$$BW = \frac{f}{Q_U} \quad (94)$$

where BW and  $f$  are in the same units, that is, in Hz, kHz or MHz.

Example: What is the bandwidth of a series-resonant circuit operating at 14 MHz with a  $Q_U$  of 100?

$$BW = \frac{f}{Q_U} = \frac{14 \text{ MHz}}{100} = 0.14 \text{ MHz} = 140 \text{ kHz}$$

The relationship between  $Q_U$ ,  $f$  and BW provides a means of determining the value of circuit  $Q$  when inductor losses may be difficult to measure. By constructing the series-resonant circuit and measuring the current as the frequency varies above and below resonance, the half-power points can be determined. Then:

$$Q_U = \frac{f}{BW} \quad (95)$$

Example: What is the  $Q_U$  of a series-resonant circuit operating at 3.75 MHz, if

the bandwidth is 375 kHz?

$$Q_U = \frac{f}{BW} = \frac{3.75 \text{ MHz}}{0.375 \text{ MHz}} = 10.0$$

**Table 6.6** provides some simple formulas for estimating the maximum current and phase angle for various bandwidths, if both  $f$  and  $Q_U$  are known.

**Voltage Drop Across Components**

The voltage drop across the coil and across the capacitor in a series-resonant circuit are each proportional to the reactance of the component for a given current (since  $E = IX$ ). These voltages may be many times the source voltage for a high- $Q$  circuit. In fact, at resonance, the voltage drop is:

$$E_X = Q_U E \quad (96)$$

where:

$E_X$  = the voltage across the reactive component,

$Q_U$  = the circuit unloaded  $Q$ , and

$E$  = the source voltage.

(Note that the voltage drop across the inductor is the vector sum of the voltages across the resistance and the reactance; however, for  $Q$ s greater than 10, the error created by using equation 96 is not ordinarily significant.) Since the calculated value of  $E_X$  is the RMS voltage, the peak voltage will be higher by a factor of 1.414. Antenna couplers and other high- $Q$  circuits handling significant power may experience arcing from high values of  $E_X$ , even though the source voltage to the circuit is well within component ratings.

**Capacitor Losses**

Although capacitor energy losses tend to be insignificant compared to inductor losses up to about 30 MHz, the losses may affect circuit  $Q$  in the VHF range. Leakage resistance, principally in the solid dielectric that forms the insulating support for the capacitor plates, is not exactly like the wire resis-

tance losses in a coil. Instead of forming a series resistance, capacitor leakage usually forms a parallel resistance with the capacitive reactance. If the leakage resistance of a capacitor is significant enough to affect the  $Q$  of a series-resonant circuit, the parallel resistance must be converted to an equivalent series resistance before adding it to the inductor's resistance.

$$R_S = \frac{X_C^2}{R_p} = \frac{1}{R_p \times (2\pi f C)^2} \quad (97)$$

Example: A 10.0 pF capacitor has a leakage resistance of 10000  $\Omega$  at 50.0 MHz. What is the equivalent series resistance?

$$\begin{aligned} R_S &= \frac{1}{R_p \times (2\pi f C)^2} \\ &= \frac{1}{1.00 \times 10^4 \times (6.283 \times 50.0 \times 10^6 \times 10.0 \times 10^{-12})^2} \\ R_S &= \frac{1}{1.00 \times 10^4 \times 9.87 \times 10^{-6}} \\ &= \frac{1}{0.0987} = 10.1 \Omega \end{aligned}$$

In calculating the impedance, current and bandwidth for a series-resonant circuit in which this capacitor might be used, the series-equivalent resistance of the unit is added to the loss resistance of the coil. Since inductor losses tend to increase with frequency because of skin effect, the combined losses in the capacitor and the inductor can seriously reduce circuit  $Q$ , without special component- and circuit-construction techniques.

**PARALLEL-RESONANT CIRCUITS**

Although series-resonant circuits are common, the vast majority of resonant circuits used in radio work are *parallel-resonant circuits*. Fig 6.66 represents a typical HF parallel-resonant circuit. As is

**Fig 6.66 — A typical parallel-resonant circuit, with the resistance shown in series with the inductive leg of the circuit. Below a  $Q_U$  of 10, resonance definitions may lead to three separate frequencies which converge at higher  $Q_U$  levels. See text.**

the case for series-resonant circuits, the inductor is the chief source of resistive losses, and these losses appear in series with the coil. Because current through parallel-resonant circuits is lowest at resonance, and impedance is highest, they are sometimes called *antiresonant* circuits. Likewise, the names *acceptor* and *rejector* are occasionally applied to series- and parallel-resonant circuits, respectively.

Because the conditions in the two legs of the parallel circuit in Fig 6.66 are not the same — the resistance is in only one of the legs — all of the conditions by which series resonance is determined do not occur simultaneously in a parallel-resonant circuit. Fig 6.67 graphically illustrates the situation by showing the currents through the two components. When the inductive and capacitive reactances are identical, the condition defined for series resonance is met as shown in line (a). The impedance of the inductive leg is composed of both  $X_L$  and  $R$ , which yields an impedance that is greater than  $X_C$  and that is not  $180^\circ$  out of phase with  $X_C$ . The resultant current is greater than its minimum possible value and not in phase with the voltage.

By altering the value of the inductor slightly (and holding the  $Q$  constant), a new frequency can be obtained at which the current reaches its minimum. When parallel circuits are tuned using a current meter as an indicator, this point (b) is ordinarily used as an indication of resonance. The current “dip” indicates a condition of maximum impedance and is sometimes called the *antiresonant* point or *maximum impedance resonance* to distinguish it from the condition where  $X_C = X_L$ . Maximum impedance is achieved by vector addition of  $X_C$ ,  $X_L$  and  $R$ , however, and the result is a current somewhat out of phase with the voltage.

Point (c) on the curve represents the *unity-power-factor* resonant point. Adjusting the inductor value and hence its reactance (while holding  $Q$  constant) produces a new resonant frequency at which the resultant current is in phase with the voltage. The inductor’s new value of reactance is the value required for a parallel-equivalent inductor and its parallel-equivalent resistor (calculated according to the formulas in the last section) to just cancel the capacitive reactance. The value of the parallel-equivalent inductor is always smaller than the actual inductor in series with the resistor and has a proportionally smaller reactance. (The parallel-equivalent resistor, conversely, will always be larger than the coil-loss resistor shown in series with the inductor.) The result is a resonant frequency slightly different from the one for minimum current

Fig 6.67 — Resonant conditions for a low- $Q$  parallel circuit. Resonance may be defined as (a)  $X_L = X_C$ , (b) minimum current flow and maximum impedance or (c) voltage and current in phase with each other. With the circuit of Fig 6.66 and a  $Q$  of less than 10, these three definitions may represent three distinct frequencies.

and the one for  $X_L = X_C$ .

The points shown in the graph in Fig 6.67 represent only one of many possible situations, and the relative positions of the three resonant points do not hold for all possible cases. Moreover, specific circuit designs can draw some of the resonant points together, for example, compensating for the resistance of the coil by retuning the capacitor. The differences among these resonances are significant for circuit  $Q$ s below 10, where the inductor’s series resistance is a significant percentage of the reactance. Above a  $Q$  of 10, the three points converge to within a percent of the frequency and can be ignored for practical calculations. Tuning for minimum current will not introduce a sufficiently large phase angle between voltage and current to create circuit difficulties.

### Parallel Circuits of Moderate to High $Q$

The resonant frequencies defined above converge in parallel-resonant circuits with  $Q$ s higher than about 10. Therefore, a single set of formulas will sufficiently approximate circuit performance for accurate predictions. Indeed, above a  $Q$  of 10, the performance of a parallel circuit appears in many ways to be simply the inverse of the performance of a series-

Fig 6.68 — Series and parallel equivalents when both circuits are resonant. The series resistance,  $R_S$  in A, is replaced by the parallel resistance,  $R_P$  in B, and vice versa.  $R_P = X_L^2 / R_S$ .

resonant circuit using the same components.

Accurate analysis of a parallel-resonant circuit requires the substitution of a parallel-equivalent resistor for the actual inductor-loss series resistor, as shown in Fig 6.68. Sometimes called the *dynamic resistance* of the parallel-resonant circuit, the parallel-equivalent resistor value will

increase with circuit  $Q$ , that is, as the series resistance value decreases. To calculate the approximate parallel-equivalent resistance, use the formula:

$$R_p = \frac{X_L^2}{R_s} = \frac{(2\pi f L)^2}{R_s} = Q_U X_L \quad (98)$$

Example: What is the parallel-equivalent resistance for a coil with an inductive reactance of  $350\ \Omega$  and a series resistance of  $5.0\ \Omega$  at resonance?

$$\begin{aligned} R_p &= \frac{X_L^2}{R_s} = \frac{(350\ \Omega)^2}{5.0\ \Omega} \\ &= \frac{120000\ \Omega^2}{5.0\ \Omega} = 24000\ \Omega \end{aligned}$$

Since the coil  $Q_U$  remains the inductor's reactance divided by its series resistance, the coil  $Q_U$  is 70. Multiplying  $Q_U$  by the reactance also provides the approximate parallel-equivalent resistance of the coil series resistance.

At resonance, where  $X_L = X_C$ ,  $R_p$  defines the impedance of the parallel-resonant circuit. The reactances just equal each other, leaving the voltage and current in phase with each other. In other words, the circuit shows only the parallel resistance. Therefore, equation 98

can be rewritten as:

$$Z = \frac{X_L^2}{R_s} = \frac{(2\pi f L)^2}{R_s} = Q_U X_L \quad (99)$$

In this example, the circuit impedance at resonance is  $24000\ \Omega$ .

At frequencies below resonance the current through the inductor is larger than that through the capacitor, because the reactance of the coil is smaller and that of the capacitor is larger than at resonance. There is only partial cancellation of the two reactive currents, and the line current therefore is larger than the current taken by the resistance alone. At frequencies above resonance the situation is reversed and more current flows through the capacitor than through the inductor, so the line current again increases. The current at resonance, being determined wholly by  $R_p$ , will be small if  $R_p$  is large, and large if  $R_p$  is small. Fig 6.69 illustrates the relative current flows through a parallel-tuned circuit as the frequency is moved from below resonance to above resonance. The base line represents the minimum current level for the particular circuit. The actual current at any frequency off resonance is simply the vector sum of the currents through the parallel equivalent resistance and

through the reactive components.

To obtain the impedance of a parallel-tuned circuit either at or off the resonant frequency, apply the general formula:

$$Z = \frac{Z_C Z_L}{Z_s} \quad (100)$$

where:

$Z$  = overall circuit impedance

$Z_C$  = impedance of the capacitive leg (usually, the reactance of the capacitor),

$Z_L$  = impedance of the inductive leg (the vector sum of the coil's reactance and resistance), and

$Z_s$  = series impedance of the capacitor-inductor combination as derived from the denominator of equation 93.

After using vector calculations to obtain  $Z_L$  and  $Z_s$ , converting all the values to polar form — as described earlier in this chapter — will ease the final calculation. Of course, each impedance may be derived from the resistance and the application of the basic reactance formulas on the values of the inductor and capacitor at the frequency of interest.

Since the current rises off resonance, the parallel-resonant-circuit impedance must fall. It also becomes complex, resulting in an ever greater phase difference between the voltage and the current. The rate at which the impedance falls is a function of  $Q_U$ . Fig 6.70 presents a family of curves showing the impedance drop from resonance for circuit  $Q_s$  ranging from 10 to 100. The curve family for parallel-circuit

Fig 6.69 — The currents in a parallel-resonant circuit as the frequency moves through resonance. Below resonance, the current lags the voltage; above resonance the current leads the voltage. The base line represents the current level at resonance, which depends on the impedance of the circuit at that frequency.

Fig 6.70 — Relative impedance of parallel-resonant circuits with different values of  $Q_U$ . The curves are similar to the series-resonant circuit current level curves of Fig 6.64. The effect of  $Q_U$  on impedance is most pronounced within 10% of the resonance frequency.

impedance is essentially the same as the curve family for series-circuit current.

As with series tuned circuits, the higher the  $Q$  of a parallel-tuned circuit, the sharper the response peak. Likewise, the lower the  $Q$ , the wider the band of frequencies to which the circuit responds. Using the half-power ( $-3$  dB) points as a comparative measure of circuit performance, equations 94 and 95 apply equally to parallel-tuned circuits. That is,  $BW = f / Q_U$  and  $Q_U = f / BW$ , where the resonant frequency and the bandwidth are in the same units. As a handy reminder, **Table 6.7** summarizes the performance of parallel-resonant circuits at high and low  $Q$ s and above and below resonant frequency.

It is possible to use either series or parallel-resonant circuits do the same work in many circuits, thus giving the designer considerable flexibility. **Fig 6.71** illustrates this general principle by showing a series-resonant circuit in the signal path and a parallel-resonant circuit shunted from the signal path to ground. Assume both circuits are resonant at the same frequency,  $f$ , and have the same  $Q$ . The series tuned circuit at A has its lowest impedance at  $f$ , permitting the maximum possible current to flow along the signal path. At all other frequencies, the impedance is greater and the current at those frequencies is less. The circuit passes the desired signal and tends to impede signals at undesired frequencies. The parallel circuit at B provides the highest impedance at resonance,  $f$ , making the signal path the lowest impedance path for the signal. At frequencies off resonance, the parallel-resonant circuit presents a lower impedance, thus presenting signals with a path to ground and away from the signal path. In theory, the effects will be the same relative to a signal current on the signal path. In actual circuit design exercises, of course, many other variables will enter the design picture to make one circuit preferable to the other.

### Circulating Current

In a parallel-resonant circuit, the source voltage is the same for all the circuit elements. The current in each element, however, is a function of the element's reactance. **Fig 6.72** redraws the parallel-tuned circuit to indicate the line current and the current circulating between the coil and the capacitor. The current drawn from the source may be low, because the overall circuit impedance is high. The current through the individual elements may be high, how-

**Table 6.7**

### The Performance of Parallel-Resonant Circuits

#### A. High and Low $Q$ Circuits (in relative terms)

Characteristic	High $Q$ Circuit	Low $Q$ Circuit
Selectivity	high	low
Bandwidth	narrow	wide
Impedance	high	low
Line current	low	high
Circulating current	high	low

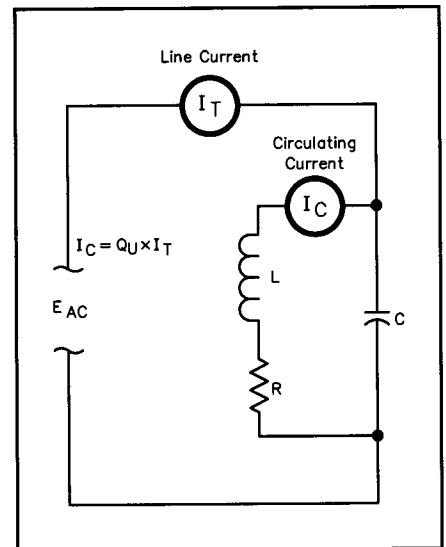

#### B. Off-Resonance Performance for Constant Values of Inductance and Capacitance

Characteristic	Above Resonance	Below Resonance
Inductive reactance	increases	decreases
Capacitive reactance	decreases	increases
Circuit resistance	unchanged*	unchanged*
Circuit impedance	decreases	decreases
Line current	increases	increases
Circulating current	decreases	decreases
Circuit behavior	capacitive	inductive

\*This is true for frequencies near resonance. At distant frequencies, skin effect may alter the resistive losses of the inductor.  
(Reference: A. Shure, ed., *Resonant Circuits*, pp 63-64, modified.)

**Fig 6.71 — Series- and parallel-resonant circuits configured to perform the same theoretical task: passing signals in a narrow band of frequencies along the signal path. A real design example would consider many other factors.**

**Fig 6.72 — A parallel-resonant circuit redrawn to illustrate both the line current and the circulating current.**

ever, because there is little resistive loss as the current circulates through the inductor and capacitor. For parallel-resonant circuits with an unloaded  $Q$  of 10 or greater, this *circulating current* is approximately:

$$I_C = Q_U I_T \quad (101)$$

where:

$I_C$  = circulating current in A, mA or A,  
 $Q_U$  = unloaded circuit  $Q$ , and  
 $I_T$  = line current in the same units as  $I_C$ .

Example: A parallel-resonant circuit permits an ac or RF line current of 30 mA and has a  $Q$  of 100. What is the circulating current through the elements?

$$I_X = Q_U I = 100 \times 30 \text{ mA} = 3000 \text{ mA} = 3 \text{ A}$$

Circulating currents in high- $Q$  parallel-tuned circuits can reach a level that causes component heating and power loss. Therefore, components should be rated for the anticipated circulating currents, and not just the line current.

## The Q of Loaded Circuits

In many resonant-circuit applications, the only power lost is that dissipated in the resistance of the circuit itself. At frequencies below 30 MHz, most of this resistance is in the coil. Within limits, increasing the number of turns in the coil increases the reactance faster than it raises the resistance, so coils for circuits in which the Q must be high are made with relatively large inductances for the frequency.

When the circuit delivers energy to a load (as in the case of the resonant circuits used in transmitters), the energy consumed in the circuit itself is usually negligible compared with that consumed by the load. The equivalent of such a circuit is shown in Fig 6.73, where the parallel resistor,  $R_L$ , represents the load to which power is delivered. If the power dissipated in the load is at least 10 times as great as the power lost in the inductor and capacitor, the parallel impedance of the resonant circuit itself will be so high compared with the resistance of the load that for all practical purposes the impedance of the combined circuit is equal to the load impedance.

Fig 6.73 — A loaded parallel-resonant circuit, showing both the inductor-loss resistance and the load,  $R_L$ . If smaller than the inductor resistance,  $R_L$  will control the loaded Q of the circuit ( $Q_L$ ).

Fig 6.74 — A parallel-resonant circuit with a tapped coil to effect an impedance match. Although the impedance presented by the entire circuit is very high, the impedance "seen" by the load,  $R_L$ , is lower.

ance. Under these conditions, the load resistance replaces the circuit impedance in calculating Q. The Q of a parallel-resonant circuit loaded by a resistive impedance is:

$$Q_L = \frac{R_L}{X} \quad (102)$$

where:

$Q_L$  = circuit loaded Q,

$R_L$  = parallel load resistance in ohms, and

$X$  = reactance in ohms of either the inductor or the capacitor.

Example: A resistive load of  $3000 \Omega$  is connected across a resonant circuit in which the inductive and capacitive reactances are each  $250 \Omega$ . What is the circuit Q?

$$Q_L = \frac{R_L}{X} = \frac{3000 \Omega}{250 \Omega} = 12$$

The effective Q of a circuit loaded by a parallel resistance increases when the reactances are decreased. A circuit loaded with a relatively low resistance (a few thousand ohms) must have low-reactance elements (large capacitance and small inductance) to have reasonably high Q. Many power-handling circuits, such as the output networks of transmitters, are designed by first choosing a loaded Q for the circuit and then determining component values. See the **Amplifiers** chapter for more details.

Parallel load resistors are sometimes added to parallel-resonant circuits to lower the circuit Q and increase the circuit bandwidth. By using a high-Q circuit and adding a parallel resistor, designers can tailor the circuit response to their needs. Since the parallel resistor consumes power, such techniques ordinarily apply to receiver and similar low-power circuits, however.

Example: Specifications call for a parallel-resonant circuit with a bandwidth of 400. kHz at 14.0 MHz. The circuit at hand has a  $Q_U$  of 70.0 and its components have reactances of  $350 \Omega$  each. What is the parallel load resistor that will increase the bandwidth to the specified value? The bandwidth of the existing circuit is:

$$BW = \frac{f}{Q_U} = \frac{140 \text{ MHz}}{70.0} = 0.200 \text{ MHz} = 200. \text{ kHz}$$

The desired bandwidth, 400. kHz, requires a circuit with a Q of:

$$Q = \frac{f}{BW} = \frac{14.0 \text{ MHz}}{0.400 \text{ MHz}} = 35.0$$

Since the desired Q is half the original value, halving the resonant impedance or parallel-resistance value of the circuit is

in order. The present impedance of the circuit is:

$$Z = Q_U X_L = 70.0 \times 350. \Omega = 24500 \Omega$$

The desired impedance is:

$$Z = Q_U X_L = 35.0 \times 350. \Omega = 12300 \Omega = 12.3 \text{ k}\Omega$$

or half the present impedance.

A parallel resistor of  $24500 \Omega$ , or the nearest lower value (to guarantee sufficient bandwidth), will produce the required reduction in Q and bandwidth increase. Although this example simplifies the situation encountered in real design cases by ignoring such factors as the shape of the band-pass curve, it illustrates the interaction of the ingredients that determine the performance of parallel-resonant circuits.

## Impedance Transformation

An important application of the parallel-resonant circuit is as an impedance matching device in the output circuit of an RF power amplifier. There is an optimum value of load resistance for each type of tube or transistor and each set of required operating conditions. The resistance of the load to which the active device delivers power may be considerably lower than the value required for proper device operation, or the load impedance may be considerably higher than the amplifier output impedance.

To transform the actual load resistance to the desired value, the load may be tapped across part of the coil, as shown in Fig 6.74. This is equivalent to connecting a higher value of load resistance across the whole circuit, and is similar in principle to impedance transformation with an iron-core transformer (described in the next section of this chapter). In high-frequency resonant circuits, the impedance ratio does not vary exactly as the square of the turns ratio, because all the magnetic flux lines do not cut every turn of the coil. A desired impedance ratio usually must be obtained by experimental adjustment.

When the load resistance has a very low value (say below  $100 \Omega$ ) it may be connected in series in the resonant circuit ( $R_S$  in Fig 6.68A, for example), in which case it is transformed to an equivalent parallel impedance as previously described. If the Q is at least 10, the equivalent parallel impedance is:

$$Z_R = \frac{X_L^2}{R_L} \quad (103)$$

where:

$Z_R$  = resistive parallel impedance at resonance,

$X$  = reactance (in ohms) of either the coil or the capacitor, and  
 $R_L$  = load resistance inserted in series.

If the  $Q$  is lower than 10, the reactance will have to be adjusted somewhat — for the reasons given in the discussion of low- $Q$  circuits — to obtain a resistive impedance of the desired value.

Networks like the one in Fig 6.74 have some serious disadvantages for some applications. For instance, the common connection between the input and the output provides no dc isolation. Also, the common ground is sometimes troublesome with regard to ground-loop currents. Consequently, a network with only mutual

magnetic coupling is often preferable. With the advent of ferrites, constructing impedance transformers that are both broadband and permit operation well up into the VHF portion of the spectrum has become relatively easy. The basic principles of broadband impedance transformers appear in the following section.

## Transformers

When the ac source current flows through every turn of an inductor, the generation of a counter-voltage and the storage of energy during each half cycle is said to be by virtue of *self-inductance*. If another inductor — not connected to the source of the original current — is positioned so the expanding and contracting magnetic field of the first inductor cuts across its turns, a current will be induced into the second coil. A load such as a resistor may be connected across the second coil to consume the energy transferred magnetically from the first inductor. This phenomenon is called *mutual inductance*.

Two inductors positioned so that the magnetic field of one (the *primary* inductor) induces a current in the other (the *secondary* inductor) are *coupled*. Fig 6.75 illustrates a pair of coupled inductors, showing an ac energy source connected to one and a load connected to the other. If the coils are wound tightly on an iron core so that nearly all the lines of force or magnetic flux from the first coil link with the turns of the second coil, the pair is said to be *tightly coupled*. Coils with air cores separated by a distance would be loosely coupled. The signal source for the primary inductor may be household ac power lines, audio or other waveforms at lower frequencies, or RF currents. The load may be a device needing power, a speaker converting electrical energy into sonic energy, an antenna using RF energy for communications or a particular circuit set up to process a signal from a preceding circuit. The uses of magnetically-coupled energy in electronics are innumerable.

Mutual inductance ( $M$ ) between coils is measured in henrys. Two coils have a mutual inductance of 1 H under the following conditions: as the primary inductor current changes at a rate of 1 A/s, the voltage across the secondary inductor is 1 V. The level of mutual inductance varies with many factors: the size and shape of the inductors, their relative positions and distance from each other,

and the permeability of the inductor core material and of the space between them.

If the self-inductance values of two coils are known, it is possible to derive the mutual inductance by way of a simple experiment schematically represented in Fig 6.76. Without altering the physical setting or position of two coils, measure the inductance of the series-connected coils with their windings complementing each other and again with their windings opposing each other. Since, for the two coils,  $L_C = L_1 + L_2 + 2M$ , in the complementary case, and  $L_O = L_1 + L_2 - 2M$  for the opposing case,

$$M = \frac{L_C - L_O}{4} \quad (104)$$

The ratio of magnetic flux set up by the secondary coil to the flux set up by the primary coil is a measure of the extent to which two coils are coupled, compared to the maximum possible coupling between them. This ratio is the *coefficient of coupling* ( $k$ ) and is always less than 1. If  $k$  were to equal 1, the two coils would have the maximum possible mutual coupling. Thus:

$$M = k\sqrt{L_1 L_2} \quad (105)$$

where:

$M$  = mutual inductance in henrys,  
 $L_1$  and  $L_2$  = individual coupled inductors, each in henrys, and  
 $k$  = the coefficient of coupling.

Fig 6.75 — A basic transformer: two inductors — one connected to an ac energy source, the other to a load — with coupled magnetic fields.

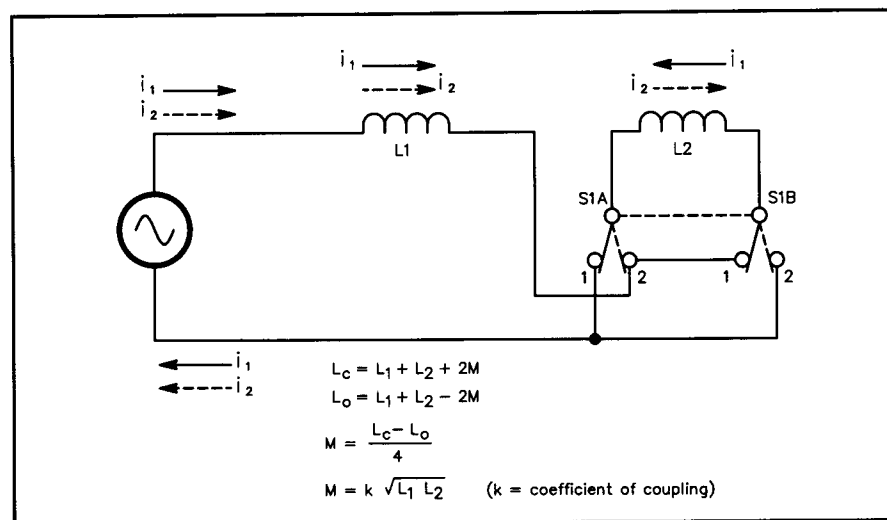

Fig 6.76 — An experimental setup for determining mutual inductance. Measure the inductance with the switch in each position and use the formula in the text to determine the mutual inductance.

**Fig 6.77 — A transformer.** A is a pictorial diagram. Power is transferred from the primary coil to the secondary by means of the magnetic field. B is a schematic diagram of an iron-core transformer, and C is an air-core transformer.

**Fig 6.78 — The conditions for transformer action:** two coils that exhibit mutual inductance, an ac power source, and a load. The magnetic field set up by the energy in the primary circuit transfers energy to the secondary for use by the load, resulting in a secondary voltage and current.

Using the experiment above, it is possible to solve equation 105 for  $k$  with reasonable accuracy.

Any two coils having mutual inductance comprise a *transformer* having a *primary winding* or inductor and a *secondary winding* or inductor. **Fig 6.77** provides a pictorial representation of a typical iron-core transformer, along with the schematic symbols for both iron-core and air-core transformers. Conventionally, the term *transformer* is most commonly applied to coupled inductors having a magnetic core material, while coupled air-wound inductors are not called by that name. They are still transformers, however.

We normally think of transformers as ac devices, since mutual inductance only occurs when magnetic fields are expanding or contracting. A transformer connected to a dc source will exhibit mutual inductance only at the instants of closing and opening the primary circuit, or on the rising and falling edges of dc pulses, because only then does the primary winding have a changing field. The principle uses of transformers are three: to physically isolate the primary circuit from the secondary circuit, to transform voltages and currents from one level to another, and to transform circuit impedances from one level to an-

other. These functions are not mutually exclusive and have many variations.

### IRON-CORE TRANSFORMERS

The primary and secondary coils of a transformer may be wound on a core of magnetic material. The permeability of the magnetic material increases the inductance of the coils so a relatively small number of turns may be used to induce a given voltage value with a small current. A closed core having a continuous magnetic path, such as that shown in **Fig 6.77**, also tends to ensure that practically all of the field set up by the current in the primary coil will cut the turns of the secondary coil. For power transformers and impedance-matching transformers used in audio work, cores of iron strips are most common and generally very efficient.

The following principles presume a coefficient of coupling ( $k$ ) of 1, that is, a perfect transformer. The value,  $k = 1$ , indicates that all the turns of both coils link with all the magnetic flux lines, so that the voltage induced per turn is the same with both coils. This condition makes the induced voltage independent of the inductance of the primary and secondary inductors. Iron-core transformers for low frequencies most closely approach this ideal condition. **Fig 6.78** illustrates the conditions for transformer action.

### Voltage Ratio

For a given varying magnetic field, the voltage induced in a coil within the field is proportional to the number of turns in the coil. When the two coils of a transformer are in the same field (which is the case when both are wound on the same closed core), it follows that the induced voltages will be proportional to the number of turns in each coil. In the primary, the induced voltage practically equals, and opposes, the applied voltage, as described earlier. Hence:

$$E_S = E_P \left( \frac{N_S}{N_P} \right) \quad (106)$$

where:

$E_S$  = secondary voltage,  
 $E_P$  = primary applied voltage,  
 $N_S$  = number of turns on secondary, and  
 $N_P$  = number of turns on primary.

**Example:** A transformer has a primary of 400 turns and a secondary of 2800 turns, and a voltage of 120 V is applied to the primary. What voltage appears across the secondary winding?

$$E_S = 120 \text{ V} \left( \frac{2800}{400} \right) = 120 \text{ V} \times 7 = 840 \text{ V}$$

(Notice that the number of turns is taken as a known value rather than a measured quantity, so they do not limit the significant figures in the calculation.) Also, if 840 V is applied to the 2800-turn winding (which then becomes the primary), the output voltage from the 400-turn winding will be 120 V.

Either winding of a transformer can be used as the primary, provided the winding has enough turns (enough inductance) to induce a voltage equal to the applied voltage without requiring an excessive current. The windings must also have insulation with a voltage rating sufficient for the voltage present.

### Current or Ampere-Turns Ratio

The current in the primary when no current is taken from the secondary is called the *magnetizing current* of the transformer. An ideal transformer, with no internal losses, would consume no power, since the current through the primary inductor would be 90° out of phase with the voltage. In any properly designed transformer, the power consumed by the transformer when the secondary is open (not delivering power) is only the amount necessary to overcome the losses in the iron core and in the resistance of the wire with which the primary is wound.

When power is taken from the secondary winding by a load, the secondary current sets up a magnetic field that opposes the field set up by the primary current. For the induced voltage in the primary to equal the applied voltage, the original field must be maintained. The primary must draw enough additional current to set up a field exactly equal and opposite to the field set up by the secondary current.

In practical transformer calculations it may be assumed that the entire primary current is caused by the secondary load. This is justifiable because the magnetizing current should be very small in comparison with the primary load current at rated power output.

If the magnetic fields set up by the primary and secondary currents are to be equal, the primary current multiplied by

the primary turns must equal the secondary current multiplied by the secondary turns.

$$I_P = I_S \left( \frac{N_S}{N_P} \right) \quad (107)$$

where:

$I_P$  = primary current,  
 $I_S$  = secondary current,  
 $N_P$  = number of turns on primary, and  
 $N_S$  = number of turns on secondary.

Example: Suppose the secondary of the transformer in the previous example is delivering a current of 0.20 A to a load. What will be the primary current?

$$I_P = 0.20 \text{ A} \times \left( \frac{2800}{400} \right) = 0.20 \text{ A} \times 7 = 1.4 \text{ A}$$

Although the secondary voltage is higher than the primary voltage, the secondary current is lower than the primary current, and by the same ratio. The secondary current in an ideal transformer is 180° out of phase with the primary current, since the field in the secondary just offsets the field in the primary. The phase relationship between the currents in the windings holds true no matter what the phase difference between the current and the voltage of the secondary. In fact, the phase difference, if any, between voltage and current in the secondary winding will be reflected back to the primary as an identical phase difference.

### Power Ratio

A transformer cannot create power; it can only transfer it and change the voltage level. Hence, the power taken from the secondary cannot exceed that taken by the primary from the applied voltage source. There is always some power loss in the resistance of the coils and in the iron core, so in all practical cases the power taken from the source will exceed that taken from the secondary.

$$P_O = n P_I \quad (108)$$

where:

$P_O$  = power output from secondary,  
 $P_I$  = power input to primary, and  
 $n$  = efficiency factor.

The efficiency,  $n$ , is always less than 1. It is usually expressed as a percentage: if  $n$  is 0.65, for instance, the efficiency is 65%.

Example: A transformer has an efficiency of 85.0% at its full-load output of 150. W. What is the power input to the primary at full secondary load?

$$P_I = \frac{P_O}{n} = \frac{150. \text{ W}}{0.850} = 176 \text{ W}$$

A transformer is usually designed to have the highest efficiency at the power output for which it is rated. The efficiency decreases with either lower or higher outputs. On the other hand, the losses in the transformer are relatively small at low output but increase as more power is taken. The amount of power that the transformer can handle is determined by its own losses, because these losses heat the wire and core. There is a limit to the temperature rise that can be tolerated, because too high a temperature can either melt the wire or cause the insulation to break down. A transformer can be operated at reduced output, even though the efficiency is low, because the actual loss will be low under such conditions. The full-load efficiency of small power transformers such as are used in radio receivers and transmitters usually lies between about 60 and 90%, depending on the size and design.

### IMPEDANCE RATIO

In an ideal transformer — one without losses or leakage reactance — the following relationship is true:

$$Z_P = Z_S \left( \frac{N_P}{N_S} \right)^2 \quad (109)$$

where:

$Z_P$  = impedance looking into the primary terminals from the power source,  
 $Z_S$  = impedance of load connected to secondary, and  
 $N_P, N_S$  = turns ratio, primary to secondary.

A load of any given impedance connected to the transformer secondary will be transformed to a different value looking into the primary from the power source. The impedance transformation is proportional to the square of the primary-to-secondary turns ratio.

Example: A transformer has a primary-to-secondary turns ratio of 0.6 (the primary has six-tenths as many turns as the secondary) and a load of 3000.  $\Omega$  is connected to the secondary. What is the impedance at the primary of the transformer?

$$Z_P = 3000. \Omega \times (0.6)^2 = 3000. \Omega \times 0.36$$

$$Z_P = 1080. \Omega$$

By choosing the proper turns ratio, the impedance of a fixed load can be transformed to any desired value, within practical limits. If transformer losses can be neglected, the transformed (reflected) impedance has the same phase angle as the actual load impedance. Thus, if the load is a pure resistance, the load presented by the primary to the power source will also be a pure resistance. If the load impedance is

complex, that is, if the load current and voltage are out of phase with each other, then the primary voltage and current will show the same phase angle.

Many devices or circuits require a specific value of load resistance (or impedance) for optimum operation. The impedance of the actual load that is to dissipate the power may differ widely from the impedance of the source device or circuit, so a transformer is used to change the actual load into an impedance of the desired value. This is called impedance matching.

$$\frac{N_P}{N_S} = \sqrt{\frac{Z_P}{Z_S}} \quad (110)$$

where:

$N_P/N_S$  = required turns ratio, primary to secondary,  
 $Z_P$  = primary impedance required, and  
 $Z_S$  = impedance of load connected to secondary.

Example: A transistor audio amplifier requires a load of 150.  $\Omega$  for optimum performance, and is to be connected to a loudspeaker having an impedance of 4.0  $\Omega$ . What is the turns ratio, primary to secondary, required in the coupling transformer?

$$\frac{N_P}{N_S} = \sqrt{\frac{Z_P}{Z_S}} = \frac{N_P}{N_S} \sqrt{\frac{150. \Omega}{4.0 \Omega}} = \sqrt{38} = 6.2$$

The primary therefore must have 6.2 times as many turns as the secondary.

These relationships may be used in practical work even though they are based on an ideal transformer. Aside from the normal design requirements of reasonably low internal losses and low leakage reactance, the only other requirement is that the primary have enough inductance to operate with low magnetizing current at the voltage applied to the primary.

The primary terminal impedance of an iron-core transformer is determined wholly by the load connected to the secondary and by the turns ratio. If the characteristics of the transformer have an appreciable effect on the impedance presented to the power source, the transformer is either poorly designed or is not suited to the voltage and frequency at which it is being used. Most transformers will operate quite well at voltages from slightly above to well below the design figure.

### Transformer Losses

In practice, none of the formulas given so far provides truly exact results, although they afford reasonable approximations. Transformers in reality are not simply two coupled inductors, but a network

Fig 6.79 — A transformer as a network of resistances, inductances and capacitances. Only  $L_1$  and  $L_2$  contribute to the transfer of energy.

Fig 6.80 — A typical transformer iron core. The E and I pieces alternate direction in successive layers to improve the magnetic path while attenuating eddy currents in the core.

of resistances and reactances, most of which appear in Fig 6.79. Since only the terminals numbered 1 through 4 are accessible to the user, transformer ratings and specifications take into account the additional losses created by these complexities.

In a practical transformer not all of the magnetic flux is common to both windings, although in well designed transformers the amount of flux that cuts one coil and not the other is only a small percentage of the total flux. This *leakage flux* causes a voltage of self-induction. Consequently, there are small amounts of leakage inductance associated with both windings of the transformer. Leakage inductance acts in exactly the same way as an equivalent amount of ordinary inductance inserted in series with the circuit. It has, therefore, a certain reactance, depending on the amount of leakage inductance and the frequency. This reactance is called

Fig 6.81 — Two common transformer constructions: shell and core.

*leakage reactance*, shown as  $X_{L1}$  and  $X_{L2}$  in Fig 6.79.

Current flowing through the leakage reactance causes a voltage drop. This voltage drop increases with increasing current; hence, it increases as more power is taken from the secondary. Thus, the greater the secondary current, the smaller the secondary terminal voltage becomes. The resistances of the transformer windings,  $R_1$  and  $R_2$ , also cause voltage drops when there is current. Although these voltage drops are not in phase with those caused by leakage reactance, together they result in a lower secondary voltage under load than is indicated by the transformer turns ratio.

Thus, the voltage regulation in a real transformer is not perfect. At power frequencies (60 Hz), the voltage at the secondary, with a reasonably well-designed transformer, should not drop more than about 10% from open-circuit conditions to full load. The voltage drop may be considerably more than this in a transformer operating at voice and music frequencies, because the leakage reactance increases directly with the frequency.

In addition to wire resistances and leakage reactances, certain stray capaci-

ties occur in transformers. An electric field exists between any two points having a different voltage. When current flows through a coil, each turn has a slightly different voltage than its adjacent turns, creating a capacitance between turns. This *distributed capacitance* appears in Fig 6.79 as  $C_1$  and  $C_2$ . Another capacitance,  $C_m$ , appears between the two windings for the same reason. Moreover, transformer windings can exhibit capacitance relative to nearby metal, for example, the chassis, the shield and even the core.

Although these stray capacitances are of little concern with power and audio transformers, they become important as the frequency increases. In transformers for RF use, the stray capacitance can resonate with either the leakage reactance or, at lower frequencies, with the winding reactances,  $L_1$  or  $L_2$ , especially under very light or zero loads. In the frequency region around resonance, transformers no longer exhibit the properties formulated above or the impedance properties to be described below.

Iron-core transformers also experience losses within the core itself. *Hysteresis losses* include the energy required to overcome the retentivity of the core's magnetic material. Circulating currents through the core's resistance are *eddy currents*, which form part of the total core losses. These losses, which add to the required magnetizing current, are equivalent to adding a resistance in parallel with  $L_1$  in Fig 6.79.

### Core Construction

Audio and power transformers usually employ one or another grade of silicon steel as the core material. With permeabilities of 5000 or greater, these cores saturate at flux densities approaching  $10^5$  lines per square inch of cross section. The cores consist of thin insulated laminations to break up potential eddy current paths.

Each core layer consists of an E and an I piece butted together, as represented in Fig 6.80. The butt point leaves a small gap. Since the pieces in adjacent layers have a continuous magnetic path, however, the flux density per unit of applied magnetic force is increased and flux leakage reduced.

Two core shapes are in common use, as shown in Fig 6.81. In the shell type, both windings are placed on the inner leg, while in the core type the primary and secondary windings may be placed on separate legs, if desired. This is sometimes done when it is necessary to minimize capacitive effects between the primary and secondary, or when one of the windings must operate at

very high voltage.

The number of turns required in the primary for a given applied voltage is determined by the size, shape and type of core material used, as well as the frequency. The number of turns required is inversely proportional to the cross-sectional area of the core. As a rough indication, windings of small power transformers frequently have about six to eight turns per volt on a core of 1-square-inch cross section and have a magnetic path 10 or 12 inches in length. A longer path or smaller cross section requires more turns per volt, and vice versa.

In most transformers the coils are wound in layers, with a thin sheet of treated-paper insulation between each layer. Thicker insulation is used between adjacent coils and between the first coil and the core.

### Shielding

Because magnetic lines of force are continuous and closed upon themselves, shielding requires a path for the lines of force of the leakage flux. The high-permeability of iron cores tends to concentrate the field, but additional shielding is often needed. As depicted in Fig 6.82, enclosing the transformer in a good magnetic material can restrict virtually all of the magnetic field in the outer case. The nonmagnetic material between the case and the core creates a region of high reluctance, attenuating the field before it reaches the case.

### AUTOTRANSFORMERS

The transformer principle can be used with only one winding instead of two, as shown in Fig 6.83A. The principles that relate voltage, current and impedance to the turns ratio also apply equally well. A one-winding transformer is called an *autotransformer*. The current in the common section (A) of the winding is the difference between the line (primary) and the load (secondary) currents, since these currents are out of phase. Hence, if the line and load currents are nearly equal, the common section of the winding may be wound with comparatively small wire. The line and load currents will be equal only when the primary (line) and secondary (load) voltages are not very different.

Autotransformers are used chiefly for boosting or reducing the power-line voltage by relatively small amounts. Fig 6.83B illustrates the principle schematically with a switched, stepped autotransformer. Continuously variable autotransformers are commercially available under a variety of trade names;

Fig 6.82 — A shielded transformer: the core plus an outer shield of magnetic material contain nearly all of the magnetic field.

Variac and Powerstat are typical examples.

Technically, tapped air-core inductors, such as the one in the network in Fig 6.74 at the close of the discussion of resonant circuits, are also autotransformers. The voltage from the tap to the bottom of the coil is less than the voltage across the entire coil. Likewise, the impedance of the tapped part of the winding is less than the impedance of the entire winding. Because leakage reactances are great and the coefficient of coupling is quite low, the relationships true of a perfect transformer grow quite unreliable in predicting the exact values. For this reason, tapped inductors are rarely referred to as transformers. The stepped-down situation in Fig 6.74 is better approximated — at or close to resonance — by the formula

$$R_p = \frac{R_L X_{COM}^2}{X_L} \quad (111)$$

where:

$R_p$  = tuned-circuit parallel-resonant impedance,

$R_L$  = load resistance tapped across part of the coil,

$X_{COM}$  = reactance of the portion of the coil common to both the resonant circuit and the load tap, and

$X_L$  = reactance of the entire coil.

The result is approximate and applies only to circuits with a Q of 10 or greater.

### AIR-CORE RF TRANSFORMERS

Air-core transformers often function as mutually coupled inductors for RF applications. They consist of a primary winding and a secondary winding in close prox-

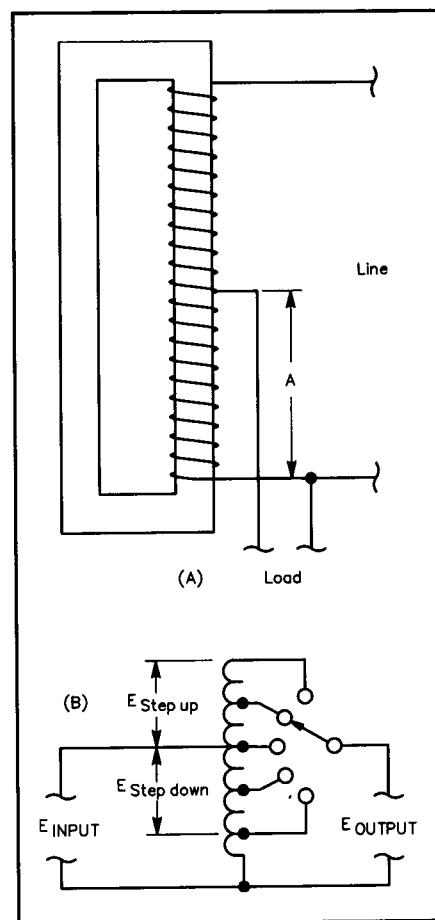

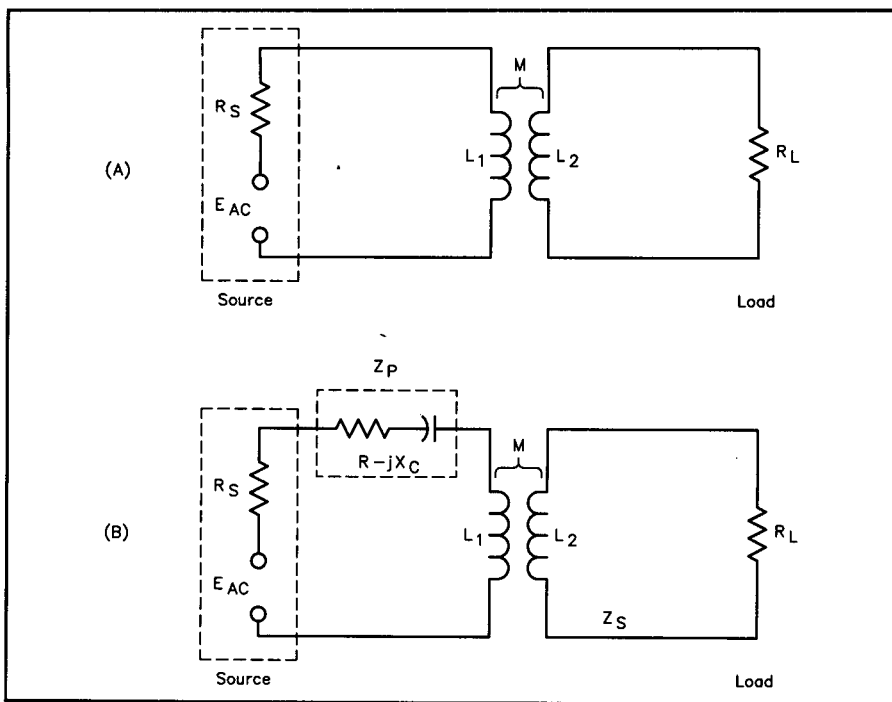

Fig 6.83 — The autotransformer is based on the transformer, but uses only one winding. The pictorial diagram at A shows the typical construction of an autotransformer. The schematic diagram at B demonstrates the use of an autotransformer to step up or step down ac voltage, usually to compensate for excessive or deficient line voltage.

imity. Leakage reactances are ordinarily high, however, and the coefficient of coupling between the primary and secondary windings is low. Consequently, unlike transformers having a magnetic core, the turns ratio does not have as much significance. Instead, the voltage induced in the secondary depends on the mutual inductance.

### Nonresonant RF Transformers

In a very basic transformer circuit operating at radio frequencies, such as in Fig 6.84A, the source voltage is applied to L1.  $R_s$  is the series resistance inherent in the source. By virtue of the mutual inductance, M, a voltage is induced in L2. A current flows in the secondary circuit through the reactance of L2 and the load resistance of  $R_L$ . Let  $X_{L2}$  be the reactance of L2 independent of L1, that is, indepen-

**Fig 6.84 — The coupling of a complex impedance back into the primary circuit of a transformer composed of nonresonant air-core inductors.**

**Fig 6.85 — An air-core transformer circuit consisting of a resonant primary circuit and an untuned secondary.  $R_S$  and  $C_S$  are functions of the source, while  $R_L$  and  $C_L$  are functions of the load circuit.**

dent of the effects of mutual inductance. The impedance of the secondary circuit is then:

$$Z_S = \sqrt{R_L^2 + X_{L2}^2} \quad (112)$$

where:

$Z_S$  = the impedance of the secondary circuit in ohms,

$R_L$  = the load resistance in ohms, and

$X_{L2}$  = the reactance of the secondary inductance in ohms.

The effect of  $Z_S$  upon the primary circuit is the same as a coupled impedance in series with  $L1$ . Fig 6.84B displays the coupled impedance ( $Z_P$ ) in a dashed enclosure to indicate that it is not a new physical component. It has the same absolute value of phase

angle as in the secondary impedance, but the sign of the reactance is reversed; it appears as a capacitive reactance. The value of  $Z_P$  is:

$$Z_P = \frac{(2 \pi f M)^2}{Z_S} \quad (113)$$

where:

$Z_P$  = the impedance introduced into the primary,

$Z_S$  = the impedance of the secondary circuit in ohms, and

$2 \pi f M$  = the mutual reactance between the reactances of the primary and secondary coils (also designated as  $X_M$ ).

### Resonant RF Transformers

The use of at least one resonant circuit in place of a pair of simple reactances

eliminates the reactance from the transformed impedance in the primary. For loaded or operating  $Q$ s of at least 10, the resistances of individual components is negligible. Fig 6.85 represents just one of many configurations in which at least one of the inductors is in a resonant circuit. The reactance coupled into the primary circuit is cancelled if the circuit is tuned to resonance while the load is connected. If the reactance of the load capacitance,  $C_L$  is at least 10 times any stray capacitance in the circuit, as is the case for low impedance loads, the value of resistance coupled to the primary is

$$R1 = \frac{X_M^2 R_L}{X^2 + R_L^2} \quad (114)$$

where:

$R1$  = series resistance coupled into the primary circuit,

$X_M$  = mutual reactance,

$R_L$  = load resistance, and

$X^2$  = reactance of the secondary inductance.

The parallel impedance of the resonant circuit is just  $R1$  transformed from a series to a parallel value by the usual formula,  $R_p = X^2 / R1$ .

The higher the loaded or operating  $Q$  of the circuit, the smaller the mutual inductance required for the same power transfer. If both the primary and secondary circuits consist of resonant circuits, they can be more loosely coupled than with a single tuned circuit for the same power transfer. At the usual loaded  $Q$  of 10 or greater, these circuits are quite selective, and consequently narrowband.

Although coupling networks have to a large measure replaced RF transformer coupling that uses air-core transformers, these circuits are still useful in antenna tuning units and other circuits. For RF work, powdered-iron toroidal cores have generally replaced air-core inductors for almost all applications except where the circuit handles very high power or the coil must be very temperature stable. Sluggish solenoid coils for low-power circuits offer the ability to tune the circuit precisely to resonance. For either type of core, reasonably accurate calculation of impedance transformation is possible. It is often easier to experiment to find the correct values for maximum power transfer, however. For further information on coupled circuits, see the section on Matching Networks in the **Transceivers** chapter.

### BROADBAND FERRITE RF TRANSFORMERS

The design concepts and general theory

of ideal transformers presented earlier in this chapter apply also to transformers wound on ferromagnetic-core materials (ferrite and powdered iron). As is the case with stacked cores made of laminations in the classic I and E shapes, the core material has a specific permeability factor that determines the inductance of the windings versus the number of wire turns used.

Toroidal cores are useful from a few hundred hertz well into the UHF spectrum. The principal advantage of this type of core is the self-shielding characteristic. Another feature is the compactness of a transformer or inductor. Therefore, toroidal-core transformers are excellent for use not only in dc-to-dc converters, where tape-wound steel cores are employed, but at frequencies up to at least 1000 MHz with the selection of the proper core material for the range of operating frequencies. Toroidal cores are available from micro-miniature sizes up to several inches in diameter. The latter can be used, as one example, to build a 20-kW balun for use in antenna systems.

One of the most common ferromagnetic transformers used in Amateur Radio work is the *conventional broadband transformer*. Broadband transformers with losses of less than 1 dB are employed in circuits that must have a uniform response over a substantial frequency range, such as a 2- to 30-MHz broadband amplifier. In applications of this sort, the reactance of the windings should be at least four times the impedance that the winding is designed to look into at the lowest design frequency.

Example: What should be the winding reactances of a transformer that has a 300.- $\Omega$  primary and a 50.- $\Omega$  secondary load? Relative to the 50.- $\Omega$  secondary load:

$$X_S = 4 Z_S = 4 \times 50.\Omega = 200 \Omega.$$

The primary winding reactance ( $X_P$ ) is:

$$X_P = 4 Z_P = 4 \times 300.\Omega = 1200 \Omega.$$

The core-material permeability plays a vital role in designing a good broadband transformer. The effective permeability of the core must be high enough to provide ample winding reactance at the low end of the operating range. As the operating frequency is increased, the effects of the core tend to disappear until there are scarcely any core effects at the upper limit of the operating range. The limiting factors for high frequency response are distributed capacity and leakage inductance due to uncoupled flux. A high-permeability core minimizes the number of turns needed for a given reactance and therefore also mini-

mizes the distributed capacitance at high frequencies.

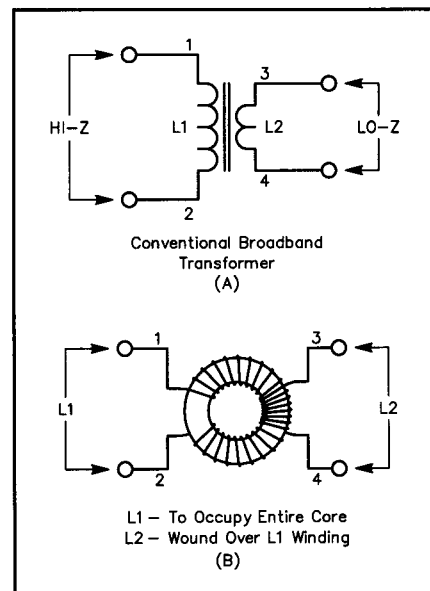

Ferrite cores with a permeability of 850 are common choices for transformers used between 2 and 30 MHz. Lower frequency ranges, for example, 1 kHz to 1 MHz, may require cores with permeabilities up to 2000. Permeabilities from 40 to 125 are useful for VHF transformers. Conventional broadband transformers require resistive loads. Loads with reactive components should use appropriate networks to cancel the reactance.

Conventional transformers are wound in the same manner as a power transformer. Each winding is made from a separate length of wire, with one winding placed over the previous one with suitable insulation between. Unlike some transmission-line transformer designs, conventional broadband transformers provide dc isolation between the primary and secondary circuits. The high voltages encountered in high-impedance-ratio step-up transformers may require that the core be wrapped with glass electrical tape before adding the windings (as an additional protection from arcing and voltage breakdown), especially with ferrite cores that tend to have rougher edges. In addition, high voltage applications should also use wire with high-voltage insulation and a high temperature rating.

**Fig 6.86** illustrates one method of transformer construction using a single toroid as the core. The primary of a step-down impedance transformer is wound to occupy the entire core, with the secondary wound over the primary. The first step in planning the winding is to select a core of the desired permeability. Convert the required reactances determined earlier into inductance values for the lowest frequency of use. To find the number of turns for each winding, use the  $A_L$  value for the selected core and equation 51 from the section on ferrite toroidal inductors earlier in this chapter. Be certain the core can handle the power by calculating the maximum flux using equation 49, given earlier in the chapter, and comparing the result with the manufacturer's guidelines.

Example: Design a small broadband transformer having an impedance ratio of 16:1 for a frequency range of 2.0 to 20.0 MHz to match the output of a small-signal stage (impedance  $\approx 500 \Omega$ ) to the input (impedance  $\approx 32 \Omega$ ) of an amplifier.

1. Since the impedance of the smallest winding should be at least 4 times the lower impedance to be matched at the lowest frequency,  $X_S = 4 \times 32 \Omega = 128 \Omega$ .

**Fig 6.86 — Schematic and pictorial representation of a conventional broadband transformer wound on a ferrite toroidal core. The secondary winding (L2) is wound over the primary winding (L1).**

2. The inductance of the secondary winding should be  $L_S = X_S / 2 \pi f = 128 / (6.2832 \times 2.0 \times 10^6 \text{ Hz}) = 0.010 \text{ mH}$
3. Select a suitable core. For this low-power application, a  $3/8$ -inch ferrite core with a permeability of 850 is suitable. The core has an  $A_L$  value of 420. Calculate the number of turns for the secondary.

$$N_S = 1000 \sqrt{\frac{L}{A_L}} = 1000 \sqrt{\frac{0.010}{420}} \\ = 1000 \times 0.0049 = 4.9 \text{ turns}$$

4. A 5-turn secondary winding should suffice. The primary winding derives from the impedance ratio:

$$N_P = N_S \sqrt{\frac{Z_P}{Z_S}} = 5 \sqrt{\frac{16}{1}} = 5 \times 4 = 20 \text{ turns}$$

This low power application will not approach the maximum flux density limits for the core, and #28 enamel wire should both fit the core and handle the currents involved.

A second style of broadband transformer construction appears in **Fig 6.87**. The key elements in this transformer are the stacks of ferrite cores aligned with tubes soldered to pc-board end plates. This style of transformer is suited to high power applications, for example, at the input and output ports of transistor RF power amplifiers. Low-power versions of this transformer can be wound on "binocular" cores

having pairs of parallel holes through them.

For further information on conventional transformer matching using ferromagnetic materials, see the Matching Networks section in the **Amplifiers** chapter. Refer to the **Component Data** chapter for more detailed information on available ferrite

cores. A standard reference on conventional broadband transformers using ferromagnetic materials is *Ferromagnetic Core Design and Applications Handbook* by Doug DeMaw, W1FB, published by Prentice Hall.

## TRANSMISSION-LINE TRANSFORMERS

Conventional transformers use flux linkages to deliver energy to the output circuit. *Transmission line transformers* use transmission line modes of energy transfer between the input and the output terminals of the devices. Although toroidal versions of these transformers physically resemble toroidal conventional broadband transformers, the principles of operations differ significantly. Stray inductances and interwinding capacitances form part of the characteristic impedance of the transmission line, largely eliminating resonances that limit high frequency response. The limiting factors for transmission line transformers include line length, deviations in the constructed line from the design value of characteristic impedance, and parasitic capacitances and inductances that are independent of the characteristic impedance of the line.

The losses in conventional transformers depend on current and include wire, eddy-current and hysteresis losses. In contrast, transmission line transformers exhibit voltage-dependent losses, which make higher impedances and higher VSWR values limiting factors in design. Within design limits, the cancellation of flux in the cores of transmission line transformers permits very high efficiencies across their passbands. Losses may be lower than 0.1 dB with the proper core choice.

Transmission-line transformers can be configured for several modes of operation, but the chief amateur use is in *baluns* (balanced-to-unbalanced transformers) and in

*ununs* (unbalanced-to-unbalanced transformers). The basic principle behind a balun appears in Fig 6.88, a representation of the classic Guanella 1:1 balun. The input and output impedances are the same, but the output is balanced about a real or virtual center point (terminal 5). If the characteristic impedance of the transmission line forming the inductors with numbered terminals equals the load impedance, then  $E_2$  will equal  $E_1$ . With respect to terminal 5, the voltage at terminal 4 is  $E_1 / 2$ , while the voltage at terminal 2 is  $-E_1 / 2$ , resulting in a balanced output.

The small losses in properly designed baluns of this order stem from the potential gradient that exists along the length of transmission line forming the transformer. The value of this potential is  $-E_1 / 2$ , and it forms a dielectric loss that can't be eliminated. Although the loss is very small in well-constructed 1:1 baluns at low impedances, the losses climb as impedances climb (as in 4:1 baluns) and as the VSWR climbs. Both conditions yield higher voltage gradients.

The inductors in the transmission-line transformer are equivalent to — and may be — coiled transmission line with a characteristic impedance equal to the load. They form a choke isolating the input from the output and attenuating undesirable currents, such as antenna current, from the remainder of the transmission line to the energy source. The result is a *current* or *choke* balun. Such baluns may take many forms: coiled transmission line, ferrite beads placed over a length of transmission line, windings on linear ferrite cores or windings on ferrite toroids.

Reconfiguring the windings of Fig 6.88 can alter the transformer operation. For example, if terminal 2 is connected to terminal 3, a positive potential gradient appears across the lengths of line, resulting in a terminal 4 potential of  $2 E_1$  with respect to ground. If the load is disconnected from terminal 2 and reconnected to ground,  $2 E_1$  appears across the load — instead of  $\pm E_1 / 2$ . The product of this experiment is a 4:1 impedance ratio, forming an unun. The bootstrapping effect of the new connection is applicable to many other design configurations involving multiple windings to achieve custom impedance ratios from 1:1 up to 9:1.

Balun and unun construction for the impedances of most concern to amateurs requires careful selection of the feed line used to wind the balun. Building transmission line transformers on ferrite toroids may require careful attention to wire size and spacing to approximate a 50- $\Omega$  line. Wrapping wire with polyimide tape (one or two coatings, depending upon the wire

**Fig 6.87 — Schematic and pictorial representation of a "binocular" style of conventional broadband transformer. This style is used frequently at the input and output ports of transistor RF amplifiers. It consists of two rows of high-permeability toroidal cores, with the winding passed through the center holes of the resulting stacks.**

**Fig 6.88 — Schematic representation of the basic Guanella "choke" balun or 1:1 transmission line transformer. The inductors are a length of two-wire transmission line.  $R_S$  is the source impedance and  $R_L$  is the load impedance.**

size) and then glass taping the wires together periodically produces a reasonable 50- $\Omega$  transmission line. Ferrite cores in the permeability range of 125 to 250 are generally optimal for transformer windings, with 1.25-inch cores suitable to 300-W power levels and 2.4-inch cores usable to the 5 kW level. Special designs may alter the power-handling capabilities of the core sizes. For the 1:1 balun shown in Fig 6.88, 10 bifilar turns (#16 wire for the smaller core and #12 wire for the larger, both Thermaleze wire) yields a transformer operable from 160 to 10 m.

Transmission-line transformers have their most obvious application to antennas, since they isolate the antenna currents

from the feed line, especially where a coaxial feed line is not exactly perpendicular to the antenna. The balun prevents antenna currents from flowing on the outer surface of the coax shielding, back to the transmitting equipment. Such currents would distort the antenna radiation pattern. Appropriately designed baluns can also transform impedance values at the same time. For example, one might use a 4:1 balun to match a 12.5- $\Omega$  Yagi antenna impedance to a 50- $\Omega$  feed line. A 4:1 balun might also be used to match a 75- $\Omega$  TV antenna to 300- $\Omega$  feed line.

Interstage coupling within solid-state transmitters represents another potential for transmission-line transformers. Broad-

band coupling between low-impedance, but mismatched stages can benefit from the low losses of transmission-line transformers. Depending upon the losses that can be tolerated and the bandwidth needed, it is often a matter of designer choice between a transmission-line transformer and a conventional broadband transformer as the coupling device.

For further information on transmission-line transformers and their applications, see the **Amplifiers** chapter. Another reference on the subject is *Transmission Line Transformers*, second edition, by Jerry Sevick, W2FMI, published by the ARRL.

# Digital Signal Theory and Components

## 7

### Digital Fundamentals

**D**igital signal theory is an important aspect of Amateur Radio. With a knowledge of digital theory, there are many new worlds for the radio amateur to explore. Applications of digital signal theory include digital communications, code conversion, signal processing, station control, frequency synthesis, amateur satellite telemetry, message handling, word processing and other information handling operations.

This chapter, written by Christine Montgomery, KGØGN, presents digital-theory fundamentals and some applications of that theory in Amateur Radio. The fundamentals introduce digital mathematics, including number systems, logic devices and simple digital circuits. Next, the implementation of these simple circuits is explored in integrated circuits, their families and interfacing. Integrated circuits continue with memory chips and microprocessors, culminating in a synthesis of these components in the modern digital computer. Where possible, this chapter mentions Amateur Radio applications associated with the technologies being discussed, as well as pointers to other chapters that discuss such applications in greater depth.

#### DIGITAL VS ANALOG

An essential first step in understanding digital theory is to understand the differ-

ence between a *digital* and an *analog* signal. An analog value, a real number, has no end; for example, the number  $1/3$  is  $0.333\dots$  where the 3 can be repeated forever, or  $3/4$  equals  $0.7500\dots$  with infinite repeated 0s. A digital approximation of an analog number breaks the real number line into discrete steps, for example the integers. This process of approximating a value with discrete steps either truncates or rounds an analog value to some number of decimal places. For example, rounding  $1/3$  to an integer gives 0 and rounding  $3/4$  gives 1.

For a simple physical example, look at your wristwatch. A watch with a face — with the hands of the watch rotating in a continuous, smooth motion — is an analog display. Here, the displayed time has a *continuous* range of values, such as from 12:00 exactly to 12:00 and  $1/3$  second or any values in between. In contrast, a watch with a digital display is limited to *discrete* states. Here the displayed time jumps from 12:00 and 0 seconds to 12:00 and 1 second, without showing the time in between. (A watch with a second hand that jerks from one second to another could also fit the digital analogy.)

In the digital watch example, time is represented by ten distinct states (0, 1, 2, 3, 4, 5, 6, 7, 8 and 9). Digital electronic signals, however, will usually be much more limited in the number of states al-

**Fig 7.1 — An analog signal and its digital approximation. Note that the analog waveform has continuously varying voltage while the digital waveform is composed of discrete steps.**

lowed. *Binary*, the most common system, has only two states: 0 and 1. Ternary (3 states), quaternary (4 states) and other digital systems also exist. **Fig 7.1** illustrates the contrast of an analog signal (in this case a sine wave) and its digital approximation.

While the focus in this chapter will be on digital theory, many circuits and systems involve *both* digital and analog components. Often, a designer may choose between using digital technology, analog technology or a combination.

# Number Systems

In order to understand digital electronics, you must first understand the digital numbering system. Any number system has two distinct characteristics: a set of *symbols* (digits or numerals) and a *base* or *radix*. A *number* is a collection of these digits, where the left-most digit is the *most significant digit (MSD)* and the right-most digit is the *least significant digit (LSD)*. The value of this number is a weighted sum of its digits. The *weights* are determined by the system's base and the digit's position relative to the decimal point.

While these definitions may seem strange with all the technical terms, they will be more familiar when seen in a decimal system example. This is the "traditional" number system we are all familiar with.

## DECIMAL

The decimal system is a base-10 system, with ten symbols: {0, 1, 2, 3, 4, 5, 6, 7, 8, 9}. In the decimal number, 548.21, the digits are 5, 4, 8, 2 and 1, where 5 is the most significant digit since it is positioned to the far left and 1 is the least significant digit since it is positioned to the far right. The value of this number is a weighted sum of its digits, as shown in **Table 7.1**.

The weight of a position is the system's base raised to a power,  $10^P$  with the power determined by the position relative to the decimal. For example, digit 8, immedi-

ately to the left of the decimal, is at position 0; therefore, its weight factor is  $10^0 = 1$ . Similarly, digit 5 is 2 positions to the left of the decimal and has a weight factor  $10^2 = 100$ . The value of the number is the sum of each digit times its weight.

## BINARY

Binary is a *base-2* number system that is limited to two symbols: {0, 1}. The weight factors are now powers of 2, like  $2^0$ ,  $2^1$  and  $2^2$ . For example, the decimal number, 163 and its equivalent binary number, 10100011, are shown in **Table 7.2**.

The digits of a binary number are now *bits* (short for binary digit). The MSD is the *most significant bit (MSB)* and the LSD is the *least significant bit (LSB)*. Four bits make a *nibble* and two nibbles, or eight bits, make a *byte*. A *word* can consist of two or four bytes, and two words (a most significant word, *MSW*, and a least significant word, *LSW*) is sometimes called a *longword*. These groupings are useful when converting to hexadecimal notation, which is explained later.

## OCTAL

Octal is a *base-8* number system, using the symbols {0, 1, 2, 3, 4, 5, 6, 7}. The weight factors are now powers of 8, such as  $8^0$ ,  $8^1$  and  $8^2$ . For example, the decimal number 163 is equivalent to octal 243.

Since  $2^3 = 8$ , it is easy to switch between

binary and octal just by viewing the binary number in groups of 3. (Add a leading 0 on the left most group, if the number of digits doesn't divide evenly into groups of three.)

## HEXADECIMAL

The hexadecimal, or hex, *base-16* number system uses both numbers and characters in its set of sixteen symbols: {0, 1, 2, 3, 4, 5, 6, 7, 8, 9, A, B, C, D, E, F}. Here, the letters A to F have the decimal equivalents of 10 to 15 respectively: A=10, B=11, C=12, D=13, E=14 and F=15. Again, the weights are powers of the base, such as  $16^0$ ,  $16^1$  and  $16^2$ . The decimal number 163 is equivalent to hex A3.

## CONVERSION TECHNIQUES

An easy way to convert a number from decimal to another number system is to do repeated division, recording the remainders in a tower just to the right. The converted number, then, is the remainders, reading up the tower. This technique is illustrated in **Table 7.3** for hexadecimal, octal and binary conversions of the decimal number 163.

For example, to convert decimal 163 to hex, repeated divisions by 16 are performed. The first division gives  $163 / 16 = 10$  remainder 3. The remainder 3 is written in a column to the right. The second division gives  $10 / 16 = 0$  remainder 10. Since 10 decimal = A hex, A is written in the remainder column to the right. This division gave a divisor of 0 so the process is complete. Reading up the remainders column, the result is A3. The most common mistake in this technique is to forget that the Most Significant Digit ends up at the bottom.

Using the repeated division for binary is rather cumbersome, since the tower quickly grows large. Combining this technique with the grouping technique discussed earlier should make conversions fairly easy. Simply perform the tower di-

		Byte																					

vision on one of the larger numbers, such as hexadecimal 16, then use grouping to put the result into binary form.

Another technique that should be briefly mentioned can be even easier: get a calculator with a binary and/or hex mode option. One warning for this technique: this chapter doesn't discuss negative binary numbers. If your calculator does not give you the answer you expected, it may have interpreted the number as negative. This would happen when the number's binary form has a 1 in its MSB, such as the highest (leftmost) bit for the binary mode's default size. To avoid learning about negative binary numbers, always use a leading 0 when you enter a number in binary or hex into your calculator.

### BINARY CODED DECIMAL (BCD)

Scientists have experimented with many devices out of a desire for fast computations. The first generation computers were born when J. Vincent Atanasoff decided to use binary numbers instead of decimal to do his computations. A binary number system representation is the most appropriate form for internal computations since there is a direct mathematical relationship for every bit in the number. To interface with a user — who usually wants to see I/O in terms of decimal numbers — other codes are more useful. The *Binary Coded Decimal (BCD)* system is the simplest and most widely used form for inputs and outputs of user-oriented digital systems.

In the Binary Coded Decimal (BCD) system, each decimal digit is expressed as a corresponding 4-bit binary number. In other words, the decimal digits 0 to 9 are encoded as the bit strings 0000 to 1001. To

**Table 7.3**  
**Number System Conversions**

Hex	Remainder	Octal	Remainder	Binary	Remainder
16   163		8   163		2   163	
10	3	20	3	81	1   LSB
0	A	12	4	40	1
		10	2	20	0
				10	0
				5	0
				2	1
				1	0
				0	1   MSB
A3 hex		243 octal		1010 0011 binary	

**Table 7.4**  
**Binary Coded Decimal Number Conversion**

	0	0	0	1	0	1	1	0	0	0	1	1		BCD
=	1(2 <sup>0</sup> )				1(2 <sup>2</sup> ) + 1(2 <sup>1</sup> )				1(2 <sup>1</sup> ) + 1(2 <sup>0</sup> )					
=	(1)				(4 + 2)				(2 + 1)					
163 =	1				6				3					decimal

make the number easier to read, a space is left between each 4-bit group. For example, the decimal number 163 is equivalent to the BCD number 0001 0110 0011, as shown in **Table 7.4**.

A generic code could use any n-bit string to represent a piece of information. BCD uses 4 bits because that is the minimum needed to represent a 9. All four bits are always written; even a decimal 0 is written as 0000 in BCD.

The important difference between BCD and the previous number systems is that, starting with decimal 10, BCD loses the

standard mathematical relationship of a weighted sum. Instead of using the 4-bit code strings 1010 to 1111 for decimal 10 to 15, BCD uses 0001 0000 to 0001 0101. There are other n-bit decimal codes in use and, even for specifically 4 bits, there are millions of combinations to represent the decimal digits 0-9. BCD is the simplest way to convert between decimal and a binary code, thus it is the ideal form for I/O interfacing. The binary number system, since it maintains the mathematical relationship between bits, is the ideal form for the computer's internal computations.

## Physical Representation Of Binary States

### STATE LEVELS

Most digital systems use the binary number system because many simple physical systems are most easily described by two state levels (0 and 1). For example, the two states may represent "on" and "off," a punched hole or the absence of a hole in paper tape or a card, or a "mark" and "space" in a communications transmission. In electronic systems, state levels are physically represented by voltages. A typical choice is

- state 0 = 0 V
- state 1 = 5 V

Since it is unrealistic to obtain these

exact voltage values, a more practical choice is a range of values, such as

- state 0 = 0.0 to 0.4 V
- state 1 = 2.4 to 5.0 V

**Fig 7.2** illustrates this representation of states by voltage levels. The undefined region between the two binary states is also known as the *transition region* or *noise margin*.

### Transition Time

The gap in Fig 7.2, between binary 0 and binary 1, shows that a change in state does not occur instantly. There is a *transition time* between states. This transition

**Fig 7.2 — Representation of binary states 1 and 0 by a selected range of voltage levels.**

time is a result of the time it takes to charge or discharge the stray capacitance in wires and other components because voltage cannot change instantaneously across a

capacitor. (Stray inductance in the wires also has an affect because the current through an inductor can't change instantaneously.) The transition from a 0 to a 1 state is called the *rise time*. Similarly, the transition from a 1 to a 0 state is called the *fall time*. Note that these times need not be the same. Fig 7.3A shows an ideal signal, or *pulse*, with zero-time switching. Fig 7.3B shows a typical pulse, as it changes between states in a smooth curve.

Rise and fall times vary with the logic family used and the location in a circuit. Typical values of transition time are in the microsecond to nanosecond range. In a circuit, distributed inductances and capacitances in wires or PC-board traces may cause rise and fall times to increase as the pulse moves away from the source.

### Propagation Delay

Rise and fall times only describe a relationship within a pulse. For a circuit, a pulse input into the circuit must propagate through the circuit; in other words it must pass through each component in the circuit until eventually it arrives at the circuit output. The time delay between providing an input to a circuit and to seeing a response at the output is the *propagation*

Fig 7.3 — (A) An ideal digital pulse and (B) a typical actual pulse, showing the gradual transition between states.

delay, and is illustrated by Fig 7.4.

For modern switching logic, typical propagation delay values are in the 1 to 15 nanosecond range. (It is useful to remember that the propagation delay along a wire

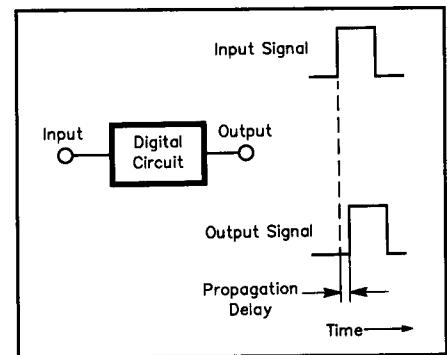

Fig 7.4 — Propagation delay in a digital circuit.

or printed-circuit-board trace is about 1.0 to 1.5 ns per inch.) Propagation delay is the result of cumulative transition times as well as transistor switching delays, reactive element charging times and the time for signals to travel through wires. In complex circuits, different propagation delays through different paths can cause problems when pulses must arrive somewhere at exactly the same time. Solutions to this timing problem include adding a buffer amplifier to the circuit and synchronization of circuits. These are discussed in later sections.

## Combinational Logic

Having defined a way to use voltage levels to physically represent digital numbers, we can apply digital signal theory to design useful circuits. Digital circuits combine binary inputs to produce a desired binary output or combination of outputs. This simple combination of 0s and 1s can become very powerful, implementing everything from simple switches to powerful computers.

A digital circuit falls into one of two types: combinational logic or sequential logic. In a *combinational logic* circuit, the output depends only on the *present inputs*. (If we ignore propagation delay.) In contrast, in a *sequential logic* circuit, the output depends on the present inputs, the *previous sequence of inputs* and often a clock signal. John F. Wakerly, on page 147 of *Digital Design Principles and Practices*, described this difference as follows: "The rotary channel selector knob on an inexpensive TV is like a combinational circuit — its 'output' selects a channel based only on the current position of the knob ('input'). In contrast, the channel selector controlled by the up [+] and down [-]

pushbuttons on a fancy TV or VCR is a sequential circuit — the channel selection depends on the past sequence of up/down pushes...as far back as when you first powered-up the device."

The next section discusses combinational logic circuits. Later, we will build sequential logic circuits from the basics established here.

### BOOLEAN ALGEBRA AND THE BASIC LOGICAL OPERATORS

Combinational circuits are composed of logic gates, which perform binary operations. Logic gates manipulate binary numbers, so you need an understanding of the algebra of binary numbers to understand how logic gates operate. *Boolean algebra* is the mathematical system to describe and design binary digital circuits. It is named after George Boole, the mathematician who developed the system. Standard algebra has a set of basic operations: addition, subtraction, multiplication and division. Similarly, Boolean algebra has a set of basic operations, called *logical operations*: NOT, AND and OR.

The function of these operators can be described by either (A) a Boolean equation or (B) a truth table. A Boolean *equation* describes an operator's function by representing the inputs and the operations performed on them. An equation is of the form " $B = A$ ," while an *expression* is of the form " $A$ ." In an assignment equation, the inputs and operations appear on the right and the result, or output, is assigned to the variable on the left.

A *truth table* describes an operator's function by listing all possible inputs and the corresponding outputs. Truth tables are sometimes written with Ts and Fs (for true and false) or with their respective equivalents, 1s and 0s. In company databooks (catalogs of logic devices a company manufactures), truth tables are usually written with Hs and Ls (for high and low). In the figures, 1 will mean high and 0 will mean low. This representation is called positive logic. The meaning of different logic types and why they are useful is discussed in a later section.

Each Boolean operator also has two circuit symbols associated with it. The tradi-

tional symbol — used by ARRL and other US publications — appears on top in each of the figures; for example, the triangle and bubble for the NOT function in Fig 7.5. In the traditional symbols, a small circle, or *bubble*, always represents “NOT.” (This *bubble* is called a state indicator.) Appearing just below the traditional symbol is the newer ANSI/IEEE Standard symbol. This symbol is always a square box with notations inside it. In these newer symbols, a small flag represents “NOT.” The new notation is an attempt to replace the detailed logic drawing of a complex function with a simpler block symbol.

Figs 7.5, 7.6 and 7.7 show the truth tables, Boolean algebra equations and circuit symbols for the three basic Boolean operations: NOT, AND and OR. All combinational logic functions, no matter how complex, can be described in terms of these three operators.

The NOT operation is also called *inversion*, *negation* or *complement*. The circuit that implements this function is called an *inverter* or *inverting buffer*. The most common notation for NOT is a bar over a variable or expression. For example, NOT A is denoted  $\bar{A}$ . This is read as either “Not A” or as “A bar.” A less common notation is to denote Not A by  $A'$ , which is read as “A prime.”

While the inverting buffer and the noninverting buffer covered later have only one input and output, many combina-

tional logic elements can have multiple inputs. When a combinational logic element has two or more inputs and one output, it is called a *gate*. (The term “gate” has many different but specific technical uses. For a clarification of the many definitions of gate, see the section on Synchronicity and Control Signals, later in this chapter.) For simplicity, the figures and truth tables for multiple-input elements will show the operations for only two inputs, the minimum number.

The output of an AND function is 1 only if *all* of the inputs are 1. Therefore, if *any* of the inputs are 0, then the output is 0. The notation for an AND is either a dot ( $\bullet$ ) between the inputs, as in  $C = A \bullet B$ , or nothing between the inputs, as in  $C = AB$ . Read these equations as “C equals A AND B.”

The OR gate detects if one or more inputs are 1. In other words, if *any* of the inputs are 1, then the output of the OR gate is 1. Since this includes the case where more than one input may be 1, the OR operation is also known as an *INCLUSIVE OR*. The OR operation detects if *at least one* input is 1. Only if all the inputs are 0, then the output is 0. The notation for an OR is a plus sign (+) between the inputs, as in  $C = A + B$ . Read this equation as “C equals A OR B.”

### Other Common Gates

More complex logical functions are derived from combinations of the basic logical operators. These operations —

NAND, NOR, XOR, XNOR and the noninverter — are illustrated in Figs 7.8 through 7.12 respectively. As before, each is described by a truth table, Boolean algebra equation and circuit symbols. Also as before, except for the noninverter, each could have more inputs than the two illustrated.

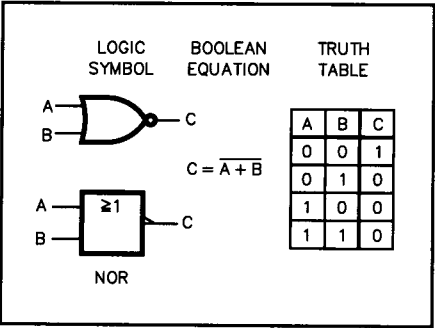

Fig 7.9 — Two-input NOR gate.

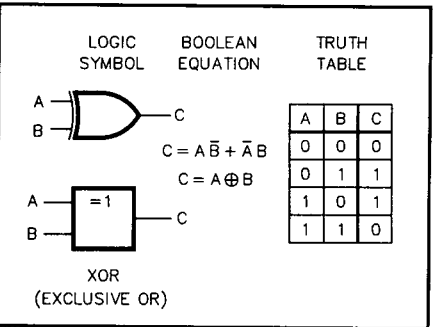

Fig 7.10 — Two-input XOR gate.

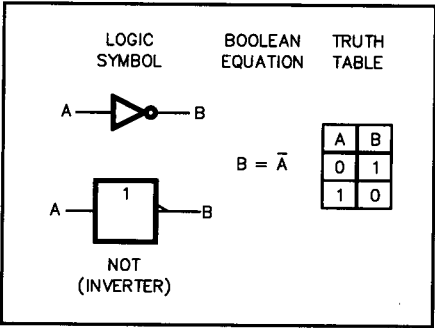

Fig 7.5 — Inverter.

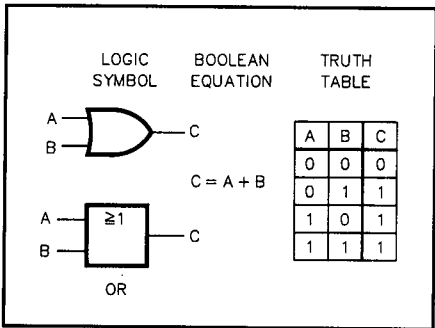

Fig 7.7 — Two-input OR gate.

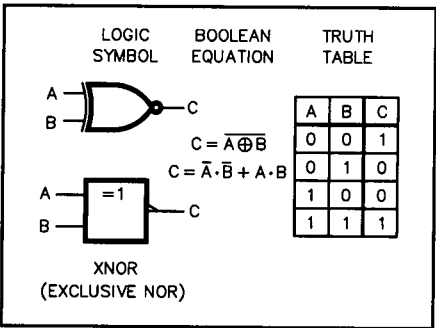

Fig 7.11 — Two-input XNOR gate.

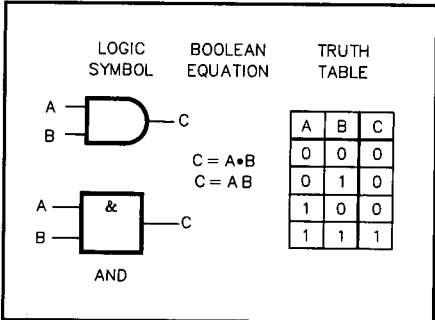

Fig 7.6 — Two-input AND gate.

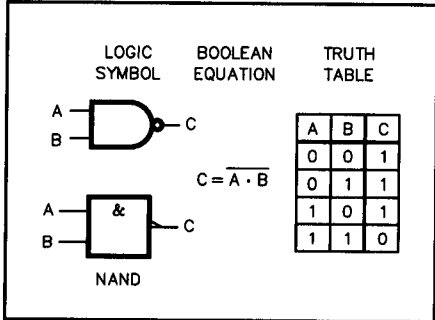

Fig 7.8 — Two-input NAND gate.

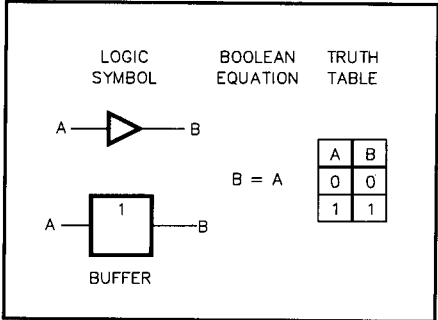

Fig 7.12 — Noninverting buffer

The NAND gate (short for NOT AND) is equivalent to an AND gate followed by a NOT gate. Thus, its output is the complement of the AND output: The output is a 0 only if all the inputs are 1. If any of the inputs is 0, then the output is a 1.

The NOR gate (short for NOT OR) is equivalent to an OR gate followed by a NOT gate. Thus, its output is the complement of the OR output: If any of the inputs are 1, then the output is a 0. Only if all the inputs are 0, then the output is a 1.

The operations so far enable a designer to determine two general cases: (1) if *all* inputs have a desired state or (2) if *at least one* input has a desired state. The XOR and XNOR gates enable a designer to determine if *one and only one* input of a desired state is present.

The XOR gate (read as EXCLUSIVE OR) has an output of 1 if one and only one of the inputs is a 1 state. The output is 0 otherwise. The symbol for XOR is  $\oplus$ . This is easy to remember if you think of the “+” OR symbol enclosed in an “O” for *only one*.

The XOR gate is also known as a “half adder,” because in binary arithmetic it does everything but the “carry” operation. The following examples show the possible binary additions for a two-input XOR.

0	0	1	1
0	1	0	1
0	1	1	0

The XNOR gate (read as EXCLUSIVE NOR) is the complement of the XOR gate. The output is 0 if one and only one of the inputs is a 1. The output is 1 either if all inputs are 0 or more than one input is 1.

### Noninverter

A *noninverter*, also known as a *buffer*, *amplifier* or *driver*, at first glance does not seem to do anything. It simply receives an input and produces the same output. In reality, it is changing other properties of the signal in a useful fashion, such as amplifying the current level. The practical

uses of a noninverter include (A) providing sufficient current to drive a number of gates, (B) interfacing between two logic families, (C) obtaining a desired pulse rise time and (D) providing a slight delay to make pulses arrive at the proper time.

## BOOLEAN THEOREMS

The analysis of a circuit starts with a logic diagram and then derives a circuit description. In digital circuits, this description is in the form of a truth table or logical equation. The *synthesis*, or design, of a circuit goes in the reverse: starting with an informal description, determining an equation or truth table and then expanding the truth table to components that will implement the desired response. In both of these processes, we need to either sim-

plify or expand a complex logical equation.

To manipulate an equation, we use mathematical *theorems*. Theorems are statements that have been proven to be true. The theorems of Boolean algebra are very similar to those of standard algebra, such as commutativity and associativity. Proofs of the Boolean algebra theorems can be found in an introductory digital design textbook.

### Basic Theorems

**Table 7.5** lists the theorems for a single variable and **Table 7.6** lists the theorems for two or more variables. These tables illustrate the *principle of duality* exhibited by the Boolean theorems: Each theorem has a dual in which, after swapping all

**Table 7.5**

#### Boolean Algebra Single Variable Theorems

Identities:	$A \cdot 1 = A$	$A + 0 = A$
Null elements:	$A \cdot 0 = 0$	$A + 1 = 1$
Idempotence:	$A \cdot A = A$	$A + A = A$
Complements:	$A \cdot \bar{A} = 0$	$A + \bar{A} = 1$
Involution:	$\overline{\bar{A}} = A$	

**Table 7.6**

#### Boolean Algebra Multivariable Theorems

Commutativity:	$A \cdot B = B \cdot A$ $A + B = B + A$
Associativity:	$(A \cdot B) \cdot C = A \cdot (B \cdot C)$ $(A + B) + C = A + (B + C)$
Distributivity:	$(A + B) \cdot (A + C) = A + B \cdot C$ $A \cdot B + A \cdot C = A \cdot (B + C)$
Covering:	$A \cdot (A + B) = A$ $A + A \cdot B = A$
Combining:	$(A + B) \cdot (A + \bar{B}) = A$ $A \cdot B + A \cdot \bar{B} = A$
Consensus:	$A \cdot B + \bar{A} \cdot C + B \cdot C = A \cdot B + \bar{A} \cdot C$ $(A + B) \cdot (\bar{A} + C) \cdot (B + C)$ $= (A + B) \cdot (A + C)$

**Table 7.7**

#### DeMorgan's Theorem

(A)  $\overline{A \cdot B} = \bar{A} + \bar{B}$

(B)  $\overline{A + B} = \bar{A} \cdot \bar{B}$

(C)

(1)	(2)	(3)	(4)	(5)	(6)	(7)	(8)	(9)	(10)
A	B	$\bar{A}$	$\bar{B}$	$A \cdot B$	$\overline{A \cdot B}$	$A + B$	$\overline{A + B}$	$\bar{A} \cdot \bar{B}$	$\bar{A} + \bar{B}$
0	0	1	1	0	1	0	1	1	1
0	1	1	0	0	1	1	0	0	1
1	0	0	1	0	1	1	0	0	1
1	1	0	0	1	0	1	0	0	0

(A) and (B) are statements of DeMorgan's Theorem. The truth table at (C) is proof of these statements: (A) is proven by the equivalence of columns 6 and 10 and (B) by columns 8 and 9.

ANDs with ORs and all 1s with 0s, the statement is still true.

The tables also illustrate the *precedence* of the Boolean operations: the order in which operations are performed when not specified by parenthesis. From highest to lowest, the precedence is NOT, AND then OR. For example, the distributive law includes the expression " $A + B \cdot C$ ." This is equivalent to " $A + (B \cdot C)$ ." The parenthesis around  $(B \cdot C)$  can be left out since an AND operation has higher priority than an OR operation. Precedence for Boolean algebra is similar to the convention of standard algebra: raising to a power, then multiplication, then addition.

### DeMorgan's Theorem

One of the most useful theorems in Boolean algebra is DeMorgan's Theorem:  $\overline{A \cdot B} = \overline{A} + \overline{B}$  and its dual  $\overline{A + B} = \overline{A} \cdot \overline{B}$ . The truth table in Table 7.7 proves these statements. DeMorgan's Theorem provides a way to simplify the complement of a large expression. It also enables a designer to interchange a number of equivalent gates, as shown by Fig 7.13.

The equivalent gates show that the duality principle works with symbols the same as it does for Boolean equations: just swap ANDs with ORs and switch the bubbles. For example, the NAND gate — an AND gate followed by an inverter bubble — becomes an OR gate preceded by two inverter bubbles. DeMorgan's Theorem is important because it means any logical function can be implemented using either inverters and AND gates or inverters and OR gates. Also, the ability to change placement of the bubbles using DeMorgan's theorem is useful in dealing with mixed logic, to be discussed next.

### POSITIVE AND NEGATIVE LOGIC

The truth tables shown in the figures in this chapter are drawn for positive logic. In *positive logic*, or *high true*, a higher voltage means true (logic 1), while a lower voltage means false (logic 0). This is also referred to as *active high*: a signal performs a named action or denotes a condi-

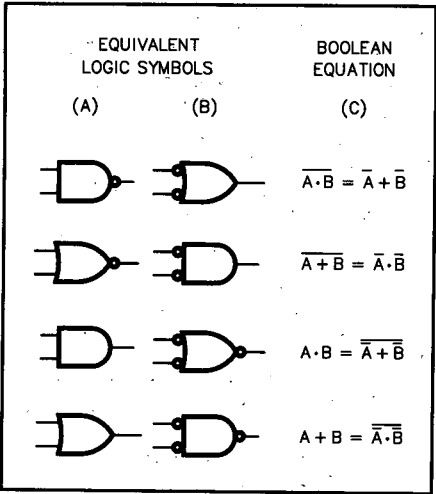

Fig 7.13 — Equivalent gates from DeMorgan's Theorem: Each gate in column A is equivalent to the opposite gate in column B. The Boolean equations in column C formally state the equivalencies.

tion when it is "high" or 1. In *negative logic*, or *low true*, a lower voltage means true (1) and a higher voltage means false (0). An *active low* signal performs an action or denotes a condition when it is "low" or 0.

In both logic types, true = 1 and false = 0; but whether true means high or low differs. Company databooks are drawn for general truth tables: an "H" for high and an "L" for low. (Some tables also have an "X" for a "don't care" state.) The function of the table can differ depending on whether it is interpreted for positive logic or negative logic. Fig 7.14 shows how a general truth table differs when interpreted for different logic types. The same truth table gives the function of a NAND gate while negative logic gives the function of a NOR gate.

Note that these gates correspond to the equivalent gates from DeMorgan's theorem. A bubble on an input or output terminal indicates an active low device. The

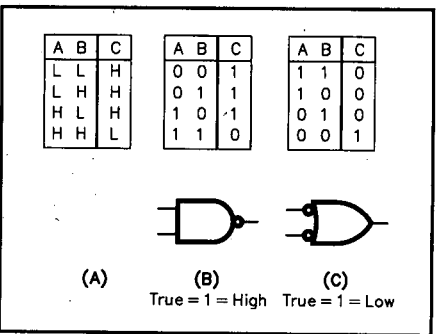

Fig 7.14 — (A) A general truth table, (B) a truth table and NAND symbol for positive logic and (C) a truth table and NOR symbol for negative logic.

absence of bubbles indicates an active high device.

Like the bubbles, signal names can be used to indicate logic states. These names can aid the understanding of a circuit by indicating control of an action (GO, /ENABLE) or detection of a condition (READY, /ERROR). The action or condition occurs when the signal is in its active state. When a signal is in its active state, it is called *asserted*; a signal not in its active state is called *negated* or *deasserted*. A prefix can easily indicate a signal's active state: active low signals are preceded by a "/", like /READY, while active high signals have no prefix. Standard practice is that the signal name and input pin match (have the same active level). For example, an input with a bubble (active low) may be called /READY while an input with no bubble (active high) is called READY. Output signal names should always match the device output pin.

In this chapter, positive logic is used unless indicated otherwise. Although using mixed logic can be confusing, it does have some advantages. Mixed logic combined with DeMorgan's Theorem can promote more effective use of available gates. Also, well-chosen signal names and placement of bubbles can promote more understandable logic diagrams.

# Sequential Logic

The previous section discussed combinational logic, whose outputs depend only on the present inputs. In contrast, in *sequential logic* circuits, the new output depends not only on the present inputs but also on the present outputs. The present outputs depended on the previous inputs and outputs and those earlier outputs depended on even earlier inputs and outputs and so on. Thus, the present outputs depend on the previous *sequence of inputs* and the system has *memory*. Having the outputs become part of the new inputs is known as *feedback*.

This section first introduces a number of terms necessary to understand sequential logic: types of synchronicity, types of control signals and ways to illustrate circuit function. Numerous sequential logic circuits are then introduced. These circuits provide an overview of the basic sequential circuits that are commercially available. Depending on your approach to learning, you may choose to either (1) read the material in the order presented, definitions then examples, or (2) start with the example circuits, which begin with the flip-flop, referring back to the definitions as needed.

## SYNCHRONICITY AND CONTROL SIGNALS

When a combinational circuit is given a set of inputs, the outputs take on the expected values after a propagation delay during which the inputs travel through the circuit to the output. In a sequential circuit, however, the travel through the circuit is more complicated. After application of the first inputs and one propagation delay, the outputs take on the resulting state; but then the outputs start trickling back through and, after a second propagation delay, new outputs appear. The same happens after a third propagation delay. With propagation delays in the nanosecond range, this cycle around the circuit is rapidly and continually generating new outputs. A user needs to know when the outputs are valid.

There are two types of sequential circuits: synchronous circuits and asynchronous circuits, which are analyzed differently for valid outputs. In *asynchronous* operation, the outputs respond to the inputs immediately after the propagation delay. To work properly, this type of circuit must eventually reach a *stable* state: the inputs and the fed back outputs result in the new outputs staying the same. When the nonfeedback inputs are changed, the feedback cycle needs to eventually reach a new stable state.

In *synchronous* operation, the outputs change state only at specific times. These times are determined by the presence of a particular input signal: a clock, toggle, latch or enable. Synchronicity is important because it ensures proper timing: all the inputs are present where needed when the control signal causes a change of state.

Some authors vary the meanings slightly for the different control signals. The following is a brief illustration of common uses, as well as showing uses for noun, verb and adjective. *Enabling* a circuit generally means the control signal goes to its asserted level, allowing the circuit to change state. *Latch* implies memory: (noun) a circuit that stores a bit of information or (verb) to hold at the same output state. *Gate* has many meanings, some unrelated to synchronous control: (A) a signal used to trigger the passage of other signals through a circuit (for example, "A gate circuit passes a signal only when a gating pulse is present."), (B) any logic circuit with two or more inputs and one output (used earlier in this chapter) or (C) one of the electrodes of an FET (as described in the *Analog Signals and Components* chapter). To *toggle* means a signal changes state, from 1 to 0 or vice versa. A *clock* signal is one that toggles at a regular rate.

Clock control is the most common method, so it has some additional terms, illustrated by Fig 7.15. The *clock period* is the time between successive transitions in the same direction; the *clock frequency* is the reciprocal of the period. A *pulse* or *clock tick* is the first edge in a clock period, or sometimes the period itself or the first half of the period. The *duty cycle* is the percentage of time that the clock signal is at its asserted level.

The reaction of a synchronous circuit to its control signal is *static* or *dynamic*. Static, *gated* or *level-triggered* control allows the circuit to change state whenever the control signal is at its active or asserted level. Dynamic, or *edge-triggered*, control allows the circuit to change state only when the control signal *changes* from unasserted to asserted. By convention, a control signal is active high if state changes occur when the signal is high or at the rising edge and active low in the opposite case. Thus, for positive logic, the convention is enable = 1 or enable goes from 0 to 1. This transition from 0 to 1 is called *positive edge-triggered* and is indicated by a small triangle inside the circuit box. A circuit responding to the opposite transition, from 1 to 0, is called *negative edge-triggered*, indicated by a bubble with the

triangle. Whether a circuit is level-triggered or edge-triggered can affect its output, as shown by Fig 7.16. Input D includes a very brief pulse, called a *glitch*, which may be caused by noise. The differing results at the output illustrate how noise can cause errors.

## ILLUSTRATING CIRCUIT FUNCTION

Since the action of sequential circuits is more complex, many ways have been developed to examine circuit function. Fig 7.17 shows an example for each type of table or diagram. Each type has advantages and disadvantages.

### State Transition Tables

Describing a sequential circuit with the

Fig 7.15 — Clock signal terms. The duty cycle would be  $t_H / t_{\text{PERIOD}}$  for an active high signal and  $t_L / t_{\text{PERIOD}}$  for an active low signal.

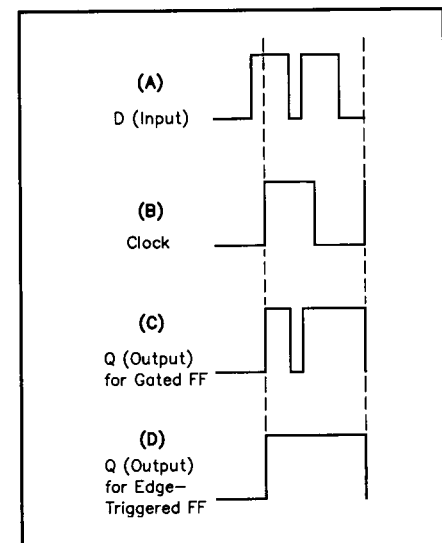

Fig 7.16 — Level-triggered vs edge-triggered for a D flip-flop: (A) input D, (B) clock input, (C) output Q for level-triggered: circuit responds whenever clock is 1. (D) output Q for edge-triggered: circuit responds only at rising edge of clock. Notice that the short negative pulse on the input D is not reproduced by the edge-triggered flip-flop.

conventional truth table would require an infinite number of previous events as the possible inputs. Instead, the sequential logic form of the truth table is called a state transition table. A *state transition* (or excitation) *table* lists all combinations of present inputs and feedback outputs — the *current state*, represented by small  $q$ , and the resulting outputs, both feedback and nonfeedback and the *next state*, represented by capital  $Q$ . The state transition table is the most common way to describe sequential circuit function, since it lists all possibilities.

### Characteristic Equation

An equivalent equation for a state transition table or excitation table can be written in terms of the state variables, a symbol for each input and output. Although the number of state variables can be very large for a complex system, there is always a limited number of inputs and outputs; thus, the combinations of inputs and outputs is also limited. A circuit with  $n$  binary state variables has  $2^n$  possible states. Since the possible states,  $2^n$ , are always finite, sequential circuits are also known as *finite-state machines*. Each of the sequential logic circuits in this section includes a state table to illustrate the circuit functions. As before, these tables are for positive logic, so 1s and 0s are already substituted for Highs and Lows.

### Excitation Table

An *excitation table* is derived from the truth table. Its usefulness is to show, for each possible output  $Q_n$  what inputs are needed to obtain a desired output  $Q_{n+1}$ . For some outputs, one or more of the input variables may not have an effect. In this case, the input variable corresponds to a *don't care* state, represented by an "X" or dash.

### Timing Diagram

When a clock is the controlling signal, a timing diagram can describe the circuit operation. A *timing diagram* draws a circuit's signals as a function of time. This form emphasizes the cause-and-effect delays between critical signals. It is especially useful in detecting errors, as will be shown in the flip-flop implementations to be presented. There are software packages available to *simulate* a circuit. The simulation produces the timing diagram for a given set of inputs, allowing the designer to examine the timing diagram for expected results.

### State Diagram

A *state diagram* depicts output changes in terms of a flow chart. Each possible

Fig 7.17 — Sequential circuit function for a clocked S-R flip-flop: (A) state transition table or truth table, (B) characteristic equation, including its derivation from the state table, (C) excitation table, (D) partial timing diagram, (E) state diagram.

state is listed inside a circle with arrows between the circles to indicate possible next states. State diagrams are especially useful for studying a sequence of inputs and the corresponding result.

### FLIP-FLOPS

Flip-flops are the basic building blocks of sequential circuits. A *flip-flop* is a device with two stable states: the *set* state (1) or the *reset* state (0). (The reset state is also called the *cleared* state.) The flip-flop can be placed in one or the other of the two states by applying the appropriate input. (Since a common use of flip-flops is to store one bit of information, some use the term *latch* interchangeably with flip-flop. A set of latches, or flip-flops holding an  $n$ -bit number is called a register.) While gates have special symbols, the schematic symbol for most components is a rectangular box with the circuit name or abbreviation, the signal names and assertion bubbles. For flip-flops, the circuit name is usually omitted since the signal names are enough to indicate a flip-flop and its type. The four basic types of flip-flops are the S-R, D, T and J-K. The first section examines the S-R flip-flop for each of the various control methods. The next section introduces each of the other basic flip-flops and their uses.

### S-R Flip-Flop

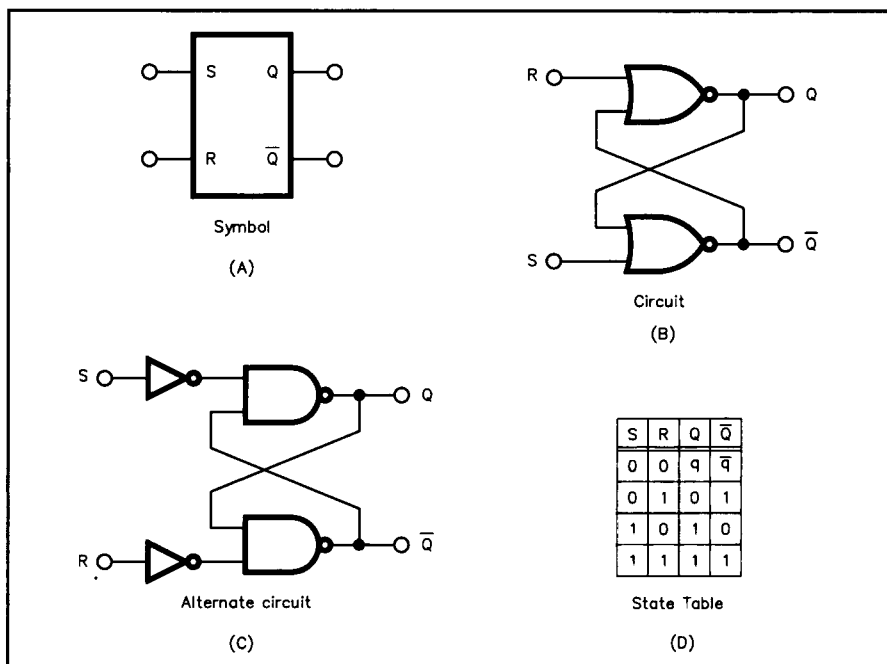

The S-R flip-flop is one of the simplest circuits for storing a bit of information. It

has two inputs, represented by  $S$  (set) and  $R$  (reset). These inputs, naturally, cause the two possible output states: if  $S = 1$  and  $R = 0$ , then output  $Q$  is set to 1; if  $S = 0$  and  $R = 1$ , then output  $Q$  is reset to 0; if both inputs are 0, then the output remains unchanged; and if both inputs are 1, then the output cannot be determined. The S-R flip-flop can illustrate each of the types of control signals: unlocked (asynchronous, no control signal), clocked or gated, master-slave and edge-triggered.

### Unlocked/Sequential

The unlocked S-R flip-flop, shown in Fig 7.18, is an asynchronous device; its outputs change immediately to reflect changes on its inputs. The circuit consists of two NOR gates. The sequential nature of the circuit is a result of the output of each NOR gate being fed back as an input to the opposite gate. The state transition table shows the expected set/reset pattern of inputs to outputs. The table shows an unpredictable result for inputs  $S = 1$  and  $R = 1$ . In actual circuits, the results vary and are usually either  $Q = \bar{Q} = 1$  or  $Q = \bar{Q} = 0$ . While  $Q = \bar{Q}$  is a logical impossibility, real flip-flops may present this output. The designer should avoid the  $R = S = 1$  input and make no assumptions about the resulting output. The flip-flop is not predictable if both inputs go to 0 at exactly the same time.

Fig 7.18C shows an alternate implementation of the S-R flip-flop, with two NAND

**Fig 7.18 — Unclocked S-R Flip-Flop. (A) schematic symbol. (B) circuit diagram. (C) alternate circuit. (D) state table.**

gates and two inverters. Since a NAND gate can become an inverter by having its two inputs receive the same signal, the S-R flip-flop can be implemented with four NAND gates. This alternate version is important because a 4-NAND gate chip is one of the most readily available commercial integrated circuits; thus, the 4-NAND gate S-R flip-flop can be implemented on a single IC.

### Gated or Level-triggered

The gated S-R flip-flop, or gated latch, has a controlling input in addition to its S and R inputs. The inputs S and R produce the same results as those on an unlocked S-R flip-flop, but a change in output will only occur when the control input is high. A gated S-R flip-flop is illustrated in Fig 7.19 along with a timing diagram for a clock input. This flip-flop is also called the R-S-T flip-flop, where "T," for toggle, is the clock input. Although not often used, the R-S-T flip-flop is important because it illustrates a step between the R-S flip-flop and the J-K flip-flop.

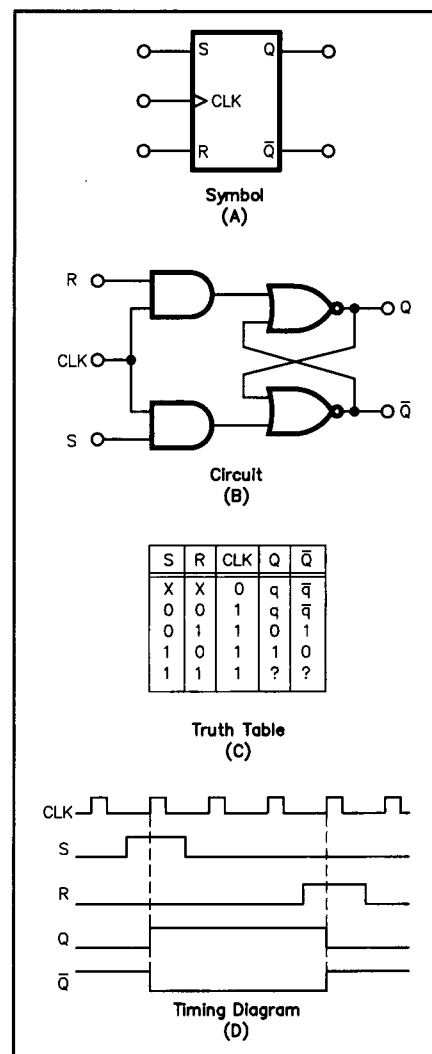

A problem with the level-triggered flip-flop is that the Q output can change more than once while the clock is asserted. We would prefer the output to change only once per clock period for easier timing design. A second problem can occur when flip-flops are connected in series and triggered by the same clock pulse or, similarly, when a flip-flop is in series with itself, using its own output as an input. Since

the series-connected flip-flop feeds back to itself, its output will be changing at about the same time as it receives new input. This can result in an erroneous output.

### Master/Slave Flip-Flop

A solution to the problems of the level-triggered method is a circuit that samples and stores its inputs before changing its outputs. Such a circuit is built by placing two flip-flops in series; both flip-flops are triggered by a common clock but an inverter on the second flip-flop's clock causes it to be asserted only when the first flip-flop is not asserted. The action for a given clock pulse is as follows: The first, or *master*, flip-flop is active when the clock is high, sampling and storing the inputs. The second, or *slave*, flip-flop gets its input from the master and acts when the clock is low. Hence, when the clock is 1, the input is sampled; then when the clock becomes 0, the output is generated. A master/slave flip-flop is built with either two S-R flip-flops, as shown by Fig 7.20, or with two J-K flip-flops. Note that a bubble appears on the schematic symbol's clock input, reminding us that the output appears when the clock is asserted low. This is conventional for TTL-style J-K flip-flops, but it can be different for CMOS devices.

The master/slave method isolates output changes from input changes, eliminating the problem of series-fed circuits. It also ensures only one new output per clock period, since the slave flip-flop responds

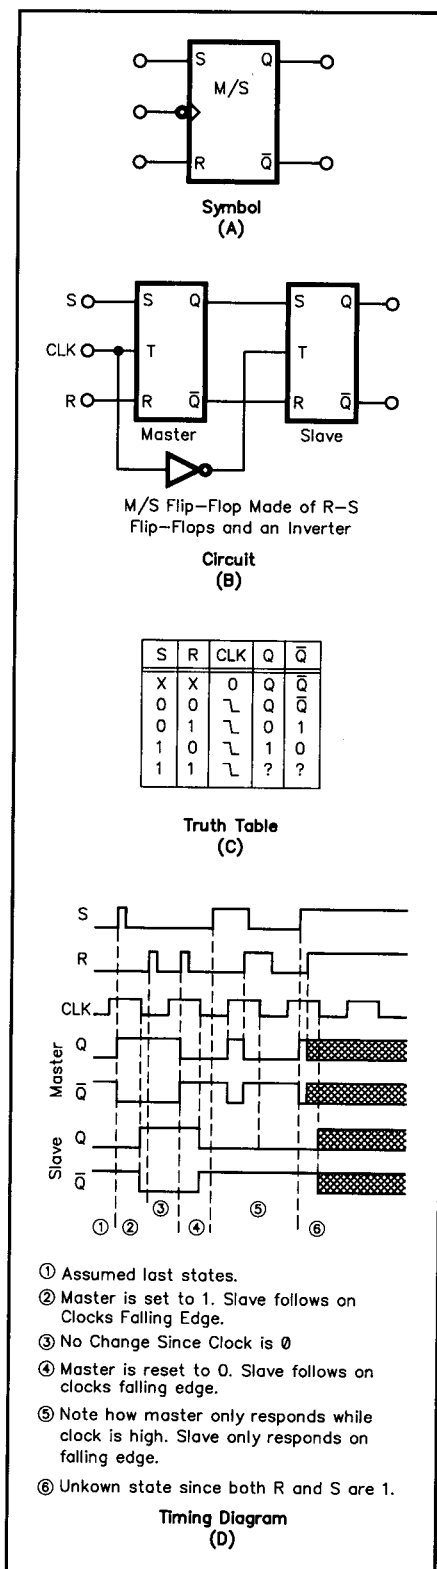

**Fig 7.19 — Clocked S-R Flip-Flop. (A) schematic symbol. (B) circuit. (C) truth table. (D) timing diagram.**

to only the single sampled input. A problem can still occur, however, because the master flip-flop can change more than once while it is asserted; thus, there is the potential for the master to sample at the wrong time. There is also the potential that either flip-flop can be affected by noise.

### Edge-Triggered Flip-Flop

The edge-triggered flip-flop solves the problem of noise. An example of noise is the glitch shown earlier in Fig 7.16. The different outputs for the level and edge-triggered methods in this figure show how a glitch can cause an output error. Edge-triggering avoids the problem of noise by minimizing the time during which a circuit responds to its inputs: the chance of a glitch occurring during the nanosecond transition of a clock pulse is remote. A side benefit of edge-triggering is that only one new output is produced per clock

**Fig 7.20 — Master/Slave S-R Flip-Flop.** (A) schematic symbol. (B) circuit. (C) truth table. (D) timing diagram.

period. Edge-triggering is denoted by a small rising-edge or falling-edge symbol such as  $\lrcorner$  or  $\llcorner$ ; sometimes an arrow is included such as  $\lrcorner$  or  $\llcorner$ . This symbol

appears in the circuit's truth table and can also appear, instead of the clock triangle, inside the schematic symbol.

### Other Flip-flops

**Table 7.8** provides a summary of the four basic flip-flops: the S-R (Set-Reset), D (Data or Delay), T (Toggle) and J-K. Each is briefly explained below, including its particular applications. The internal circuitry of each of these flip-flops is similar to the components and complexity of the S-R flip-flop. Readers may be interested in trying to design their own circuit implementation for a flip-flop type and control method; however, in practical use, a commercially available integrated circuit chip would probably be used. Company databooks include the individual circuit implementation for each IC. Digital design textbooks will also show sample

circuit implementations for each of the flip-flops.

### D Flip-Flop

In a D (data) flip-flop, the *data* input is transferred to the outputs when the flip-flop is enabled: The logic level at input D is transferred to Q when the clock is positive; the Q output retains this logic level until the next positive clock pulse (see Fig 7.21). The flip-flop is also called a *delay* flip-flop because, once enabled, it passes D after a propagation delay. A D flip-flop is useful to store one bit of information. A collection of D flip-flops forms a register.

### Toggle Flip-Flop

In a T flip-flop, the output *toggles* (changes state) with each positive clock pulse. The T flop-flop is also called a

Fig 7.21 — (A) The D flip-flop. When  $T = 0$ ,  $Q$  and  $\bar{Q}$  states don't change. When  $T = 1$ , the output states change to reflect the D input. (C) A truth table for the D flip-flop.

Fig 7.22 — (A) A clocked S-R-T flip-flop wired as a T flip-flop. (B) A D flip-flop wired as a T flip-flop. (C) Timing diagram. Notice that the output frequency is half the input frequency.

complementing flip-flop. Fig 7.22 shows how a T flip-flop can be created from either an S-R or D flip-flop. The timing diagram in Fig 7.22 shows an important result of the T-flip-flop: the output frequency is one half of the input frequency. Thus, a T flip-flop is a 2:1 (also called *modulo-2* or *radix-2*) frequency divider. Two T flip-flops connected in series form a 4:1 divider and so on.

### J-K Flip-Flop

It's somewhat ironic that the most readily available flip-flop, the J-K flip-flop, is discussed last and so briefly. The discussion is short because the J-K flip-flop acts the same as the S-R flip-flop

(where  $J = S$  and  $K = R$ ) with only one difference: The S-R flip-flop had the disadvantage of invalid results for the inputs 1,1. For the J-K flip-flop, simultaneous 1,1 inputs cause  $Q$  to change state after the clock transition.

### Summary

Only the D and J-K flip-flops are generally available as commercial integrated circuit chips. Since memory and temporary storage are so often desirable, the D flip-flop is manufactured as the simplest way to provide memory. When more functionality is needed, the J-K flip-flop is available. The J-K flip-flop can substitute for an S-R flip-flop and a T flip-flop can

be created from either the D or J-K flip-flop.

## COUNTERS

Groups of flip-flops can be combined to make counters. Toggle flip-flops are the most common for implementing a counter. Intuitively, a counter is a circuit that starts at state 0 and sequences up through states 1, 2, 3, ... to  $m$ , where  $m$  is the maximum number of states available. From state  $m$ , the next state will return the counter to 0. This describes the most common counter: the *n-bit binary counter*, with  $n$  outputs corresponding to  $2^n = m$  states. Such a counter can be made from  $n$  flip-flops, as shown in Fig 7.23. This figure shows implementations for each of the types of synchronicity. Both circuits pass the data count from stage to stage. In the asynchronous counter, Fig 7.23A, the clock is also passed from stage to stage and the circuit is called *ripple* or *ripple-carry*. In the synchronous counter, Fig 7.23B, each stage is controlled by a common clock signal.

There are numerous variations on this first example of a counter. Most counters have the ability to *clear* the count to 0. Some counters can also *preset* to a desired count. The clear and preset control inputs are often asynchronous — they change the output state without being clocked. Counters may either count up (increment) or down (decrement). *Up/down* counters can be controlled to count in either direction. Counters can have sequences other than the standard numbers, for example a BCD counter.

Counters are also not restricted to changing state on every clock cycle. An  $n$ -bit counter that changes state only after  $m$  clock pulses is called a *divider* or *divide-by- $m$*  counter. There are still  $2^n = m$  states, however, the output after  $p$  clock pulses is now  $p / m$ . Combining different divide-by- $m$  counters can result in almost any desired count. For example, a base 12 counter can be made from a divide-by-2 and a divide-by-6 counter; a base 10 (decade) counter consists of a divide-by-2 and a BCD divide-by-5 counter.

The outputs of these counters are binary. To produce output in decimal form, the output of a counter would be provided to a binary-to-decimal decoder chip and/or an LED display.

## REGISTERS

Groups of flip-flops can be combined to make registers, usually implemented with D flip-flops. A *register* stores  $n$  bits of information, delivering that information in response to a clock pulse. Registers

usually have asynchronous *set* to 1 and *clear* to 0 capabilities.

Storage Register

A storage register simply stores temporary information, for example incoming information or intermediate results. The size is related to the basic size of information handled by a computer: 8 flip-flops for an 8-bit or *byte register* or 16 bits for a *word register*. Fig 7.24 shows a typical circuit and schematic symbols for an 8-bit storage register. In (C), although the bits are passed on 8 separate lines (from 8 flip-flops), a slash and number, “/8,” is used to simplify the symbol. Storage registers are important to computer architecture; this topic is discussed in depth later in the chapter.

Shift Register

Shift registers also store information and provide it in response to a clock signal, but they handle their information differently: When a clock pulse occurs, instead of each flip-flop passing its result to the output, the flip-flops pass their data to each other, up and down the row. For example, in up mode, each flip-flop receives the output of the preceding flip-flop. A data bit starting in flip-flop D0 in a left shifter would move to D1, then D2 and so on until it is shifted out of the register. If a 0 was input to the least significant bit, D0, on each clock pulse then, when the last data bit has been shifted out, the register contains all 0s.

Shift registers can be left shifters, right shifters or controlled to shift in either direction. The most general form, a *universal shift register*, has two control inputs for four states: Hold, Shift right, Shift left and Load. Most also have asynchronous inputs for preset, clear and parallel load. The primary use of shift registers is to convert parallel information to serial or vice versa. This is useful in interfacing between devices, and is discussed in detail in the Digital Interfacing section.

Additional uses for a shift register are to (1) delay or synchronize data, (2) multiply or divide a number by a factor  $2^n$  or (3) provide random data. Data can be delayed simply by taking advantage of the Hold feature of the register control inputs. Multiplication and division with shift registers is best explained by example: Suppose a 4-bit shift register currently has the value  $1000 = 8$ . A right shift results in the new parallel output  $0100 = 4 = 8 / 2$ . A second right shift results in  $0010 = 2 = (8 / 2) / 2$ . Together the 2 right shifts performed a division by  $2^2$ . In general, shifting right  $n$  times is equivalent to dividing by  $2^n$ . Similarly, shifting left multiplies by  $2^n$ . This can be useful to compiler writers to make a computer program run faster.

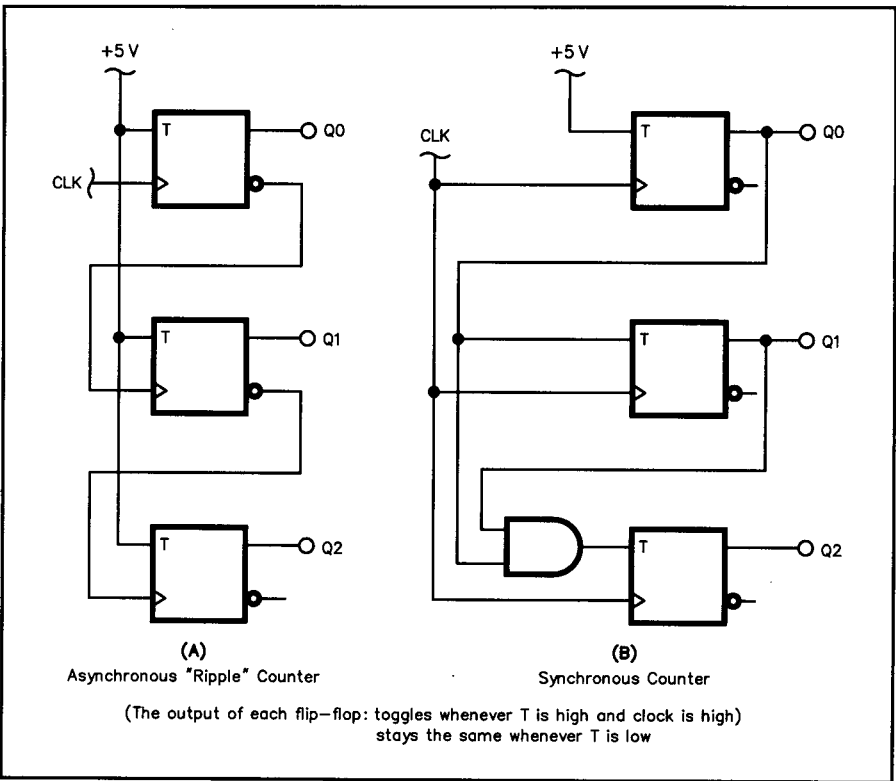

Fig 7.23 — Three-bit binary counter: (A) asynchronous or ripple counter, (B) synchronous counter.

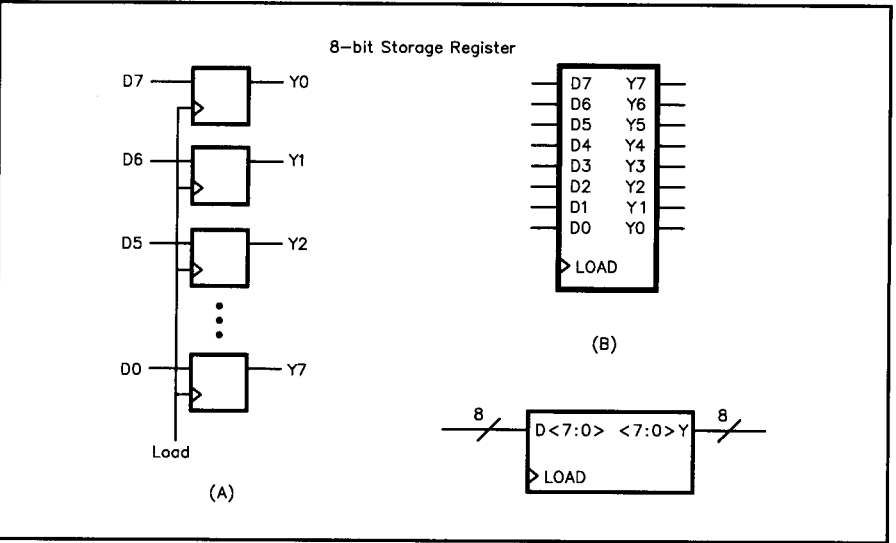

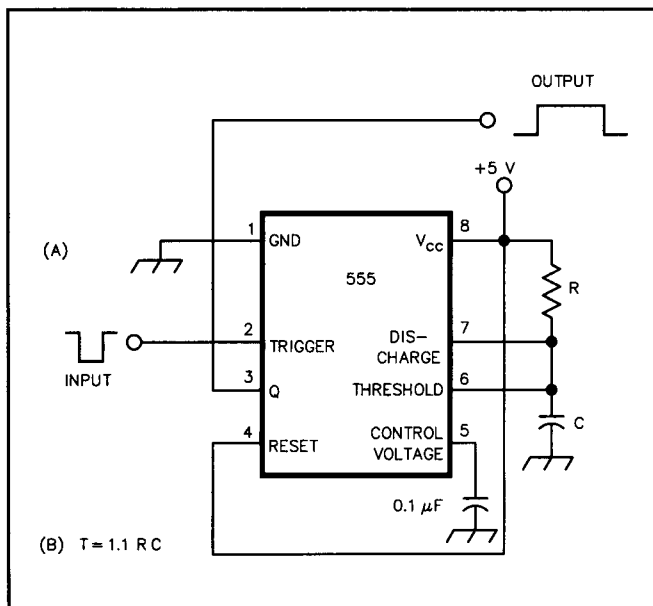

Fig 7.24 — An eight-bit storage register: (A) circuit, (B) and (C) schematic symbols.

Random data is provided via a ring counter. A *ring counter* is a shift register with its output fed back to its input. At each clock pulse, the register is shifted up or down and some of the flip-flops feedback to other flip-flops, generating a random binary number. Shift registers with several feedback paths can be used as a *pseudorandom number gen-*

*erator*, where the sequence of bits output by the generator meets one or more mathematical criteria for randomness.

MULTIVIBRATORS

A multivibrator is widely used as a switch and comes in three basic forms: bistable, monostable and astable. It is

**Fig 7.25 — (A) A 555 timer connected as a monostable multivibrator. (B) The equation to calculate values for R (in ohms) and C (in farads), where T is the pulse duration (in seconds).**

broadly defined as a closed-loop, regenerative circuit that alternates between two stable or quasi-stable states. The flip-flop is a *bistable multivibrator*: both of its two states are stable; it can be triggered from one stable state to the other by an external signal. To create *quasi-stable* or *unstable* states, energy-storing devices (capacitors) are added in the feedback loops of the multivibrator; the instability is a result of the exponential decay of the stored energy. A *monostable multivibrator* is the result of adding one energy-storing element into a feedback loop. An *astable multivibrator* is the result of adding two energy-storing elements, one in each feedback loop.

### Monostable Multivibrator

A *monostable* or *one-shot* multivibrator has one energy-storing element in its feedback paths, resulting in one stable and one quasi-stable state. It can be switched, or *triggered*, to its quasi-stable state; then returns to the stable state after a time delay. Thus, the one-shot multivibrator puts out a pulse of some duration, T. (Note that T is not the period, but the duration of the quasi-stable state.) Triggering during the stable state results in the pulse, as expected. Triggering during the unstable state has two possibilities: A *nonretriggerable* multivibrator is not affected. A *retriggerable* multivibrator will start counting its pulse duration from the most recent trigger pulse. Both types of one-shots are common.

**Fig 7.25** shows a 555 timer IC connected as a one-shot multivibrator. The one-shot is

activated by a negative-going pulse between the trigger input and ground. The trigger pulse causes the output (Q) to go positive and capacitor C to charge through resistor R. When the voltage across C reaches two-thirds of  $V_{CC}$ , the capacitor is quickly discharged to ground and the output returns to 0. The output remains at logic 1 for a time determined by  $T = 1.1 RC$ , where R is the resistance in ohms and C is the capacitance in farads.

### Astable Multivibrator

An *astable* or *free-running* multivibrator has two energy-storing elements in its feedback paths, resulting in two quasi-stable states. It continuously switches between these two states without external excitation. Thus, the astable multivibrator puts out a sequence of pulses. By properly selecting circuit components, these pulses can be of a desired frequency and width.

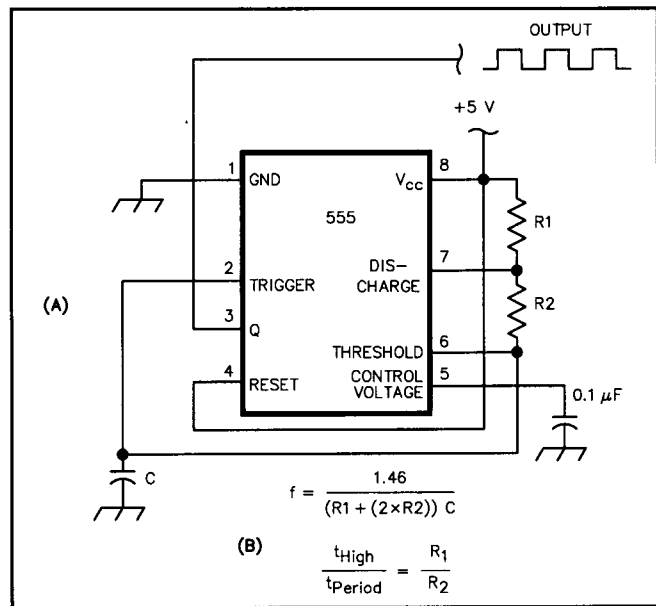

**Fig 7.26** shows a 555 timer IC connected as an astable multivibrator. The capacitor C charges to two-thirds  $V_{CC}$  through R1 and R2 and discharges to one-third  $V_{CC}$  through R2. The ratio R1 : R2 sets the asserted high duty cycle of the pulse:  $t_{HIGH} / t_{PERIOD}$ . The output frequency is determined by:

$$f = 1.46 / (R1 + 2 R2) C$$

where:

R1 and R2 are in ohms,  
C in farads and  
f in hertz.

It may be difficult to produce a 50%

**Fig 7.26 — (A) A 555 timer connected as an astable multivibrator. (B) The equations to calculate values for R1, R2 (in ohms) and C (in farads), where f is the clock frequency (in Hertz).**

duty cycle, due to manufacturing tolerance for the resistors R1 and R2. One way to ensure a 50% duty cycle is to run the astable multivibrator at 2f and then divide by 2 with a toggle flip-flop.

### Applications

An astable multivibrator is useful in generating clock pulses. When triggered by a clock pulse, the one-shot multivibrator acts to lengthen or "stretch" the pulse, which is useful to delay digital events. Either of these pulse signals, when input to the bistable multivibrator (flip-flop), can be the control of a sequential circuit. The three types of multivibrators can ensure synchronicity, so that a sequential circuit will execute correctly.

### SUMMARY

Digital logic plays an increasingly important role in Amateur Radio. Most of this logic is binary and can be described and designed using Boolean algebra. Using the NOT, AND and OR gates of combinational logic, designers can build sequential logic circuits that have memory and feedback. The simplest sequential logic circuit is called a flip-flop. By using control inputs, a flip-flop can latch a data value, retaining one bit of information and acting as memory. Combinations of flip-flops can form useful circuits such as counters, storage registers and shift registers. The primary method of controlling sequential circuits is via a clock pulse, which can be created with a multivibrator.

# Digital Integrated Circuits

Integrated circuits (ICs) are the cornerstone of digital logic devices. Modern technology has enabled electronics to become miniature in size and less expensive. Today's complex digital equipment would be impossible with vacuum tubes or even with discrete transistors.

An IC is a miniature electronic module of components and conductors manufactured as a single unit. All you see is a ceramic or black plastic package and the silver-colored pins sticking out. Inside the package is a piece of material, usually silicon, created (fabricated) in such a way that it conducts an electric current to perform logic functions, such as a gate, flip-flop or decoder.

As each generation of ICs surpassed the previous one, they became classified according to the number of gates on a single chip. These classifications are roughly defined as:

Small-scale integration (SSI):

10 or fewer gates on a chip.

Medium-scale integration (MSI):

10-100 gates.

Large-scale integration (LSI):

100-1000 gates.

Very-large-scale integration (VLSI):

1000 or more gates.

This chapter will primarily deal with SSI ICs, the basic digital building blocks. Microprocessors, memory chips and programmable logic devices are discussed later in the Computer Hardware section.

The previous section discussed the design of a digital circuit. To build that circuit, the designer must choose between IC chips available in various logic families. Each family and subfamily has its own desirable characteristics. This section reviews the primary IC logic families of interest to radio amateurs. The designer may also be challenged to interface between different logic families or between a logic device and peripheral device. The former is discussed at the end of this section; the latter with Computer Hardware, later in the chapter.

## COMPARING LOGIC FAMILIES

When selecting devices for a circuit, a designer is faced with choosing between many families and subfamilies of logic ICs. Which subfamily is right for the application at hand is among several desirable characteristics: logic speed, power consumption, fan-out, noise immunity and cost.

### Speed

Logic device families operate at widely varying clock speeds. Standard transistor

logic (TTL) devices can only operate up to a few MHz while some emitter-coupled logic (ECL) ICs can operate at several GHz. Gate propagation delay determines the maximum clock speed at which an IC can operate; the clock period must be long enough for all signals within the IC to propagate to their destinations. ICs with capacitively coupled inputs have minimum, as well as maximum, clock rates. While the initial reaction may be to use the fastest available ICs, the designer must usually choose between a trade-off of high speed and low power consumption.

### Power Consumption

In some applications, power consumption by logic gates is a critical design consideration. This power consumption can be divided into two parts: Dynamic power is the power consumed when a gate changes state. Static power is the power consumed when a gate is holding a state, either high or low. Each of these has different power requirements. Calculating the total required power can be a complex task when several gates and diverse functions are involved. Nominal power requirements, however, can be used to compare logic subfamilies.

### Fan-out

Gate impedance is another parameter to consider. To deliver high current without dropping considerable voltage, an ideal gate would have low output impedance. To draw minimal current, an ideal gate would have infinite input impedance. Such a gate does not exist. The designer must compromise on input and output impedances.

A gate output can supply only a limited amount of current. Therefore, a single output can only drive a limited number of inputs. The measure of driving ability is called fan-out, expressed as the number of inputs (of the same subfamily) that can be driven by a single output. If a logic family that is otherwise desirable does not have sufficient fan-out, consider using noninverting buffers to increase fan-out, as shown by Fig 7.27.

### Noise Immunity

The noise margin was illustrated in Fig 7.2. The choice of voltage levels for the binary states determines the noise margin. If the gap is too small, a spurious signal can too easily produce the wrong state. Too large a gap, however, produces longer, slower transitions and thus decreased switching speeds.

Circuit impedance also plays a part in noise immunity, particularly if the noise is from external sources such as radio transmitters. At low impedances, more energy is needed to change a given voltage level than at higher impedances.

### Other Considerations

The parameters above are the basic considerations to influence the selection of a logic family for a specific application. These considerations have complex interactions that come into play in demanding low-current, high-speed or high-complexity circuits. Numerous other parameters can also be examined. These are provided in the electrical specification of a device. These are given on a data sheet and usually include four sections: (1) absolute maximum ratings specify worst-case conditions, including safe storage temperatures, (2) recommended operating conditions specify power-supply, input voltage, dc output loading and temperatures for normal operation, (3) electrical characteristics specify other dc voltages and currents observed at the inputs and outputs and (4) switching characteristics specify propagation delays for "typical" operation.

The list of parameters can seem overwhelming to the novice; but with experience, the important information will be more easily spotted. If you are designing a circuit, always consult the data sheet for specific information on the device you are considering, because these parameters vary not only between the logic families but also vary between the manufacturers and with changing technologies. Each manufacturer has data books available listing their devices and the corresponding data sheets.

## BIPOLAR LOGIC FAMILIES

Two broad categories of digital logic

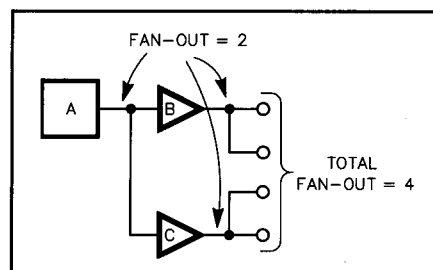

Fig 7.27 — Nonverting buffers used to increase fan-out: Gate A (fan-out = 2) is connected to two buffers, B and C, each with a fan-out of 2. Result is a total fan-out of 4.

ICs are *bipolar* and *metal-oxide semiconductor* (MOS). Numerous manufacturing techniques have been developed to fabricate each type. Each surviving, commercially available family has its particular advantages and disadvantages and has found its own special niche in the market.

Bipolar semiconductor ICs usually employ NPN junction transistors. (Bipolar ICs are possible using PNP transistors, but NPN transistors make faster circuits.) While early bipolar logic was faster and had higher power consumption than MOS logic, these distinctions have blurred as manufacturing technology has developed. There are several families of bipolar logic devices and within some of these families there are subfamilies. The most-used digital logic family is Transistor-Transistor Logic (TTL). Another bipolar logic family, Emitter Coupled Logic (ECL), has exceptionally high speed but high power consumption.

### Transistor-Transistor Logic (TTL)

The TTL family has seen widespread acceptance because it is fast and has good noise immunity. It is by far the most commonly used logic family. TTL levels were shown earlier in Fig 7.2: An input voltage between 0.0-0.4 V will represent LOW and an input voltage between 2.4-5.0 V will represent HIGH.

#### TTL Subfamilies

The original standard TTL is infrequently used today. In the standard TTL circuit, the transistors saturate, reducing the operating speed. TTL variations cure this by clamping the transistors with Schottky diodes to prevent saturation, or by using a dopant in the chip fabrication to reduce transistor recovery time. Schottky-clamped TTL is the faster of these two manufacturing processes.

TTL IC identification numbers begin with either 54 or 74. The 54 prefix denotes a military temperature range of -55 to 125°C, while 74 indicates a commercial temperature range of 0 to 70°C. The next letters, in the middle of the TTL device number, indicate the TTL subfamily. Following the subfamily designation is a 2, 3 or 4-digit device-identification number. For example, a 7400 is a standard-TTL NAND gate and a 74LS00 is a low-power Schottky NAND gate. (The NAND gate is the workhorse TTL chip. Recall, from Fig 7.18, the alternative implementation of the S-R flip-flop.) The following TTL subfamilies are available:

	74xx	standard TTL
H	74Hxx	High-speed
L	74Lxx	Low-power
S	74Sxx	Schottky
LS	74LSxx	Low-power Schottky
AS	74ASxx	Advanced Schottky
ALS	74ALSxx	Advanced Low-power Schottky

Each subfamily is a compromise between speed and power consumption. Because the speed-power product is approximately constant, less power consumption results in less speed and vice versa. For the amateur, an additional consideration to the speed-versus-power trade-off is the cost trade-off. The advanced Schottky devices offer both increased speed and reduced power consumption but at a higher cost.

In addition to the above power/speed/cost trade-offs, each TTL subfamily has particular characteristics that can make it suitable or unsuitable for a specific design. Table 7.9 shows some of these parameters. The actual parameter values may vary slightly from manufacturer to manufacturer so always consult the manufacturers' data books for complete information.

#### TTL Circuits

Fig 7.28A shows the schematic representation of a TTL hex inverter. A 7404 chip contains four of these inverters. When the input is low, Q1 is ON, conducting current from base to emitter through the input lead and into ground. Thus a low TTL input device must be prepared to sink current from the input. Since Q1 is saturated, Q2 is OFF because there is not enough voltage at its base. Similarly, Q4 is also OFF. With Q2 and Q4 OFF, Q3 will be ON and pull the output high, about one volt below  $V_{CC}$ . When the input is high, an

unusual situation occurs: Q1 is operating in the inverse mode, with current flowing from base to collector. This current causes Q2 to be ON, which causes Q4 to be ON. With Q2 and Q4 ON, there is not enough current left for Q3, so Q3 is OFF. Q4 is pulling the output low.

By replacing Q1 with a multiple-emitter transistor, as is done with the two-input Q5 in Fig 7.28B, the inverter circuit becomes a NAND gate. Commercially available TTL NAND gates have as many as 13 inputs, the limiting factor being the number of input pins on the standard 16-pin chip. The operation of this multiple-input NAND circuit is the same as described for the inverter, the difference being that any one of the emitter inputs being low will conduct current through the emitter, leading to the conditions described above to produce a high at the output. Similarly, all inputs must be high to produce the low output.

In the TTL circuit of Fig 7.28A, transistors Q3 and Q4 are arranged in a *totem-pole* configuration. This configuration gives the output circuit a low source impedance, allowing the gate to source (supply) or sink substantial output current. The 130- $\Omega$  resistor between the collector of Q3 and  $+V_{CC}$  limits the current through Q3.

When a TTL gate changes state, the amount of current that it draws changes rapidly. These changes in current, called switching transients, appear on the power supply line and can cause false triggering of other devices. For this reason, the power bus should be adequately decoupled. For proper decoupling, connect a 0.01 to 0.1  $\mu$ F capacitor from  $V_{CC}$  to ground near each device to minimize the transient currents caused by device switching and magnetic coupling. These capacitors must be low-inductance, high-frequency RF capacitors (disk-ceramic capacitors are pre-

**Table 7.9**  
**TTL and CMOS Subfamily Performance Characteristics**

TTL Family	Propagation Delay (ns)	Per Gate Power Consumption (mW)			Speed Power Product (pJ)		
		$f=100$ kHz	$f=1$ MHz	$f=10$ MHz	$f=100$ kHz	$f=1$ MHz	$f=10$ MHz

HC	18	0.0625	0.6025	6.0025	1.1	10.8	108
HCT	18	0.0625	0.6025	6.0025	1.1	10.8	108
AC	5.25	0.080	0.755	7.505	0.4	3.9	39
ACT	4.75	0.080	0.755	7.505	0.4	3.6	36

ferred). In addition, a large-value (50 to 100  $\mu\text{F}$ ) capacitor should be connected from  $V_{CC}$  to ground somewhere on the board to accommodate the continually changing  $I_{CC}$  requirements of the total  $V_{CC}$  bus line. These are generally low-inductance tantalum capacitors rather than rolled-foil mylar or aluminum-electrolytic capacitors.

### Darlington and Open-Collector Outputs

Fig 7.28C and D show variations from the totem-pole configuration. They are the Darlington transistor pair and the open-collector configuration respectively.

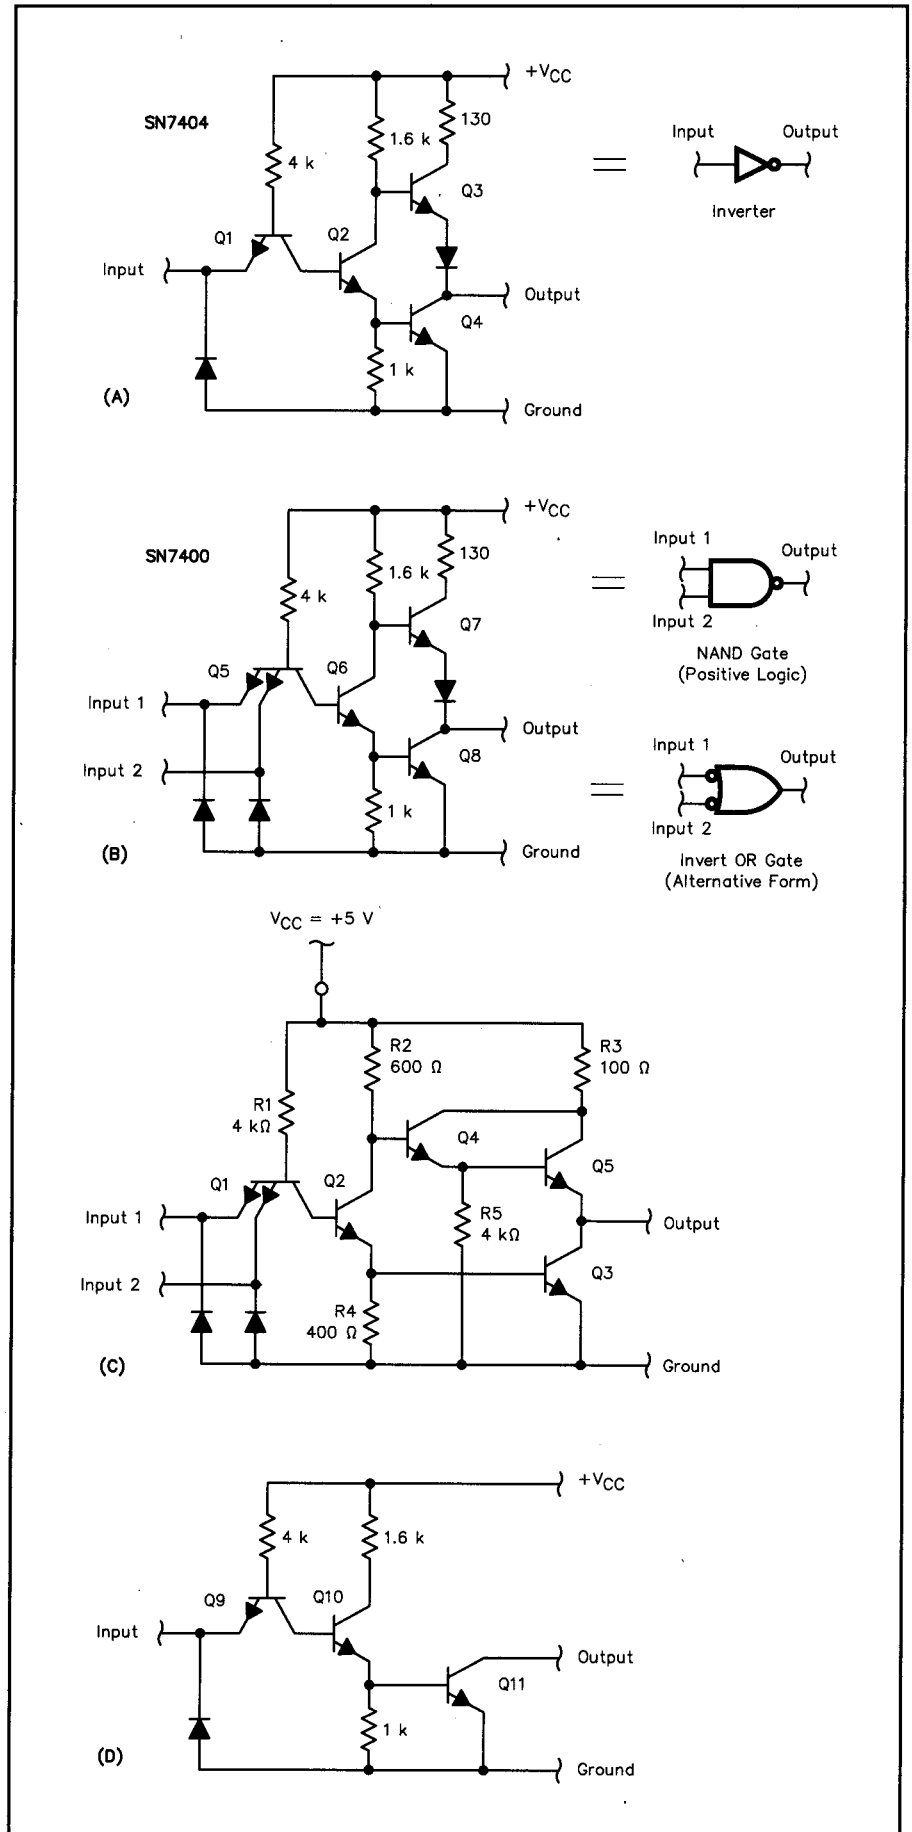

The Darlington pair configuration replaces the single transistor  $Q_4$  with two transistors,  $Q_4$  and  $Q_5$ . The effect is to provide more current-sourcing capability in the high state. This has two benefits: (1) the rise time is decreased and (2) the fanout is increased.

Transistor(s) on the output in both the totem-pole and Darlington configurations provide active pull-up. Omitting the transistor(s) and providing an external resistor for passive pull-up gives the open-collector configuration. This configuration, unfortunately, results in slower rise time, since a relatively large external resistor must be used. The technique has some very useful applications, however: driving other devices, performing wired logic, busing and interfacing between logic devices.

Devices that need other than a 5-V supply can be driven with the open-collector output by substituting the device for the external resistor. Example devices include light-emitting diodes (LEDs), relays and solenoids. Inductive devices like relay coils and solenoids need a "flyback" protection diode across the coil. You must pay attention to the current ratings of open-collector outputs in such applications. You may need a switching transistor to drive some relays or other high-current loads.

Open-collector outputs can perform wired logic, rather than gated IC logic, by wire-ANDing the outputs. This can save the designer an AND gate, potentially sim-

**Fig 7.28 — Example TTL circuits and their equivalent logic symbols: (A) an inverter and (B) a NAND gate, both with totem-pole outputs. (C) A NAND gate with a Darlington output. (D) A NAND gate with an open-collector output. (Indicated resistor values are typical. Identification of transistors is for text reference only; these are not discrete components but parts of the silicon die.)**

plifying the design. Wire-ANDed outputs are several open-collector outputs connected to a single external pull-up resistor. The overall output, then, will only be high when all pull-down transistors are OFF (all connected outputs are high), effectively performing an AND of the connected outputs. If any of the connected outputs are low, the output after the external resistor will be low. Fig 7.29 illustrates the wire-ANDing of open-collector outputs.

The wire-ANDed concept can be applied to several devices sharing a common bus. At any time, all but one device has a high-impedance (off) output. The remaining device, enabled with control circuitry, drives the bus output.

Open-collector outputs are also useful for interfacing TTL gates to gates from other logic families. TTL outputs have a minimum high level of 2.4 V and a maximum low level of 0.4 V. When driving nonTTL circuits, a pull-up resistor (typically 2.2 k $\Omega$ ) connected to the positive supply can raise the high level to 5 V. If a higher output voltage is needed, a pull-up resistor on an open-collector output can be connected to a positive supply greater than 5 V, so long as the chip output voltage and current maximums are not exceeded.

### Three-State Outputs

While open-collector outputs can perform bus sharing, a more popular method is three-state output, or tristate, devices. The three states are low, high and high impedance, also called Hi-Z or *floating*. An output in the high-impedance state behaves as if it is disconnected from the

circuit, except for possibly a small leakage current. Three-state devices have an additional disable input. When enable is low, the device provides high and low outputs just as it would normally; when enable is high the device goes into its high-impedance state.

A bus is a common set of wires, usually used for data transfer. A three-state bus has several three-state outputs wired together. With control circuitry, all devices on the bus but one have outputs in the high-impedance state. The remaining device is enabled, driving the bus with high and low outputs. Care should be taken to ensure only one of the output devices can be enabled at any time, since simultaneously connected high and low outputs may result in an incorrect logic voltage. (The condition when more than one driver is enabled at the same time is called *bus contention*.) Also, the large current drain from  $V_{CC}$  to ground through the high driver to the low driver can potentially damage the circuit or produce noise pulses that can affect overall system behavior.

### Unused TTL Inputs

A design may result in the need for an  $n$ -input gate when only an  $n + m$  input gate is available. In this case, the recommended solution for extraneous inputs is to give the extra inputs a constant value that won't effect the output. A low input is easily provided by connecting the input to ground. A high input can be provided with either an inverter whose input is ground or with a pull-up resistor. The pull-up resistor is preferred rather than a direct connection to power because the resistor lim-

its the current, thus protecting the circuit from transient voltages. Usually, a 1-k $\Omega$  to 5-k $\Omega$  resistor is used; a single 1-k $\Omega$  resistor can handle up to 10 inputs.

It's important to properly handle all inputs. Design analysis would show that an unconnected, or floating, TTL input is usually high but can easily be changed low by only a small amount of capacitively coupled noise.

### Emitter-Coupled Logic (ECL)

ECL, also called current-mode logic (CML), is the fastest commercially available logic family, with some devices operating at frequencies higher than 1.2 GHz. The fast speed is a result of reducing the propagation delay by keeping the transistors from saturating. ECL devices operate with their transistors in the active region. The voltage swing is small, less than a volt; and the circuit internally switches between two possible paths depending on the output state. The two-path arrangement provides a significant feature of ECL: complementary output states are always available.

Naturally, high speed comes at some cost, in this case high power consumption. Heat sinking is sometimes necessary because of the great deal of power being dissipated. Because of its poor speed-power product and also because it is not directly compatible with TTL and CMOS, ECL is less popular than TTL. ECL devices are most likely to be found where performance is more important than cost, including UHF frequency counters, UHF frequency synthesizers and high-speed mainframe computers.

### ECL Subfamilies

There are several ECL subfamilies, to balance the trade-off of high speed versus low power dissipation. The subfamilies differ mostly in resistance values and the presence or absence of input and output pull-down resistors.

The most popular subfamily is the 10K series, with five-digit part numbers of the form "10xxx." This family's design started one of ECL's most familiar characteristics: operation with  $V_{CC} = 0$  V (ground) and  $V_{EE}$  at a negative voltage. This feature provides immunity to power supply noise, since noise on  $V_{EE}$  is rejected by the circuit's differential amplifier. The design voltage,  $V_{EE} = -5.2$  V for the 10K subfamily, provides the best noise immunity; but other voltages can be used. Typically, a high logic state corresponds to  $-0.9$  V and a low is  $-1.75$  V.

### ECL Circuits

ECL gets its name from the emitter-coupled pair of transistors in the circuit,

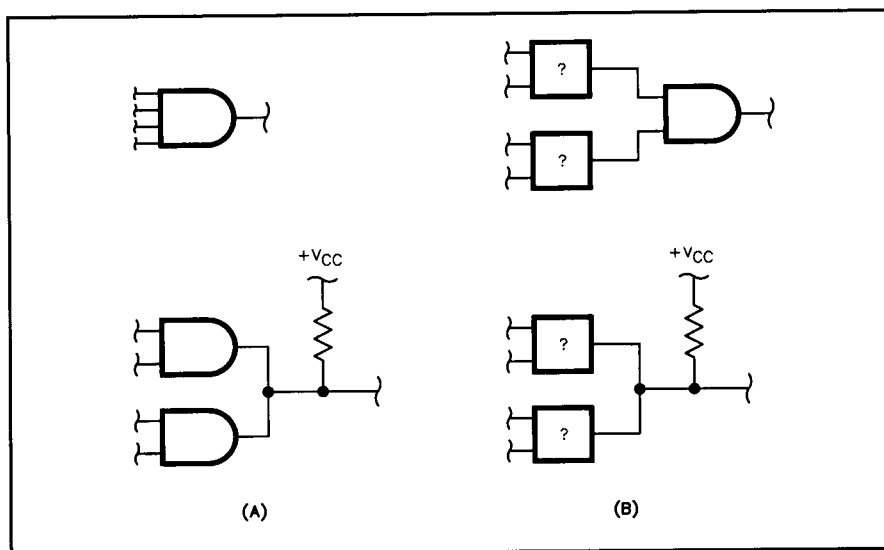

Fig 7.29 — The outputs of two open-collector-output AND gates are shorted together (wire ANDed) to produce an output the same as would be obtained from a 4-input AND gate.

connected as a differential amplifier. For example, in Fig 7.30, either Q1 or Q2 together with Q3 form a differential amplifier. This arrangement produces the complementary outputs available from each ECL circuit. The circuit in Fig 7.30 provides both an OR output and a NOR output. When an input is high, its transistor (Q1 or Q2) is ON but not in saturation; and Q3 is OFF. Q6 is then OFF so its emitter output is low; while Q5 is ON and its output high. Similarly, when both inputs are low, Q1 and Q2 are OFF so the NOR output from Q6 is high; and Q3 is ON, so the OR output from Q5 is low. Q4, D1, D2 and associated circuitry form a bias generator. The reference voltage at the base of Q3 determines the input switching threshold.

### METAL-OXIDE SEMICONDUCTOR (MOS) LOGIC FAMILIES

While bipolar devices use junction transistors, MOS devices use field effect transistors (FETs). MOS is characterized by simple device structure, small size (high density) and ease of fabrication. MOS circuits use the NOR gate as the workhorse chip rather than the NAND. MOS families are used extensively in digital watches, calculators and VLSI circuits such as microprocessors and memories.

#### P-Channel MOS (PMOS)

The first MOS devices to be fabricated were PMOS, conducting electrical current by the flow of positive charges (holes). PMOS power consumption is much lower than that of bipolar logic, but its operating speed is lower. The only extensive use of PMOS is in calculators and watches, where low speed is acceptable and low power consumption and low cost are desirable.

#### N-Channel MOS (NMOS)

With improved fabrication technology, NMOS became feasible and provided improved performance and TTL compatibility. The speed of NMOS is at least twice that of PMOS, since electrons rather than holes carry the current. NMOS also has greater gain than PMOS and supports greater packaging density through the use of smaller transistors.

#### Complementary MOS (CMOS)

CMOS combines both P-channel and N-channel devices on the same substrate to achieve high noise immunity and low power consumption: less than 1 mW per gate and negligible power during standby. This accounts for the widespread use of CMOS in battery-operated equipment. The high impedance of CMOS gates

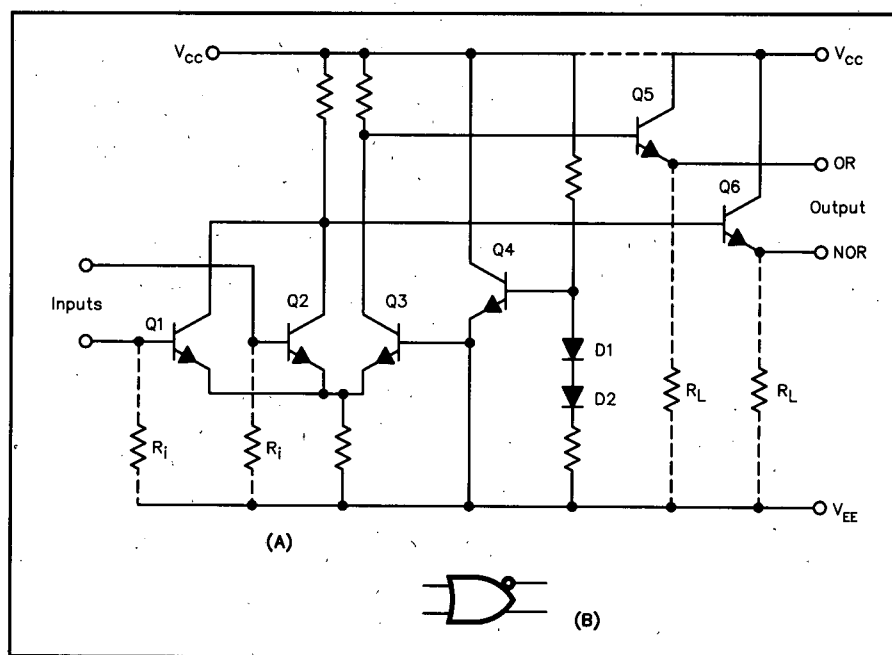

Fig 7.30 — (A) Circuit topology of the ECL family. (B) The modified logic symbol indicates the availability of the complementary output.

makes them susceptible to electromagnetic interference, however, particularly if long traces are involved. Consider a trace  $1/4$ -wavelength long between input and output. The output is a low-impedance point so the trace is effectively grounded at this point. You can get high RF potentials  $1/4$ -wavelength away, which disturbs circuit operation.

A notable feature of CMOS devices is that the logic levels swing to within a few millivolts of the supply voltages. The input switching threshold is approximately one half the supply voltage ( $V_{DD} - V_{SS}$ ). This characteristic contributes to high noise immunity on the input signal or power supply lines. CMOS input-current drive requirements are minuscule, so the fan-out is great, at least in low-speed systems. (For high-speed systems, the input capacitance increases the dynamic power dissipation and limits the fan-out.)

#### CMOS Subfamilies

There are a number of CMOS subfamilies available. Like TTL, the original CMOS has largely been replaced by later subfamilies using improved technologies. This original family, called the 4000-series, has numbers beginning with 40 or 45 followed by two or three numbers to indicate the specific device. 4000B is second generation CMOS. When introduced, this family offered low power consumption but was fairly slow and not easy to interface with TTL.

Later CMOS subfamilies provided improved performance and TTL compatibility. For simplicity, the later subfamilies were given numbers similar to the TTL numbering system, with the same leading numbers, 54 or 74, followed by 1 to 3 letters indicating the subfamily and as many as 5 numbers indicating the specific device. The subfamily letters usually include a "C" to distinguish them as CMOS.

The following CMOS device families are available:

4000	4071B	standard CMOS
C	74Cxx	CMOS versions of TTL

Devices in this subfamily are pin and functional equivalents of many of the most popular parts in the 7400 TTL family. It may be possible to replace all TTL ICs in a particular circuit with 74C-series CMOS, but this family should not be mixed with TTL in a circuit without careful design considerations. Devices in the C series are typically 50% faster than the 4000 series.

HC	74HCxx	High-speed CMOS
----	--------	-----------------

Devices in this subfamily have speed and drive capabilities similar to Low-power Schottky (LS) TTL but with better noise immunity and greatly reduced power consumption. High-speed refers to faster than the previous CMOS family, the 4000-series.

HCT	74HCTxx	High-Speed CMOS, TTL compatible
-----	---------	---------------------------------

Fig 7.31 — Internal structure of a CMOS inverter.

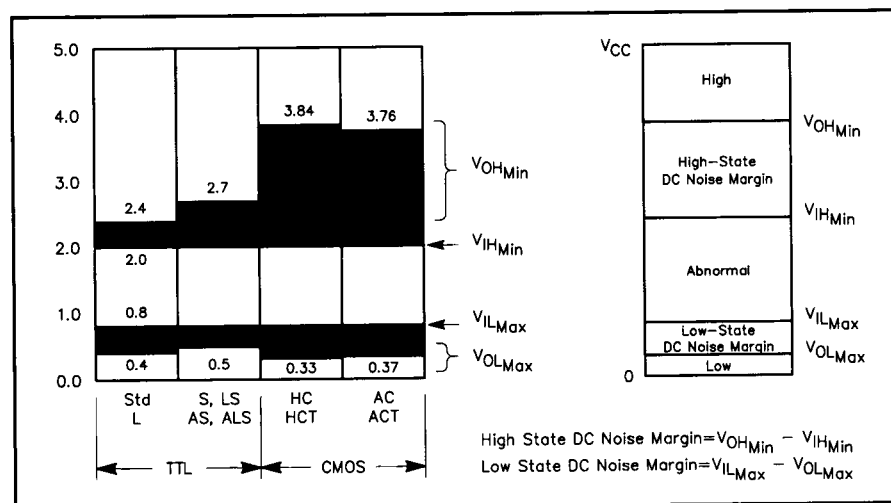

Fig 7.32 — Differences in logic levels for some TTL and CMOS families.

susceptible to damage from static charges. To protect against damage from static, the pins should not be inserted in styrofoam as is sometimes done with other components. Instead, a spongy conductive material is available for this purpose. Before removing a CMOS IC from its protective material, make certain that your body is grounded. Touching nearly any large metal object before handling the ICs is probably adequate to drain any static charge off your body. Some people prefer to touch a grounded metal object or to use a conductive bracelet connected to the ground terminal of a three-wire ac outlet through a 10-MΩ resistor. Since wall outlets aren't always wired properly, you should measure the voltage between the ground terminal and any metal objects you might touch. Connecting yourself to ground through a 1 MΩ to 10 MΩ resistor will limit any current that might flow through your body.

All CMOS inputs should be tied to an input signal; a positive supply voltage or ground if a constant input is desired. Undetermined CMOS inputs, even on unused gates, may cause gate outputs to oscillate. Oscillating gates draw high current, overheat and self destruct.

The low power consumption of CMOS ICs made them attractive for satellite applications, but standard CMOS devices proved to be sensitive to low levels of radiation — cosmic rays, gamma rays and X rays. Later, radiation-hardened CMOS ICs, able to tolerate  $10^6$  rads, made them suitable for space applications. (A rad is a unit of measurement for absorbed doses of ionizing radiation, equivalent to  $10^{-2}$  joules per kilogram.)

## SUMMARY

There are many types of logic ICs, each with its own advantages and disadvantages. If you want low power consumption, you should probably use CMOS. If you want ultra-high-speed logic, you will have to use ECL. Whatever the application, consult up-to-date literature when designing logic circuits. IC databooks and applications notes are usually available from IC manufacturers and distributors.

## INTERFACING LOGIC FAMILIES

Each semiconductor logic family has its own advantages in particular applications. For example, the highest frequency stages in a UHF counter or a frequency synthesizer would use ECL. After the frequency has been divided down to less than 25 MHz, the speed of ECL is unnecessary; and its expense and power dissipation are unjustified. TTL or CMOS are better choices at lower frequencies.

When a design mixes ICs from different

Devices in this subfamily were designed to interface TTL to CMOS systems. The HCT inputs recognize TTL levels, while the outputs are CMOS compatible.

AC 74ACxxxxx Advanced CMOS

Devices in this family have reduced propagation delays, increased drive capabilities and can operate at higher speeds than standard CMOS. They are comparable to Advanced Low-power Schottky (ALS) TTL devices.

ACT 74ACTxxxxx Advanced CMOS, TTL-compatible

This subfamily combines the improved performance of the AC series with TTL-compatible inputs.

As with TTL, each CMOS subfamily has characteristics that make it suitable or

unsuitable for a particular design. You should consult the manufacturer's data books for complete information on each subfamily you are considering.

## CMOS Circuits

A simplified diagram of a CMOS logic inverter is shown in Fig 7.31. When the input is low, the resistance of Q2 is low so a high current flows from  $V_{CC}$ ; since Q1's resistance is high, the high current flows to the output. When the input is high, the opposite occurs: Q2's resistance is high, Q1's is low and the output is low. The diodes are to protect the circuit against static charges.

## Special Considerations

Some of the diodes in the input- and output-protection circuits are an inherent part of the manufacturing process. Even with the protection circuits, however, CMOS ICs are

logic families, the designer must account for the differing voltage and current requirements each logic family recognizes. The designer must ensure the appropriate interface between the point at which one logic family ends and another begins. A knowledge of the specific input/output (I/O) characteristics of each device is necessary, and a knowledge of the general internal structure is desirable, to ensure reliable digital interfaces. Typical internal structures have been illustrated for each common logic family. Fig 7.32 illustrates the logic level changes for different TTL and CMOS families; databooks should be consulted for manufacturer's specifications.

Often more than one conversion scheme is possible, depending on whether the designer wishes to optimize power consumption or speed. Usually one quality must be traded off for the other. The following section discusses some specific logic conversions. Where an electrical connection between two logic systems isn't possible, an optoisolator can sometimes be used.

### TTL Driving CMOS

TTL and low-power TTL can drive 74C series CMOS directly over the commercial temperature range without an external pull-up resistor. However, they cannot drive 4000-series CMOS directly; and for HC-series devices, a pull-up resistor is recommended. The pull-up resistor, connected between the output of the TTL gate and  $V_{CC}$  as shown in Fig 7.33A, ensures proper operation and enough noise margin by making the high output equal to  $V_{DD}$ . Since the low output voltage will also be affected, the resistor value must be chosen with both desired high and low voltage ranges in mind. Resistor values in the range 1.5 k $\Omega$  to 4.7 k $\Omega$  should be suitable for all TTL families under worst conditions. A larger resistance reduces the maximum possible speed of the CMOS gate; a lower resistance generates a more favorable RC product but at the expense of increased power dissipation.

HCT-series and ACT-series CMOS devices were specifically designed to interface nonCMOS devices to a CMOS system. An HCT device acts as a simple buffer between the nonCMOS (usually TTL) and CMOS device and may be combined with a logic function if a suitable HCT device is available.

When the CMOS device is operating from a power supply other than +5 V, the TTL interface is more complex. One fairly simple technique uses a TTL open-collector output connected to the CMOS input,

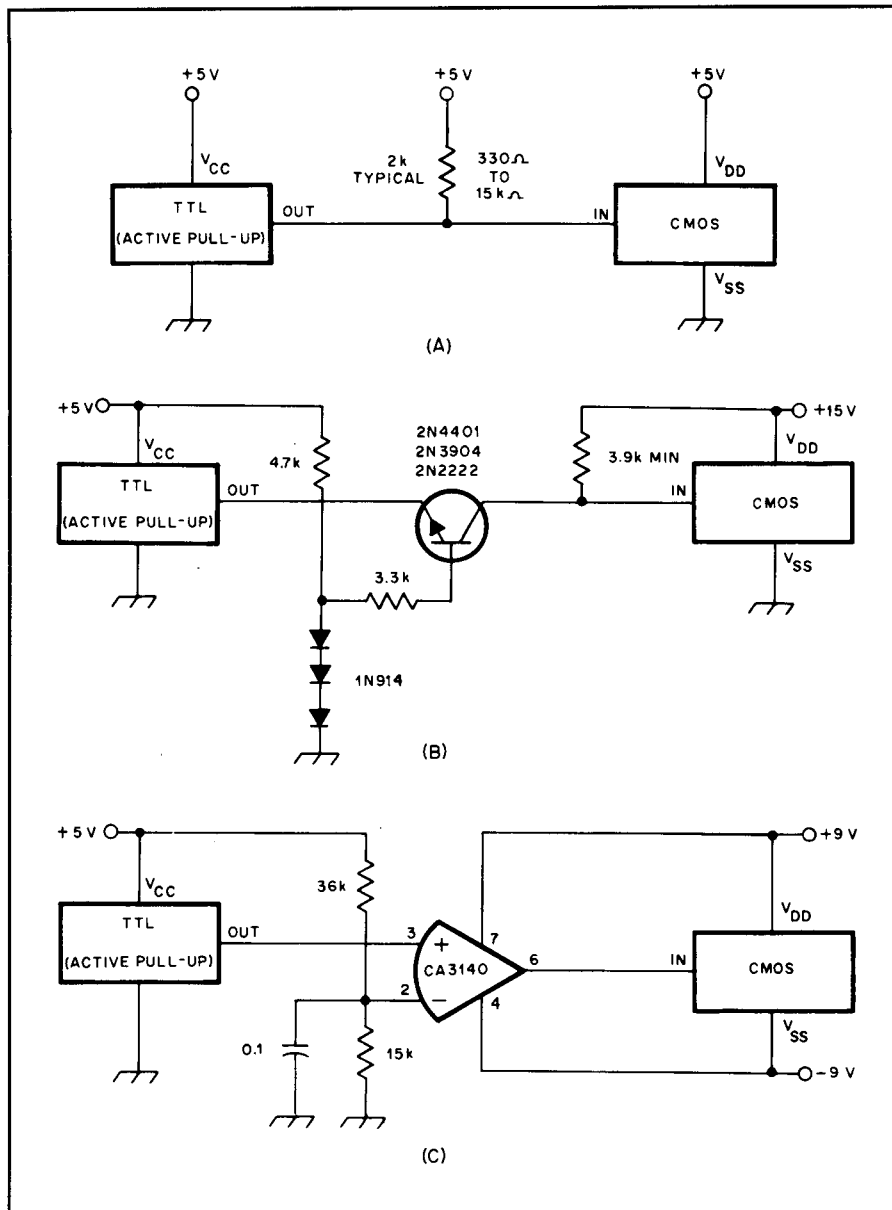

Fig 7.33 — TTL to CMOS interface circuits: (A) pull-up resistor, (B) common-base level shifter and (C) op amp configured as a comparator.

with a pull-up resistor from the CMOS input to the CMOS power supply. Another method, shown in Fig 7.33B, is a common-base level shifter. The level shifter translates a TTL output signal to a +15 V CMOS signal while preserving the full noise immunity of both gates. An excellent converter from TTL to CMOS using dual power supplies is to configure an operational amplifier as a comparator, as shown in Fig 7.33C. An FET op amp is shown because its output voltage can usually swing closer to the rails (+ and - supply voltages) than a bipolar unit.

### CMOS Driving TTL

Certain CMOS devices can drive TTL

loads directly. The output voltages of CMOS are compatible with the input requirements of TTL, but the input-current requirement of TTL limits the number of TTL loads that a CMOS device can drive from a single output (the fan-out).

Interfacing CMOS to TTL is a bit more complicated when the CMOS is operating at a voltage other than +5 V. One technique is shown in Fig 7.34A. The diode blocks the high voltage from the CMOS gate when it is in the high output state. A germanium diode is used because its lower forward-voltage drop provides higher noise immunity for the TTL device in the low state. The 68-k $\Omega$  resistor pulls the input high when the diode is back biased.

There are two CMOS devices specifically designed to interface CMOS to TTL when TTL is using a lower supply voltage. The CD4050 is a noninverting buffer that allows its input high voltage to exceed the supply voltage. This capability allows the CD4050 to be connected directly between the CMOS and TTL devices, as shown in Fig 7.34B. The CD4049 is an inverting buffer that has the same capabilities as the CD4050.

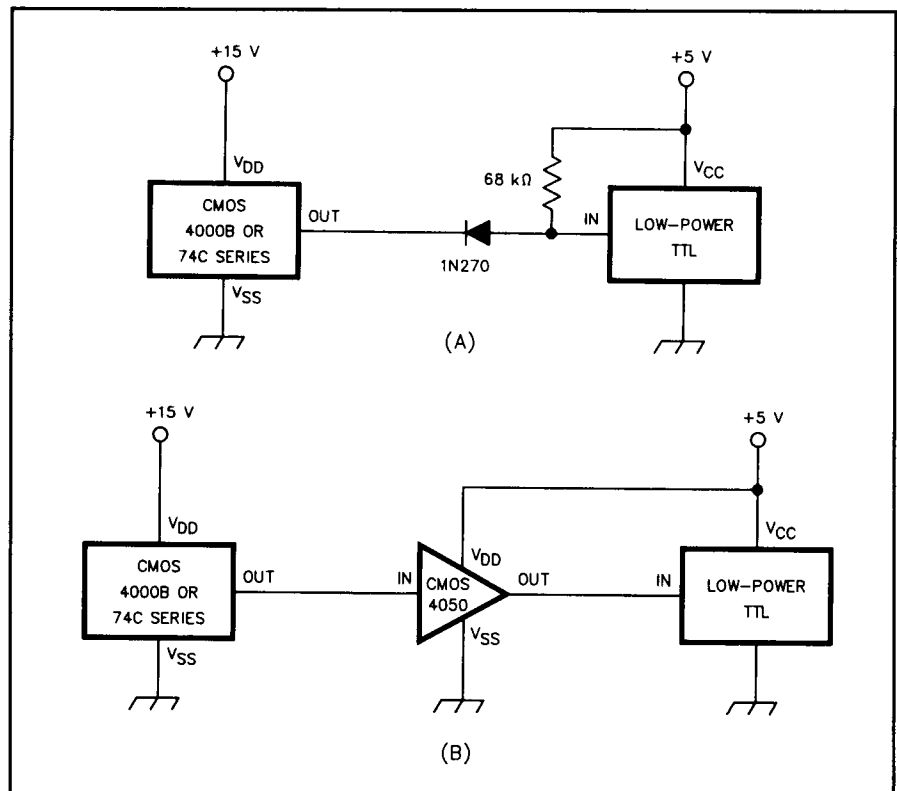

Fig 7.34 — CMOS to TTL interface circuits: (A) blocking diode used when different supply voltages are used. The diode is not necessary if both devices operate with a +5 V supply. (B) CMOS noninverting buffer IC.

# Computer Hardware

So far, this chapter has discussed digital logic, the implementation of that logic with integrated circuits, interfacing IC logic families and the use of memory to store information used by the ICs. The synthesis of all this technology is the microcomputer — combining a microprocessor IC, memory chips and user interface into the modern digital computer. A computer has both physical components; hardware and a collection of programs; software, to tell it what to do. This section will focus on the physical components of the computer: its internal physical components, the chips and how they work and interact and its external I/O devices for communication with a user.

## COMPUTER ORGANIZATION

The *architecture* of a computer is the arrangement of its internal subsystems: the microprocessor(s), memory, I/O and interfacing. Each subsystem may be concentrated on a single IC or spread between many chips. The microprocessor, also known as the *central processing unit*

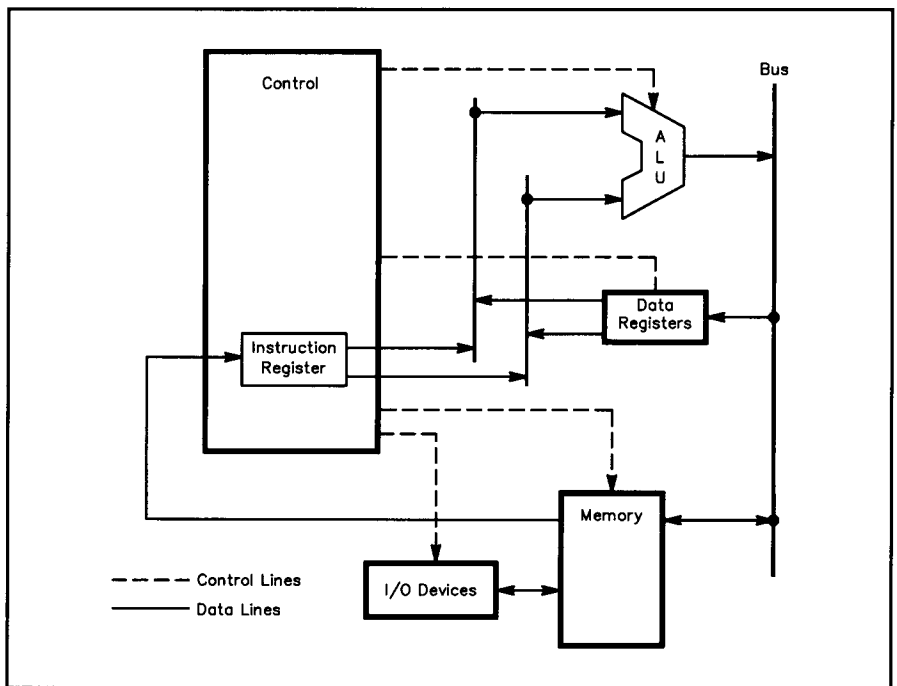

Fig 7.35 — Example of a basic computer architecture.

(CPU) and usually a single chip, consists of three parts: a control unit, an arithmetic logic unit (ALU) and temporary storage registers. A *bus* — a set of wires to carry address, data and control information — interconnects all of the subsystems. Most modern computers are some variation on the basic architecture shown in Fig 7.35.

The microprocessor, memory chips and other circuitry are all part of the system's *hardware*; the physical components of a system. The computer case, the nuts and bolts and physical parts are other parts of the hardware. A computer also includes *software*; a collection of programs or sequence of instructions to perform a specified task. Some microprocessors internally are complete circuitry. The design of general purpose computers is so complex, however, that it is nearly impossible to design an original architecture without any bugs. Thus many designers use microprocessors that include *microcode* or *microinstructions*: instructions in the control unit of a microprocessor. This hybrid between hardware and software is called *firmware*. Firmware also includes software stored in ROM or EPROM rather than being stored on magnetic disk or tape.

Computer designers make decisions on hardware, software and firmware based on cost versus performance. Thus, today's computer market includes a wide range of systems, from high-performance supercomputers, which cost millions of dollars, to the personal microcomputer, with costs in the thousands new and in the hundreds for older used models.

### THE CENTRAL PROCESSING UNIT

The central processing unit is usually a single microprocessor chip, although its subsystems can be on more than one chip. The CPU at least includes a control unit, timing circuitry, an arithmetic logic unit (ALU) and also usually contains registers for temporary storage.

#### Control Unit

The control unit directs the operation of the computer, managing the interaction between subunits. It takes instructions from the memory and executes them, performing tasks such as accessing data in memory, calling on the ALU or performing I/O. Control is one of the most difficult parts to design, thus it is the most likely source of bugs in designing an original architecture.

Microprocessors consist of both hardwired control and microprogrammed control. In both cases, the designer determines a sequence of states through which the computer cycles, each with inputs to examine and outputs to activate other CPU

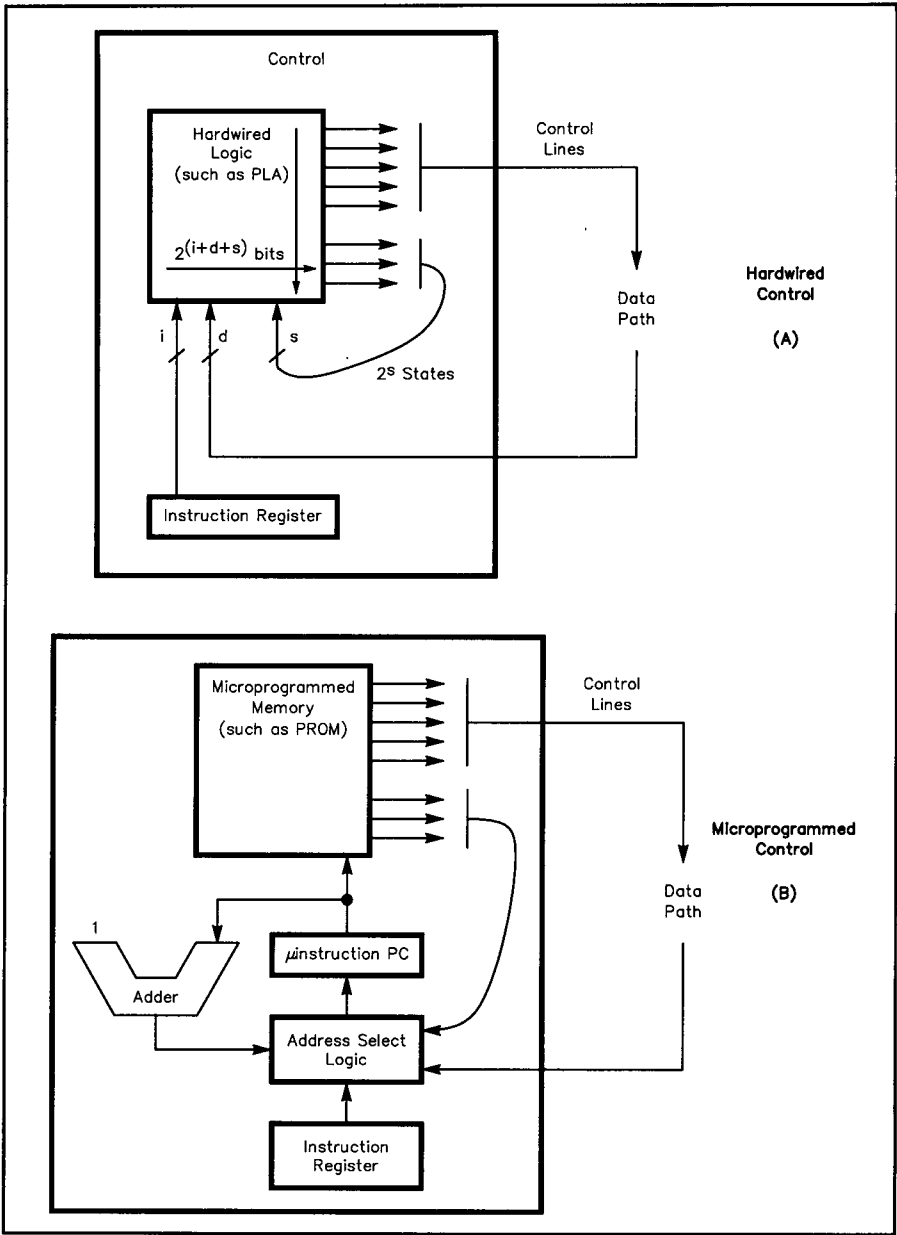

Fig 7.36 — Example arrangements of a control unit and related components: (A) hardwired control and (B) microprogrammed control.

subsystems (including activating itself, indicating which state to do next). For example, the sequence usually starts with "Fetch the next instruction from memory," with control outputs to activate memory for a read, a program counter to send the address to be fetched and an instruction register to receive the memory contents. Hardwired control is completely via circuitry, usually with a programmed logic array. Microprogrammed control uses a microprocessor with a modifiable control memory, containing microcode or microinstructions. An advantage of microprogrammed control is flexibility: the code can be changed without changing the hardware, making it easier to correct de-

sign errors. Fig 7.36 shows examples of both types of control.

#### Timing

Usually, an oscillator controlled by a quartz crystal generates the microcomputer's clock signal. The output of this clock goes to the microprocessor and to other ICs. The clock synchronizes the microcomputer subunits. For example, each of the microinstructions is designed to take only one clock cycle to execute, so any components triggered by a microinstruction's control outputs should finish their actions by the end of the clock cycle. The exception to this is memory, which may take multiple clock cycles to finish,

so the control unit repeats in its same state until memory says it's done. Since the clock rate effectively controls the rate at which instructions are executed, the clock frequency is one way to measure the speed of a computer. Clock frequency, however, cannot be the only criteria considered because the actions performed during a clock cycle vary for different designs.

## Arithmetic Logic Unit

The *arithmetic logic unit (ALU)* performs logical operations such as AND, OR and SHIFT and arithmetic operations such as addition, subtraction, multiplication and division. The ALU depends on the control unit to tell it which operation to perform and also to trigger other devices (memory, registers and I/O) to supply its input data and to send out its results to the appropriate place.

The ALU often only performs simple operations. Complex operations, such as multiplication, division and operations involving decimal numbers, are performed by dedicated hardware, called floating-point processors, or "coprocessors." These may be included on the original motherboard or may be optional upgrades.

## Registers

Microprocessor chips have some internal memory locations that are used by the control unit and ALU. Because they are inside the microprocessor IC, these registers can be accessed more quickly than other memory locations. Special purpose registers or *dedicated registers* are purely internal, have predefined uses and cannot be directly accessed by programs. *General purpose registers* hold data and addresses in use by programs and can be directly accessed, although usually only by assembly level programs.

The dedicated registers include the instruction register, program counter, effective address register and status register. The first step to execute an instruction is to fetch it from memory and put it in the *instruction register (IR)*. The *program counter (PC)* is then incremented to contain the address of the next instruction to be fetched. An instruction may change the program counter as a result of a conditional branch (if-then), loop, subroutine call or other nonlinear execution. If data from memory is needed by an instruction, the address of the data is calculated and fetched with the *effective address register (EAR)*. The *status register (SR)* keeps track of various conditions in the computer. For example, it tells the control unit when the keyboard has been typed on so the control unit

knows to get input. It also notices if something goes wrong during an instruction execution, for example an attempted divide by 0, and tells the control unit to halt the program or fix the error. Certain bits in the status register are known as the *condition codes*; flags set by each instruction. These flags tell information about the result of the latest instruction — such as if the result was negative or positive or zero and if an arithmetic overflow or a carry error occurred. The flags can then be used by a conditional branch to decide if that branch should be taken or not.

Some architectures also use a *stack pointer (SP)* and/or an *accumulator*. In a stack system, a memory location is designated as the "bottom" of the stack. Data to be stored is always added to the next memory location, the "top" of the stack; and data to be accessed must always be taken off the "top." (This technique is called "last in, first out," or LIFO.) The stack pointer keeps track of the current "top" address. Stack and accumulator architectures are distinguished from an ALU design by how they handle operations. For an ALU to perform an addition, two inputs are provided from the general-purpose registers. In the stack and accumulator systems, only one input is provided with the default second input being the top of the stack or the contents of the accumulator respectively. These different approaches significantly effect the CPU design. Stack and accumulator architectures are simpler to design but less flexible, causing them to be slower. Stacks are still in use in some machines but only for temporary storage rather than arithmetic operations. The ALU and general-purpose registers are the dominant architecture today.

## MEMORY

Computers and other digital circuits rely on stored information, either data to be acted upon or instructions to direct circuit actions. This information is stored in memory devices, in binary form. This section first discusses how to access an individual item in memory and then compares different memory types, which can vary how quickly and easily an item is accessed.

### Accessing a Memory Item

Memory devices consist of a large number of memory cells each capable of remembering one bit of binary information. The information in memory is stored in digital form with collections of bits, called words, representing numbers and symbols. The most common symbol set is the American National Standard Code for In-

formation Interchange (ASCII). Words in memory, just like the letters in this sentence, are stored one after the other. They are accessed by their location or address. The number of bits in each word, equal to the number of memory cells per memory location, is constant within a memory device but can vary for different devices. Common memory devices have word sizes of 8, 16 and 32 bits.

## Addresses and Chip Size

An *address* is the identifier, or name, given to a particular location in memory. Since this address is expressed as a binary number, the number of unique addresses available in a particular memory chip is determined by the number of bits to express the address. For example, a memory chip with 8 bit addresses has  $2^8 = 256$  memory locations. These locations are accessed as the addresses 00000000 through 11111111, 0 through 255 decimal or 00 through FF hex. (For ease of notation, programmers and circuit designers use hexadecimal, base 16, notation to avoid long strings of 1s and 0s.) The memory chip size can be expressed as  $M \times N$ , where M is the number of unique addresses, or memory locations and N is the word size, or number of bits per memory location. Memory chips come in a variety of sizes and can be arranged, together with control circuitry and decoders, to meet a designer's needs.

## Basic Structure

Memory chips, no matter how large or small, have several things in common. Each chip has address, data and control lines, as shown by the example chip in **Fig 7.37**. A memory chip must have enough address lines to uniquely address each of its words and as many data lines as there are bits per word. For example, the  $256 \times 1$  memory in Fig 7.37 has 8 address lines and 1 data line.

**Fig 7.37** — Example of a  $256 \times 1$  memory chip.

The control lines for a memory chip can vary. Fig 7.37 shows a simple example: two control lines, a  $R/\bar{W}$  and  $CS$ . In this case, data lines transfer both inputs (when writing) and outputs (when reading) so the  $R/\bar{W}$  control line is needed to put the memory chip in read mode or write mode. The chip select,  $CS$ , control line tells the chip whether it is in use. When the chip is selected, it is "on," acting upon the address, data and  $R/\bar{W}$  information presented to it. When the chip is not selected, the data line enters a high-impedance state so that it does not affect, and is not affected by, devices or circuits attached to it.

## Reading and Writing

To write (store data in) or read (retrieve data from) a memory device, it is necessary to gain access to specific memory cells. A small  $256 \times 1$  memory chip is used as an example. Later, this example will be expanded to a larger computer memory system.

If we want to write a 1 to the 11th word of the  $256 \times 1$  memory (such as memory location 10 decimal or 00001010 binary), we must execute the following steps:

- (1) Place the correct address (00001010) on the address lines.
  - (2) Place the data to be written (1) on the data line.
  - (3) Set the  $R/\bar{W}$  control line to write (low, 0).
  - (4) Set the  $CS$  control line to select (high, 1). (Many memory devices use an active low chip select,  $\bar{CS}$ .)
- This writes the data on the data line (1) to the address on the address lines (00001010).

The steps to read the contents of the 11th word are similar except that the  $R/\bar{W}$  control line is set to read (high, 1).

## Timing

Subtle timing requirements must also be incorporated into the above steps. While writing, the address and data information must be present for a minimum setup time before and hold time after, the  $CS$  and  $R/\bar{W}$  signals have been activated. This is to avoid spurious signals spraying all over the memory array. While reading, address line changes are not harmful, but the output data is only valid a minimum access time after the last address input is stable. Manufacturers' data sheets and application notes provide the timing specifications for the particular IC you are using.

## Larger Words

The one-bit-wide memory described

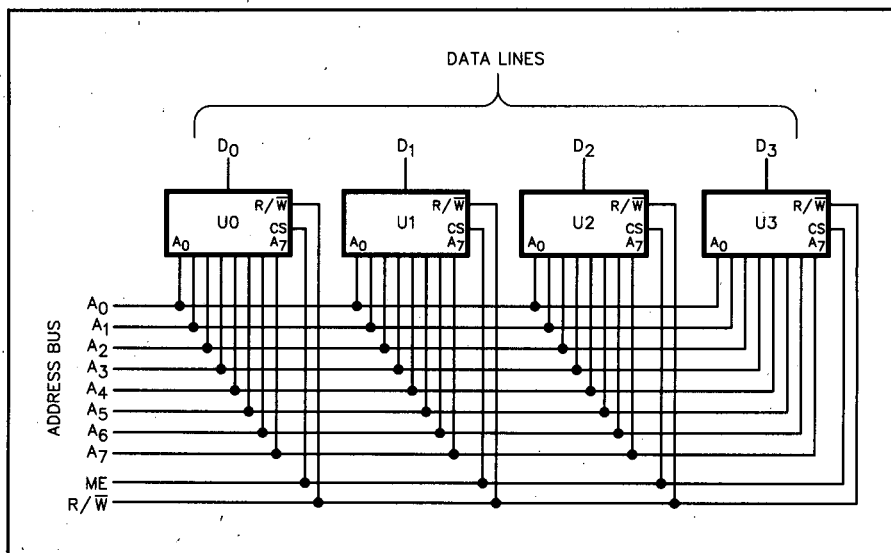

Fig 7.38 — A  $256 \times 4$  memory built with four  $256 \times 1$  memory chips.

above provides a good introduction, but usually we want a wider memory. One way to get wider memory is to use several 1-bit-wide memory chips, as shown in Fig 7.38. The address and control lines go to each chip, and data from each chip is used as a single bit in the large word. It is easy to see that when reading from address 0A (hex), the data lines D0 through D3 contain the data from address 0A of chips U0 through U3.

An address placed on the shared address lines (called an address bus) now specifies an entire word of data. Notice that one line of the address bus connects to the  $CS$  pin of each memory chip. This line is labeled ME, or memory enable, and sets all four ICs to read or write data at the same time.

If all four memory chips were put in a single package, they would make a  $256 \times 4$  IC. This IC would look like the chip in Fig 7.37, except that it would have 4 data lines.

## More Address Space

For even larger memory systems, the same principles as shown in Fig 7.38 can be applied. Fig 7.39 shows a  $1024 \times 8$  (1 kilobyte) memory built from four  $256 \times 8$  memory chips. A kilobyte, or kbyte is usually abbreviated as K. Notice this is not quite the same as the metric prefix kilo, because it represents 1024, rather than 1000.

Ten address lines are needed to address 1024 locations ( $2^{10} = 1024$ ). Eight of the 10 address lines, A0 to A7, are used as a normal address bus for chips 0 through 3. The remaining 2 address lines, A8 and A9, are run through a 2-to-

4 line decoder to choose between the 4 memory chips. When employed in this manner, the 2-to-4 line decoder is called an address decoder.

To assert the  $CS$  input for one of the memory chips, ME must be 1 and the correct output of the 2-to-4 line decoder must also be 1. When an address is placed on A0 through A9, a single memory chip is selected by ME, A8 and A9. The other 8 address lines address a single word from that chip. The three chips that are not selected enter a high-impedance state and do not affect the data lines. This example shows that, using the proper memory chips and address decoding, any size memory with any word length can be built.

## Alternate Structures

Fig 7.40 shows how the same chip can be accessed in different ways by using two decoders, a row decoder and a column decoder. The same  $256 \times 256$  memory array can be treated as a  $64 \text{ K} \times 1$  array, a  $256 \times 256$  array or other possibilities. In fact, most larger memory chips are made as square arrays:  $32 \times 32$  (1024 bytes or 1 K),  $64 \times 64$  (4096 bytes or 4 K),  $256 \times 256$  (65536 bytes or 64 K),  $1024 \times 1024$  (1 M),  $2048 \times 2048$  (4 M),  $4096 \times 4096$  (16 M) and so on. (Here the M represents a megabyte, which is 1048576 bytes.) The square array makes the chips more cost effective to manufacture (easier quality control and less waste) and easier to incorporate into a printed-circuit-board circuit layout. Notice that each  $M \times N$  is a power of 2. So while we refer to the chips by shorter names like 1 Mbyte, the actual number of memory cells is larger than 1000000. The

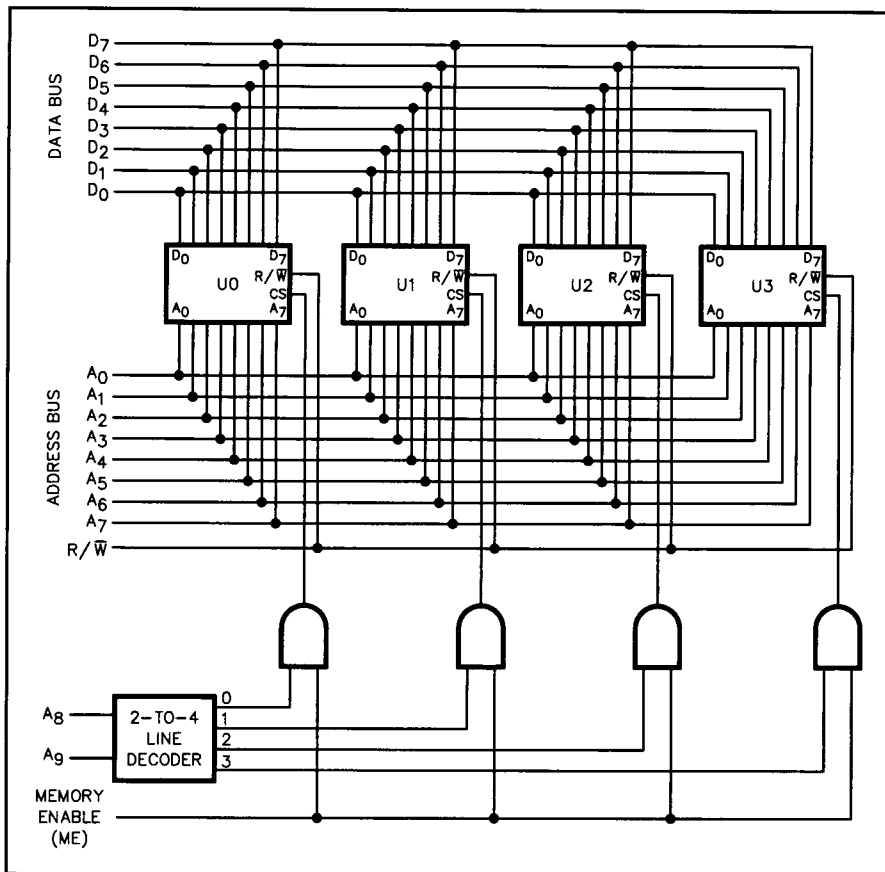

Fig 7.39 — A 1024 × 8 memory built with four 256 × 1 memory chips and appropriate control circuitry.

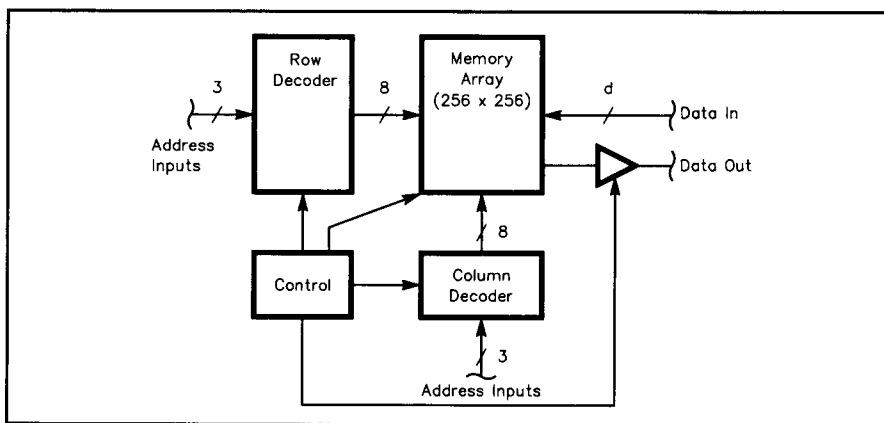

Fig 7.40 — Row and column decoders allow a memory array to be accessed in a variety of formats.

product,  $M \times N$ , only refers to the number of memory cells in the chip; and designers are free to choose the word size appropriate to their needs. In fact, they may access one location as an 8-bit word and another as a 16-bit word. For example, a computer with a Motorola MC68000 microprocessor automatically accesses a character, such as “A,” as 8 bits (a byte), an integer as 16 bits (a word) and a real value as 32

bits (a longword). (Apple Macintosh computers use the MC68000 microprocessor.) To further complicate things, a different manufacturer may call 16 bits a halfword and 32 bits a word. In using memory, the controller chips and circuitry to access the memory can be just as important as the memory itself.

### Memory Types

The concepts described above are applied to several types of random-access, semiconductor memory. Semiconductor memories are categorized by the ease and speed with which they can be accessed and their ability to “remember” in the absence of power.

### SAM versus RAM

One way to categorize memory is by what memory cells can be accessed at a given instant. *Sequential-access memory (SAM)* must be accessed by stepping past each memory location until the desired location is reached. Magnetic tapes implement SAM; to reach information in the middle of the tape, the tape head must pass over all of the information on the beginning of the tape. Two special types of SAM are the queue and the push-down stack. In a *queue*, also called a first-in, first-out (FIFO) memory, locations must be read in the order that they were written. The queue is a “first-come, first-served” device, like a line at a ticket window. The push-down stack is also called last-in, first-out (LIFO) memory. In LIFO memory, the location written most recently is the next location read. LIFO can be visualized as a stack, always adding to and removing from the “top” of the stack. *Random-access memory (RAM)* allows any memory cell to be accessed at any instant, with no time wasted stepping past the “beginning” parts of the data. Random-access memory is like a bookcase; any book can be pulled out at any time.

It is usually faster to access a desired word in RAM than in SAM. Also, all words in RAM have the same access time, while each word in a SAM has a different access time based on its position. Generally, the semiconductor memory devices internal to computers are random-access memories. Magnetic devices, such as tapes and disks, have at least some sequential access characteristics. We will leave tapes and disks for a later section and concentrate here on random-access, solid-state memories.

### Random Access Memory

Most RAM chips are *volatile*, meaning that stored information is lost if power is removed. RAM is either static or dynamic. *Dynamic RAM (DRAM)* stores a bit of information as the presence or absence of charge. This charge, since it is stored in a capacitor, slowly leaks away. It must be refreshed periodically. Memory refresh typically occurs every few milliseconds and is usually performed by a dynamic RAM controller chip. *Static RAM (SRAM)* stores a bit of information in a flip-flop. Since the bit will retain its value until ei-

ther power is removed or another bit replaces it, refresh is not necessary.

Both types of RAM have their advantages and disadvantages. The advantage of DRAM is increased density and ease of manufacture, making them significantly less expensive. SRAMs, however, have much faster access times. Most general purpose computers use DRAMs, since large memory size and low cost are the major objectives. Where the amount of memory required doesn't justify the use of DRAM, and the faster access time is important, SRAMs are common, for example, in embedded systems (telephones, toasters) and for cache memories. Both types of RAM are available in MOS families; SRAMs are also available in bipolar. Generally, MOS RAMs have lower power consumption than bipolar RAMs, while access speeds vary widely. Cost, power consumption and access time, provided in manufacturers' data sheets, are factors to consider in selecting the best RAM for a given application.

Read-Only Memory

Read-only memory (ROM) is nonvolatile; its contents are not lost when power is removed from the memory. Despite its name, all ROMs can be written or programmed at least once. The earliest ROM designs were "written" by clipping a diode between the memory bit and power supply wherever a 0 was desired. Modern MOS ROMs use a transistor instead of a diode. Mask ROMs are programmed by having ones and zeros etched into their semiconductors at manufacturing time, according to a pattern of connections and nonconnections provided in a mask. Since the "programming" of a mask ROM must be done by the manufacturer, adding expense and time delays, this type of ROM is primarily used only in high volume applications.

For low-volume applications, the programmable ROM (PROM) is the most effective choice since the data can be written after manufacture. A PROM is manufactured with all its diodes or transistors connected. A PROM programmer device then "burns away" undesired connections. This type of PROM can be written only once.

Two types of PROMs that can be "erased" and reprogrammed are EPROMs and EEPROMs. The transistors in UV erasable PROMs (EPROMs) have a floating gate surrounded by an insulating material. When programming with a bit value, a high voltage creates a negative charge on the floating gate. Exposure to ultraviolet light erases the negative charge. Similarly, electrically erasable

PROMs (EEPROMs) erase their floating-gate values by applying a voltage of the opposite polarity. Table 7.10 summarizes these ROM characteristics.

Besides being nonvolatile, PROMs are also distinguished from RAMs by their read and write times. Naturally, since PROMs are only written to infrequently, they can have slow write times (in the millisecond range). Their read times, however, are near those of RAM (in the nanoseconds). Read and write times for RAMs are nearly equal, both in the nanosecond range. Two other factors make it hard to write to PROMs: (1) PROMs must be erased before they can be reprogrammed and (2) PROMs often require a programming voltage higher than their operating voltage.

ROMs are practical only for storing data or programs that do not change frequently and must survive when power is removed from the memory. The programs that start up a computer when it is first switched on or the memory that holds the call sign in a repeater IDer are prime candidates for ROM.

Nonvolatile RAM

For some situations, the ideal memory would be as nonvolatile as ROM but as easy to write to as RAM. The primary example is data that must not be allowed to perish despite a power failure. Low-power RAMs can be used in such applications if they are supplied with NiCd or lithium cells for backup power. A more elegant and durable solution is nonvolatile RAM (NVRAM), which includes both RAM and ROM. The standard volatile RAM, called shadow RAM, is backed up by nonvolatile EEPROM. When the RECALL control is asserted, such as when power is first applied, the contents of the ROM are copied into the RAM. During normal operation, the system reads and writes to the RAM. When the STORE control is triggered, such as by a power failure or before turning off the system, the entire contents of the RAM are copied into the ROM for nonvolatile storage. In the event

of primary power failure, to successfully save the RAM data, some power must be maintained until the memory store is complete (+5 V for 20 ms).

Cache versus Main Memory

Memory is in high demand for many applications. To balance the trade-off of speed versus cost, most computers use a larger, slower, but cheaper main memory in conjunction with a smaller, faster, but more expensive cache memory. As you run a computer program, it accesses memory frequently. When it needs an item, a piece of data or the next part of the program to execute, it first looks in the cache. If the item is not found in the cache, it is copied to the cache from the main memory. As you run a computer program, it often repeats certain parts of the program and repeatedly uses pieces of data. Since this information has been copied to the high-speed cache, your computer game or other application can run faster. Information used less often or not being used at all (programs not currently being run) can stay in the slower main memory.

A "cache" is a place to store treasure; the treasure, the information you are using frequently, can be accessed quickly because it is in the high-speed cache. The use of cache versus main memory is managed by a computer's CPU so it is transparent to the user. The improvement in program execution time is similar to accessing a floppy disk versus the computer's internal memory.

I/O TRANSFERS

Input and output allow the computer to react to and affect the outside world. The ability to interact with their environment is a primary reason why computers are so useful and cost-effective. Usually, I/O is provided by a user, and a great deal of effort goes towards making computers user-friendly. Alongside the drive for user-friendly computers is the drive for automation. Data is acquired and operations are performed automatically, such as the packet bulletin board automatically

Table 7.10  
ROM Characteristics

Type	Technology	Read Time	Write Time	Comments
Mask ROM	NMOS, CMOS	25 - 500 ns	≈ 4 weeks	Write once; low power
Mask ROM	Bipolar	< 100 ns	≈ 4 weeks	Write once; high power; low density
PROM	Bipolar	< 100 ns	≈ 5 minutes	Write once; high power; no mask required
EPROM	NMOS, CMOS	25 - 500 ns	≈ 5 minutes	Reusable; low power; no mask required
EEPROM	NMOS	50 - 500 ns	10 ms / byte	10000 write cycles per location limit

forwarding a message. This section discusses the relationship of I/O to the internal operation of the computer: how the computer knows when and what I/O has been provided. The next section, on peripherals, discusses the range of devices that provide this information.

### Program-Controlled I/O

*Program-controlled I/O* might be understood by thinking of a cook who returns to the oven every few minutes to see if a meal is ready. Under program-controlled I/O, or polling, input and output events are initiated by the program currently running on the microcomputer. The program polls the I/O device, constantly checking if it is ready to accept or deliver data. When the I/O device indicates that it is ready, then the instruction that actually sends or receives the data is executed.

An advantage of program-controlled I/O is its simplicity. Program-controlled I/O is easily written and debugged. A disadvantage is wasted time. The program must spend its time checking the status of the I/O device rather than doing other useful things. If the program must have the input data before continuing, then no time is wasted; but if it could have been performing other tasks, then polling can be expensive and wasteful. Packet radio provides a familiar example of polling: the TNC repeatedly sends a packet until a confirmation message has been received from the BBS.

### Interrupt-Driven I/O

*Interrupt-driven I/O* avoids wasting time in a polling loop. The cook, rather than constantly checking the oven, goes off to other work until the timer rings. This efficiency is especially important on multiuser systems, where one program may be waiting for I/O while another program is executing.

The ring of the timer is called an *interrupt*, a temporary break in the normal execution of a program. The act of taking the food out of the oven is coded in an *interrupt service routine*. An interrupt service routine (ISR) is any code that performs the appropriate actions in response to a certain interrupt. Each interrupt has a number, and the location of each ISR is listed in a table next to its number. From the machine's perspective, the process is as follows: One of the bits in the microprocessor's status register is called the interrupt request indicator. When this bit becomes a 1, an interrupt has occurred. Circuitry indicates the number of the device requesting the interrupt. The machine temporarily suspends whatever it was working on and looks at its table of service

routes. From the table, the machine finds the location of the appropriate ISR and automatically jumps to that code and begins executing it. When finished with the ISR, the machine automatically returns to whatever it was doing before the interrupt.

The "getchar" subroutine below shows how an interrupt service routine for keyboard input might look in assembly language.

```
getchar:
MOVE RCVDATA,R7 ; Move the
                  data from the receiver to the
                  temporary storage register
RTE ; Return to normal execution
```

There are two key differences from the previous example: (1) No polling loop is involved. The READY bit, instead of being polled, triggers the interrupt request bit. (2) Leaving the main program and returning to it are done automatically by the machine instead of with a subroutine call inside the code.

The advantage of interrupt-driven I/O is that no time is wasted in a polling loop. This is especially advantageous in a multiuser environment where processing time must be juggled between the user demands. The disadvantage of interrupts is that program flow can become very confusing; for example, what happens if an interrupt service routine gets interrupted? This is usually handled by assigning priorities to each possible interrupt and, when inside an ISR, ignoring other interrupts of lesser or equal priority.

A familiar example of an interrupt is when you want to crash out of a program; for example, the CTRL - ALT - DEL key combination on an IBM, the reset button on a Macintosh, or the CTRL C or CTRL Y combination on a UNIX machine. Examples of a timer interrupt are the sending every ten minutes of a repeater's ID; the automatic save of some word processors; and, when doing packet, the BBS automatically kicks you out for too many minutes of inactivity.

### Memory-Mapped I/O

In *memory-mapped I/O*, addresses that are treated like RAM by the microprocessor are actually I/O devices. Thus, a command that would usually be used to read or write to a memory location might actually result in an I/O operation. Since memory mapping is an addressing technique, it can be used with either interrupt-driven or polled I/O.

### Direct Memory Access

Direct Memory Access (DMA) enables

data to be transferred directly between memory and an I/O device without involving the CPU. The advantages of DMA are to provide high-speed transfer of data, such as from a peripheral disk drive or communications device, while the CPU is performing internal tasks. The data transfer operation is managed by a DMA controller, either a separate chip or internal to the microprocessors. The following illustrates some of the steps involved in the I/O transfer:

An I/O device requests DMA operation.

The DMA controller requests the bus from the CPU.

The CPU acknowledges the request and releases the bus.

The DMA controller tells the I/O device to send its information.

The DMA technique is used by I/O processors. In large computer systems, these auxiliary processors perform most of the I/O functions, thus freeing the CPU for other tasks.

## PERIPHERALS

Peripherals are any devices outside the CPU. They provide additional capabilities. One of the most common examples being communication with a user via input devices and output devices. Input devices provide the computer both data to work on and programs to tell it what to do. Output devices present the results of computer operations to the user or another system and may even control an external system. Both input and output combine to provide user friendly interaction. This section discusses the most common user interfaces.

Most of these devices have adapted to certain standards and use readily available connection cables. Thus, they can be easily incorporated into a system, and a knowledge of the internal actions is not necessary. A knowledge of how external memory devices work is more useful and will be discussed in more detail.

### Input Devices

The keyboard is probably the most familiar input device. A keyboard simply makes and breaks electrical contacts. The open or closed contacts are usually sensed by a microprocessor built into the circuit board under the keys. This microprocessor decodes the key closures and sends the appropriate ASCII code to the main computer unit. Keyboards will generate the entire 128 character ASCII set and often, with CONTROL and ALT (Alternate) keys, the 256 character extended ASCII set.

The mouse is becoming increasingly popular for use with graphical user interfaces. The mouse casing holds a ball and

circuitry to act as a multidirectional detection device. By moving the mouse, the ball rolls, controlling the relative position of a cursor on the screen. Buttons on the mouse make and break connections (clicking) to select and activate items (icons) on the screen. The trackball is a variation of the mouse.

Other input devices include modems and magnetic disks and tapes. Magnetic disks and tapes, discussed at length later, provide additional external memory. Newer input devices include voice activated devices, touch screens and scanners.

## Output Devices

The most familiar output device is the computer screen, or monitor. For smaller character displays, LED arrays can be used. The next most common output device is the printer, to produce paper hardcopy. Modems and magnetic disks and tapes are output devices as well as input devices. Newer output devices include speech synthesizers.

The output devices (except the sound device) share a common display technique: images, such as characters and graphics, are formed by tiny dots, called *pixels* (picture elements). On screens, these are dots of light turned on and off. In printers, they are dots of ink imposed onto the paper. For color displays, pixels in red, green and blue (RGB) are spaced closely together and appear as numerous colors to the human eye. **Fig 7.41A** and **B** show two examples of how characters can be formed using an array of dots. Part C shows how

a series of 14 bars can be arranged to form a character display.

## Video Displays

Video monitors are usually specialized cathode-ray tube (CRT) displays. In newer notebook computers, the monitors are being fabricated with monochrome or color liquid-crystal displays (LCDs), but color LCD displays are still quite expensive. A standard TV set can even be used as a computer monitor. Two techniques are used to turn on the screen pixels. *Raster scanning* covers the screen by writing one row of pixels at a time, from left to right and top to bottom. Then, a vertical retrace brings the beam back to the top of the screen to begin again. Raster scanning signals every pixel on or off for each screen pass. An alternative, *vector mode*, only signals the pixels where something on the screen has changed.

Light-emitting diodes (LEDs) are handy when a full screen display is not necessary. A single diode easily indicates on/off states such as the power light on many devices. A popular single character display is the seven segment version, shown in **Fig 7.41D**, which is good for displaying numbers.

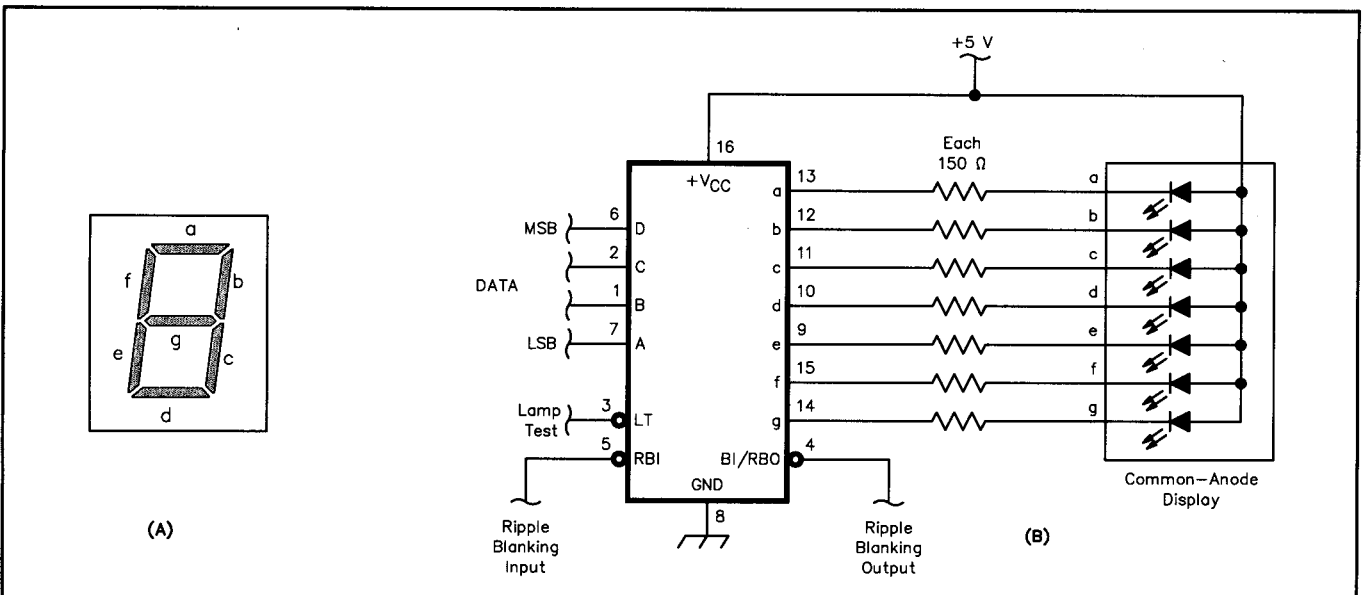

Various seven-segment decoders are available to drive common-cathode and common-anode seven-segment displays. These drivers receive a number, usually in BCD format, and decode the number into signal levels to activate the proper a-g segments of the display. **Fig 7.42** shows one example of a seven segment decoder

and display. Part B shows a TTL 7447 IC and a common-anode LED display. The TTL 7448 is designed to drive common-cathode displays. The dc illumination method shown is the easiest to implement; but higher light output with lower energy consumption can be obtained by pulsing and multiplexing the display voltage. A pulse rate of 100 Hz is imperceptible to the human eye.

As more digits are added, using a separate decoder/driver for each display becomes unfeasible from economic and PC-

**Fig 7.41 — Various character display formats.**

**Fig 7.42 — (A) The segments and their arrangement in a seven-segment display. (B) Shows how a 7447 decoder/driver IC converts BCD data into the appropriate driving signals for a common-anode seven-segment LED display. A 7448 IC will drive a common-cathode LED display.**

board points-of-view. **Fig 7.43** shows how a single decoder can be set up to drive several displays using a multiplexing setup. The multiplexer logic sends input data for a digit into the decoder and enables the common element of the correct display, ensuring that a display will be energized only when both the segment and its common lead are selected. With this system, only one digit is energized at any instant, a factor that greatly reduces power-supply requirements. To maintain the brightness of each digit, the current to each display segment must be increased. When implementing a multiplexed display, be sure not to exceed the peak and average current specifications for the display.

### Disk Drives

Magnetic media are essential input/output devices since they provide additional memory. The earliest ways to store programs and data were on punched cards and tape. Some early home computers used audio cassettes.

Disk storage is prevalent when random access is needed. In some ways, disk storage is similar to that of a record player. The data is stored in circles (tracks) on a round platter (disk or diskette) and accessed by a device (a head) moving over the platter. Unlike the record player, the tracks are concentric rather than spiral and the head can write as well as read.

**Fig 7.44A** shows an example of the disk recording surface. Usually the tracks are divided into equal-sized storage units, called sectors. Also, since the disk has two sides, most disks can store information on both sides. Therefore, locating a piece of

information in disk memory means identifying three coordinates: the side, track and sector.

Accessing a piece of information on the disk system involves a number of wait times until the data access is complete. First, disks may be either movable-head or fixed-head, as shown in **Fig 7.44B**. In the movable system, a single read/write head is attached to a movable arm, so there is a seek time for the movable arm to position the read/write head on the appropriate track. In a fixed system, each track has its own read/write head, so seek time is zero since the head is immediately in position. Second, the data must rotate into position under the read/write head. This time is called latency. Finally, there is the normal time for the read/write to occur.

A number of types of disk technology are available. In hard disk systems, the disk is rigid and the read/write head does not contact the disk directly. The absence of friction between the head and disk allows finer head positioning and higher disk speeds. Thus, hard disks hold more data and are accessed more quickly than floppy disks. Floppy disks enclose the magnetic-media platter in a casing, as shown in **Fig 7.44C**, so the disk can be carried around. The floppy disk can be inserted into a disk drive and the read/write head automatically extended; when done, the read/write head is automatically retracted before the disk is ejected from the drive. Variations in floppy disks include single-sided (SS) or double-sided (DS); single, double or high density; and  $3\frac{1}{2}$  or  $5\frac{1}{4}$  inches. The density refers to the disk format used by the disk controller. High data density allows more data to be

written to the disk but requires a higher quality diskette. Not all disks can be written as high density and not all disk drives can read high density disks.

Dust and dirt on the disk and the imperfections in the disk surface gradually damage both the disk and the head. This means that disks eventually wear out, and the data on the disk will probably be lost. Therefore, it is prudent to make backup copies of your disks, stored in a clean, dry, cool place.

### Tape

Tape is one of the more inexpensive options for auxiliary memory. Tape access time is slow, since the data must be accessed sequentially, so tape is primarily used for backup copies of a system's memory. Tape is available in cassette form (common sizes are comparable to the cassettes for a portable tape player and VCR tapes) and on reels (diameter is approximately one foot).

Digital audio tape (DAT) is replacing other forms of tape backup system in newer computer systems. A single 4-mm-wide DAT cartridge, which fits in the palm of your hand, can hold over 2 gigabytes (GB) of data (1 GB = 1000 MB).

### INTERNAL AND EXTERNAL INTERFACING

Designing an interface, or simply using an existing interface, to connect two devices involves a number of issues. For example, digital interfacing can be categorized as parallel or serial, internal or external and asynchronous or synchronous. Additional issues are the data rate, error detection methods and the signaling format or standards. The format can be especially important since many standards and conventions have developed that should be taken into consideration. This chapter focuses on some basic concepts of digital communications for interfacing between devices.

#### Parallel Versus Serial Signaling

To communicate a word to you across the room, you could hold up flash cards displaying the letters of the word. If you hold up four flash cards, each with a letter on it, all at once, then you are transmitting in parallel. If instead, you hold up each of the flashcards only one at a time, then you are transmitting in serial. *Parallel* means all the bits in a group are handled exactly at the same time. *Serial* means each of the bits is sent in turn over a single channel or wire, according to an agreed sequence. **Fig 7.45** gives a graphic illustration of parallel and serial signaling.

Both parallel and serial signaling are

**Fig 7.43 — Multiplexed character displays.** The digits are wired in parallel, or with all of the “a” segments connected together and so on. BCD data for a particular display is placed at the decoder input and the desired display is selected by its address.

(A) A Disk Recording Surface

(B) A Column of Disks

(C) 3.5" Floppy Disk (Back View)

appropriate for certain circumstances. Parallel signaling is faster, since all bits are transmitted simultaneously; but each bit needs its own conductor, which can be expensive. Parallel signaling is more likely to be used on internal communications. For longer distance communications, such as to an external device, serial signaling is more appropriate. Each bit is sent in turn, so communication is slower; but it is also less expensive, since fewer channels are needed between the devices.

Most amateur digital communications use serial transmission, to minimize cost and complexity. The number of channels needed for parallel or serial signaling also depends on the operational mode: one channel per bit for simplex (one-way, from sender to receiver only) and for half-duplex (two-way communication, but only one person can talk at a time) but two channels per bit for full-duplex (simultaneous communications in both directions).

### Parallel I/O Interfacing

Fig 7.46 shows an example of a parallel input/output chip. Typically, they have eight data lines and one or more handshaking lines. *Handshaking* involves a number of functions to coordinate the data transfer. For example, the READY line indicates that data is available on all 8 data lines. If only the READY line is used, however, the receiver may not be able to keep up with the data. Thus, the STROBE line is added so the receiver can watch to ensure the transmitter is ready for the next character.

### Serial I/O Interfacing

Serial input/output interfacing is more complex than parallel, since the data must be transmitted based on an agreed sequence. For example, transmitting the 8 bits (b7, b6, ... b0) of a word includes specifying whether the least significant bit, b0, or the most significant bit, b7, is sent first. Fortunately, a number of standards have developed to define the agreed sequence, or encoding scheme.

### Conversions

Within computers and other digital circuits, data is usually operated on, stored and transmitted in parallel. For communicating with an external device, data must

**Fig 7.44 — Disk storage: (A) a disk recording surface, (B) a column of disks illustrating fixed versus movable head and single versus double sided, (C) a floppy disk.**

[illegible]

(A)

Shift registers can be left shifters, right shifters or controlled to shift in either direction. The most general form, a universal shift register, has two control inputs for four states: Hold, Shift right, Shift left and Load. Most also have asynchronous inputs for preset, clear and parallel load.

The diagram shows a 'PARALLEL I/O' block on the left and an 'EXTERNAL DEVICE' block on the right. They are connected by four horizontal lines labeled 'DATA'. Below the data lines, there are two control lines: 'READY' with an arrow pointing from the external device to the parallel I/O block, and 'STROBE' with an arrow pointing from the parallel I/O block to the external device.

all data bits have been shifted out and the register has a value of 0.

## Asynchronous versus Synchronous Communication

To correctly receive data, the receiving interface must know when data bits will occur; it must be synchronized with the sender. In *asynchronous* communication, the receiver synchronizes on each incoming character. Each character includes start and stop bits to indicate the beginning and end of that character. In *synchronous* communication, data is sent in long blocks, without start and stop bits or gaps between characters.

## Asynchronous Communication

In asynchronous communication, each transmitted character begins with a start bit and ends with a stop bit, as shown in **Fig 7.47A**. The start bit (usually a zero) tells the receiver to begin receiving a character. The stop bit (usually a one) signals the end of a character. Between characters, the transmitting circuit sends the stop bit state (steady one or zero).

Since the receiver is always told when a character begins and ends, characters can be sent at irregular intervals. This is especially advantageous for typed input, since the person typing is usually slower than the data communications equipment and will usually work at an uneven pace. Another advantage of asynchronous data is that it does not need complex circuits to keep it synchronized. Since the receiver is newly synchronized at the beginning of each character, the characters need not be sent in a steady stream and no stringent demands are made on the person or process generating the characters.

A disadvantage of asynchronous communications is the inclusion of the start and stop bits, which are not "useful" data. If you are transmitting 8 data bits, 1 start bit and 1 stop bit, then 20% (2 of 10 bits) is overhead.

### Synchronous Communications

In synchronous communications, data is sent in blocks, usually longer than a single character, as shown in Fig 7.47B. At the beginning of each block, the sender transmits a special sequence of bits that the receiver uses for initial synchronization. After becoming synchronized at the beginning of a block, the receiver must stay synchronized throughout the block. The sender and receiver may be using slightly different clock frequencies, so it is usually not adequate for them to merely be synchronized initially. There are several ways for the receiver to stay synchronized. The transmitter may send the clock

signal on a separate channel, but this is wasteful. The modulation technique used on the communications channel may convey clock information or the clock may be implicit within the data. See Fig 7.48.

One disadvantage of synchronous transmission is that the data must be sent as a continuous stream; characters must be placed in a buffer until there are enough to make a block. Also, while errors in asynchronous signaling usually only affect one character (the receiver can resynchronize at the beginning of the next character), error recovery on synchronous channels may be a longer process involving several lost characters or an entire lost block.

The major advantage of synchronous signaling is that it does not impose overhead (the start and stop bits) on each character. This is an important consideration during large data transfers.

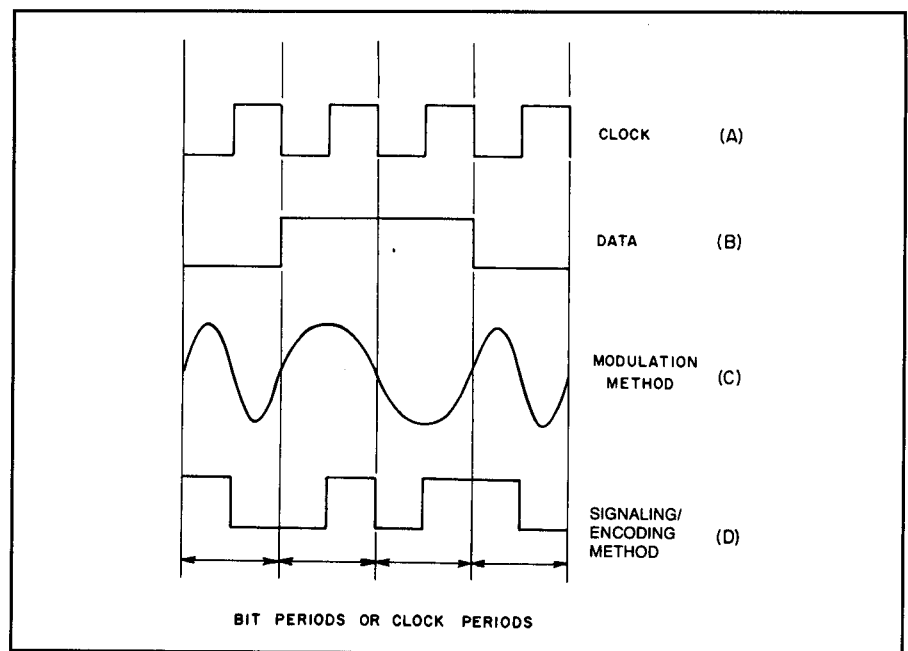

### Data Rate

There are a number of limitations on how fast data can be transferred: (1) The sending equipment has an upper limit on how fast it can produce a continuous stream of data. (2) The receiving equipment has an upper limit on how fast it can accept and process data. (3) The signaling channel itself has a speed limit, often based on how fast data can be sent without errors. (4) Finally, standards and the need for compatibility with other equipment may have a strong influence on the data rate.

Two ways to express data transmission rates are *baud* and *bits per second (bps)*. These two terms are not interchangeable: Baud describes the signaling, or symbol, rate — a measure of how fast individual signal elements **could** be transmitted through a communications system. Specifically, the baud is defined as the reciprocal of the shortest element (in seconds) in the data encoding scheme. For example, in a system where the shortest element is 1 ms long, the maximum signaling rate would be 1000 elements per second. (Note that, since baud is measured in elements per second, the term “baud rate” is incorrect since baud is already a measure of speed, or rate.) Continuous transmission is not required, because signaling speed is based only on the shortest signaling element.

Signaling rate in baud says nothing about actual information transfer rate. The maximum information transfer rate is defined as the number of equivalent binary digits transferred per second; this is measured in bits per second.

When binary data encoding is employed, each signaling element represents one bit. Complications arise when more

**Fig 7.48 —Recovering the clock (A) when the data (B) is transmitted allows a receiver to maintain synchronization during synchronous communication. The modulation method shown at C results in a transition of the received carrier at the beginning and end of each clock period. The encoding method shown at D results in a data transition in the middle of each clock period. Either of these methods provides enough information for clock recovery.**

sophisticated data encoding schemes are used. In a quadriphase shift keying (QPSK) system, a phase transition of 90° represents a level shift. There are four possible states in a QPSK system; thus, two binary digits are required to represent the four possible states. If 1000 elements per second are transmitted in a quadriphase system where each element is represented by two bits, then the actual information rate is 2000 bps.

This scheme can be extended. It is possible to transmit three bits at a time using eight different phase angles (bps = 3 × baud). In addition, each angle can have more than one amplitude. A standard 9600 bps modem uses 12 phase angles, 4 of which have two amplitude values. This yields 16 distinct states, each represented by four binary digits. Using this technique, the information transfer rate is four times the signaling speed. This is what makes it possible to transfer data over a phone line at a rate that produces an unacceptable bandwidth using simpler binary encoding. This also makes it possible to transfer data at 2400 bps on 10 m, where FCC regulations allow only 1200 baud signals.

When are transmission speed in bauds and information rate in bps equal? Three conditions must be met: (1) binary encoding must be used, (2) all elements used to encode characters must be equal in width and (3) synchronous transmission at a con-

stant rate must be employed. In all other cases, the two terms are not equivalent.

Within a given piece of equipment, it is desirable to use the highest possible data rate. When external devices are interfaced, it is normal practice to select the highest standard signaling rate at which both the sending and receiving equipment can operate.

### ERROR DETECTION

Since data transfers are subject to errors, data transmission should include some method of detecting and correcting errors. Numerous techniques are available, each used depending on the specific circumstances, such as what types of errors are likely to be encountered. Some error detection techniques are discussed in the **Modulation Sources** chapter. One of the simplest and most common techniques, parity check, is discussed here.

#### Parity Check

Parity check provides adequate error detection for some data transfers. This method transmits a parity bit along with the data bits. In systems using odd parity, the parity bit is selected such that the number of 1 bits in the transmitted character (data bits plus parity bit) is odd. In even parity systems, the parity bit is chosen to give the character an even number of ones. For example, if the data 1101001 is to be

transmitted, there are 4 (an even number) ones in the data. Thus, the parity bit should be set to 1 for odd parity (to give a total of 5 ones) or should be 0 for even parity (to maintain the even number, 4). When a character is received, the receiver checks parity by counting the ones in the character. If the parity is correct, the data is assumed to be correct. If the parity is wrong, an error has been detected.

Parity checking only detects a small fraction of possible errors. This can be intuitively understood by noting that a randomly chosen word has a 50% chance of having even parity and a 50% chance of having odd parity. Fortunately, on relatively error-free channels, single-bit errors are the most common and parity checking will always detect a single bit in error. Parity checking is a simple error detection strategy. Because it is easy to implement, it is frequently used.

### Signaling Levels

Inside equipment and for short runs of wire between equipment, the normal practice is to use neutral keying; that is, simply

to key a voltage such as +5 V on and off. In neutral keying, the off condition is considered to be 0 V. Over longer runs of wire, the line is viewed as a transmission line, with distributed inductance and capacitance. It takes longer to make the transition from 0 to 1 or vice versa because of the additional inductance and capacitance. This decreases the maximum speed at which data can be transferred on the wire and may also cause the 1s and 0s to be different lengths, called bias distortion. Also, longer lines are more likely to pick up noise, which can make it difficult for the receiver to decide exactly when the transition takes place.

Because of these problems, polar keying (technically bipolar keying) is used on longer lines. Polar keying uses one polarity (for example +) for a logical 1 and the other (– in this example) for a 0. This means that the decision threshold at the receiver is 0 V. Any positive voltage is taken as a 1 and any negative voltage as a 0.

Since neutral keying is usually used in-

side equipment and polar keying for lines leaving the equipment, signals must be converted between polar and neutral. Op amp circuits, line drivers and line receivers are ways to handle this conversion. There are a number of different types available, but the most popular ones are the 1488 quad line driver and the 1489 quad line receiver. The 1488 is capable of converting four data streams at standard TTL levels to output levels that meet EIA RS-232-C or CCITT V.24 standards. The 1489 has four receivers that can convert RS-232-C or V.24 levels to TTL/DTL levels.

### Connectors

These digital interfacing issues are simply digital communications issues for the specific case of direct wire connections between devices. Since direct wire connections are involved, the designer should consider the type of connector between the devices and its pin assignments. Numerous connectors are available or can be created.

# Analog Signals and Components

## 8

### Glossary

- Active Region** — The region in the characteristic curve of an analog device in which the signal is amplified linearly.
- Amplification** — The process of increasing the size of a signal. Also called gain.
- Analog signal** — A signal, usually electrical, that can have any amplitude (voltage or current) value and exists at any point in time.
- Anode** — The element of an analog device that accepts electrons.
- Base** — The middle layer of a bipolar transistor, often the input.
- Biasing** — The addition of a dc voltage or current to a signal at the input of an analog device, which changes the signal's position on the characteristic curve.
- Bipolar Transistor** — An analog device made by sandwiching a layer of doped semiconductor between two layers of the opposite type: PNP or NPN.
- Buffer** — An analog stage that prevents loading of one analog stage by another.
- Cascade** — Placing one analog stage after another to combine their effects on the signal.
- Cathode** — The element of an analog device that emits electrons.
- Characteristic Curve** — A plot of the relative responses of two or three analog-device parameters, usually output with respect to input.
- Clamping** — A nonlinearity in amplification where the signal can be made no larger.
- Collector** — One of the outer layers of a bipolar transistor, often the output.
- Compensation** — The process of counteracting the effects of signals that are inadvertently fed back from the output to the input of an analog system. The process increases stability and prevents oscillation.
- Cutoff Region** — The region in the characteristic curve of an analog device in which there is no current through the device. Also called the OFF region.
- Diode** — A two-element vacuum tube or semiconductor with only a cathode and an anode (or plate).
- Drain** — The connection at one end of a field-effect-transistor channel, often the output.
- Electron** — A subatomic particle that has a negative charge and is the basis of electrical current.
- Emitter** — One of the outer layers of a bipolar transistor, often the reference.
- Field-Effect Transistor (FET)** — An analog device with a semiconductor channel whose width can be modified by an electric field. Also called a unipolar transistor.
- Gain** — see **Amplification**.
- Gain-Bandwidth Product** — The interrelationship between amplification and frequency that defines the limits of the ability of a device to act as a linear amplifier. In many amplifiers, gain times bandwidth is approximately constant.
- Gate** — The connection at the control point of a field-effect transistor, often the input.
- Grid** — The vacuum-tube element that controls the electron flow from cathode to plate. Additional grids in some tubes perform other control functions to improve performance.
- Hole** — A positively charged "particle" that results when an electron is removed from an atom in a semiconductor crystal structure.
- Integrated Circuit (IC)** — A semiconductor device in which many components, such as diodes, bipolar transistors, field-effect transistors, resistors and capacitors are fabricated to make an entire circuit.
- Junction FET (JFET)** — A field-effect transistor that forms its electric field across a PN junction.
- Linearity** — The property found in nature and most analog electrical circuits that governs the processing and combination of signals by treating all signal levels the same way.
- Load Line** — A line drawn through a family of characteristic curves that shows the operating points of an analog device for a given output load impedance.
- Loading** — The condition that occurs when a cascaded analog stage modifies the operation of the previous stage.
- Metal-Oxide Semiconductor (MOSFET)** — A field-effect transistor that forms its electric field through an insulating oxide layer.
- N-Type Impurity** — A doping atom with an excess of electrons that is added to semiconductor material to give it a net negative charge.
- Noise** — Any unwanted signal.
- Noise Figure (NF)** — A measure of the noise added to a signal by an analog processing stage.
- Operational Amplifier (op amp)** — An integrated circuit that contains a symmetrical circuit of transistors and resistors with highly improved characteristics over other forms of analog amplifiers.
- Oscillator** — An unstable analog system, which causes the output signal to vary spontaneously.
- P-Type Impurity** — A doping atom with an excess of holes that is added to semiconductor material to give it a net positive charge.
- Peak Inverse Voltage (PIV)** — The highest voltage that can be tolerated by a reverse-biased PN junction before current is conducted.
- Pentode** — A five element vacuum tube with a cathode, a control grid, a screen grid, a suppressor grid, and a plate.
- Plate** — See anode, usually used with vacuum tubes.
- PN Junction** — The region that occurs when P-type semiconductor material is placed in contact with N-type semiconductor material.
- Saturation Region** — The region in the characteristic curve of an analog device in which the output signal can be made no larger. See **Clamping**.
- Semiconductor** — An elemental material whose current conductance can be controlled.
- Signal-To-Noise Ratio (SNR)** — The ratio of the strength of the desired signal to that of the unwanted signal (noise).
- Slew Rate** — The maximum rate at which a signal may change levels and still be accurately amplified in a particular device.
- Source** — The connection at one end of the channel of a field-effect transistor, often the reference.
- Superposition** — The natural process of adding two or more signals together and having each signal retain its unique identity.
- Tetrode** — A four-element vacuum tube with a cathode, a control grid, a screen grid, and a plate.
- Triode** — A three element vacuum tube with a cathode, a grid, and a plate.
- Unipolar Transistor** — see **Field-Effect Transistor (FET)**.
- Zener Diode** — A PN-junction diode with a controlled peak inverse voltage so that it will start conducting current at a preset reverse voltage.

# Introduction

This chapter, written by Greg Lapin, KD9AZ, treats analog signal processing in two major parts. Analog signals behave in certain well defined ways regardless of the specific hardware used to implement the processing. Signal processing involves various electronic stages to perform functions such as amplifying, filtering, modulation and demodulation. A piece of electronic equipment, such as a radio, cascades a number of these circuits. How these stages interact with each other and how they affect the signal individually and in tandem is the subject

of the first part of this chapter.

Implementing analog signal processing functions involves several types of active components. An active electronic component is one that requires a power source to function, and is distinguished in this way from passive components (such as resistors, capacitors and inductors) that are described in the **DC Theory and Resistive Components** chapter and the **AC Theory and Reactive Components** chapter. The second part of this chapter describes the various technologies that implement active devices. Vacuum tubes,

bipolar semiconductors, field-effect semiconductors and integrated semiconductor circuitry comprise a wide spectrum of active devices used in analog signal processing. Several different devices can perform the same function. The second part of the chapter describes the physical basis of each device. Understanding the specific characteristics of each device allows you to make educated decisions about which device would be best for a particular purpose when designing analog circuitry, or understanding why an existing circuit was designed in a particular way.

## Analog Signal Processing

### LINEARITY

The term, *analog signal*, refers to the continuously variable voltage of which all radio and audio signals are made. Some signals are man-made and others occur naturally. In nature, analog signals behave according to laws that make radio communication possible. These same laws can be put to use in electronic instruments to allow us to manipulate signals in a variety of ways.

The premier properties of signals in nature are *superposition* and *scaling*. Superposition is the property by which signals combine. If two signals are placed together, whether in a circuit, in a piece of wire, or even in air, they become one combined signal that is the sum of the individual signals. This is to say that at any one point in time, the voltage of the combined signal is the sum of the voltages of the two original signals at the same time. In a linear system any number of signals will add in this way to give a single combined signal.

One of the more important features of superposition, for the purposes of signal processing, is that signals that have been combined can be separated into their original components. This is what allows signals that have been contaminated with noise to be separated from the noise, for example.

Amplification and attenuation scale signals to be larger and smaller, respectively. The operation of scaling is the same as multiplying the signal at each point in time by a constant value; if the constant is greater than one then the signal is amplified, if less than one then the signal is attenuated.

**Fig 8.1 — Generic amplifier. (A) Symbol.** For the linear amplifier, gain is the constant value,  $G$ , and the output voltage is equal to the input voltage times  $G$ ; (B) Transfer function, input voltage along the x-axis is converted to the output voltage along the y-axis. The linear portion of the response is where the plot is diagonal; its slope is equal to the gain,  $G$ . Above and below this range are the clamping limits, where the response is not linear and the output signal is clamped.

### Linear Operations

Any operation that modifies a signal and obeys the rules of superposition and scaling is a *linear operation*. The most basic linear operation occurs in an amplifier, a circuit that increases the amplitude of a signal. Schematically, a generic amplifier is signified by a triangular symbol, its input along the left face and its output at the point on the right (see Fig 8.1). The

linear amplifier multiplies every value of a signal by a constant value. Amplifier gain is often expressed as a multiplication factor (x 5, for example).

$$\text{Gain} = \frac{V_o}{V_i} \quad (1)$$

where  $V_o$  is the output voltage from an amplifier when an input voltage,  $V_i$ , is applied.

Ideal linear amplifiers have the same gain for all parts of a signal. Thus, a gain of 10 changes 10 V to 100 V, 1 V to 10 V and -1 V to -10 V. Amplifiers are limited by their dynamic range and frequency response, however. An amplifier can only produce output levels that are within the range of its power supply. The power-supply voltages are also called the *rails* of an amplifier. As the amplified output approaches one of the rails, the output will not go beyond a given voltage that is near the rail. The output is limited at the *clamping level* of an amplifier. When an amplifier tries to amplify a signal to be larger than this value, the output remains at this level; this is called output *clamping*. Clamping is a nonlinear effect; an amplifier is considered linear only between its clamping levels. See Fig 8.1.

Another limitation of an amplifier is its frequency response. Signals within a range of frequencies are amplified consistently but outside that range the amplification changes. At higher frequencies an amplifier acts as a low-pass filter, decreasing amplification with increasing frequency. For lower frequencies, amplifiers are of two kinds: dc and ac coupled. A dc coupled amplifier equally amplifies signals with frequencies down to dc. An

ac coupled amplifier acts as a high-pass filter, decreasing amplification as the frequency decreases toward dc.

The combination of gain and frequency limitations is often expressed as a *gain-bandwidth product*. At high gains many amplifiers work properly only over a small range of frequencies. In many amplifiers, gain times bandwidth is approximately constant. As gain increases, bandwidth decreases, and vice versa. Another similar descriptor is called *slew rate*. This term describes the maximum rate at which a signal can change levels and still be accurately amplified in a particular device. There is a direct correlation between the signal-level rate of change and the frequency content of that signal.

## Feedback and Oscillation

The stability of an amplifier refers to its ability to provide gain to a signal without tending to oscillate. For example, an amplifier just on the verge of oscillating is not generally considered to be "stable." If the output of an amplifier is fed back to the input, the feedback can affect the amplifier stability. If the amplified output is added to the input, the output of the sum will be larger. This larger output, in turn, is also fed back. As this process continues, the amplifier output will continue to rise until the amplifier cannot go any higher (clamps). Such *positive feedback* increases the amplifier gain, and is called *regeneration*.

Most practical amplifiers have intrinsic feedback that is unavoidable. To improve the stability of an amplifier, *negative feedback* can be added to counteract any

unwanted positive feedback. Negative feedback is often combined with a phase-shift *compensation* network to improve the amplifier stability.

The design of feedback networks depends on the desired result. For amplifiers, which should not oscillate, the feedback network is customized to give the desired frequency response without loss of stability. For oscillators, the feedback network is designed to create a steady oscillation at the desired frequency.

## Filtering

A filter is a common linear stage in radio equipment. Filters are characterized by their ability to selectively attenuate certain frequencies (stop band) while passing or amplifying others (pass band). Passive filters are described in the **Filters and Projects** chapter. Filters can also be designed using active devices. All practical amplifiers are low-pass filters or band-pass filters, because the gain decreases as the frequency increases beyond their gain-bandwidth products.

## Summing Amplifiers

In a linear system, nature does most of the work for us when it comes to adding signals; placing two signals together naturally causes them to add. When processing signals, we would like to control the summing operation so the signals do not distort. If two signals come from separate stages and they are connected, the stages may interact, causing both stages to distort their signals. Summing amplifiers generally use a resistor in series with each stage, so the resistors connect to the

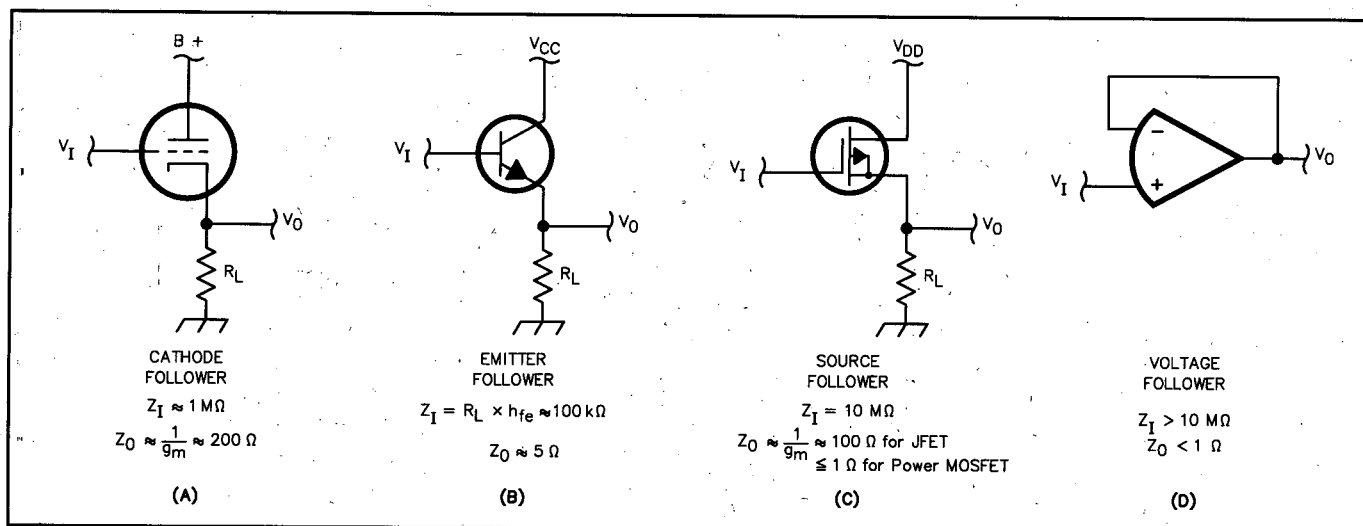

common input of the following stage. **Fig 8.2** illustrates the resistors connecting to a summing amplifier. Ideally, any time we wanted to combine signals (for example, combining an audio signal with a PL tone in a 2 m FM transmitter prior to modulating the RF signal) we could use a summing amplifier.

## Buffering

It is often necessary to isolate the stages of an analog circuit. This isolation reduces the loading, coupling and feedback between stages. An intervening stage, called a *buffer*, is often used for this purpose. A buffer is a linear circuit that is a type of amplifier. It is often necessary to change the characteristic impedance of a circuit between stages. Buffers can have high values of amplification but this is unusual. A buffer performs impedance transformations most efficiently when it has a low or unity gain. **Fig 8.3** shows common forms of buffers with low-impedance outputs:

**Fig 8.2 — Summing amplifier.** The output voltage is equal to the sum of the input voltages times the amplifier gain,  $G$ . As long as the resistance values,  $R$ , are equal and the amplifier input impedance is much higher, the actual value of  $R$  does not affect the output signal.

**Fig 8.3 — Common buffer stages and some typical input ( $Z_i$ ) and output ( $Z_o$ ) impedances.** (A) Cathode follower, made with triode tube; (B) Emitter follower, made with NPN bipolar transistor; (C) Source follower, made with FET; and (D) Voltage follower, made with operational amplifier. All of these buffers are terminated with a load resistance,  $R_L$ , and have an output voltage that is approximately equal to the input voltage (gain  $\approx 1$ ).

the cathode follower using a triode tube, the emitter follower using a bipolar transistor, the source follower using a field-effect transistor and the voltage follower, using an operational amplifier.

In some circuits, notably power amplifiers, the desired goal is to deliver a maximum amount of power to the output device (such as a speaker or an antenna). Matching the amplifier output impedance to the output-device impedance provides maximum power transfer. A buffer amplifier may be just the circuit for this type of application. Such amplifier circuits must be carefully designed to avoid distortion.

## Amplitude Modulation/ Demodulation

Voice signals are transmitted over the air by amplitude modulating them on higher frequency carrier signals (see the **Mixers** chapter). The process of amplitude modulation can be mathematically described as the multiplication (product) of the voice signal and the carrier signal. Multiplication is a linear process since amplitude modulating the sum of two audio signals produces a signal that is identical to the sum of amplitude modulating each audio signal individually. When two equal-strength SSB signals are transmitted on the same frequency, the observer hears both of the voices simultaneously. Another aspect of the linear behavior of amplitude modulation is that amplitude-modulated signals can be demodulated to be exactly in their original form. Amplitude demodulation is the converse of amplitude modulation, and is represented as a division operation.

In the linear model of amplitude modulation, the signal to be modulated (such as the audio signal in an AM transmitter) is shifted in frequency by multiplying it with the carrier. The modulated waveform is considered to be a linear function of the signal. The carrier is considered to be part of a time-varying linear system and not a second signal.

A curious trait of amplitude modulation is that it can be performed nonlinearly. Each nonlinear form of amplitude modulation generates the desired linear product term in addition to other unwanted terms that must be removed. Accurate analog multipliers and dividers are difficult and expensive to fabricate. Two common nonlinear amplitude modulating schemes are much simpler to implement but have disadvantages as well.

*Power-law modulators* generate many frequencies in addition to the desired ones. These unwanted frequencies, often called *intermodulation products*, steal energy from the desired *first order product*. The

unwanted signals must be filtered out. The inefficiency of this process makes this type of modulator good only for low-level modulation, with additional amplification required for the modulated signal. A *square-law modulator* can be implemented with a single FET, biased in its saturation region, as the only active component.

*Switching modulators* are more efficient and provide high-level modulation. A single active device acts as a switch to turn the signal on and off at the carrier frequency. Both the signal and the carrier must be amplified to relatively high levels prior to this form of modulation. The modulated carrier must be filtered by a tank circuit to remove unwanted frequency components generated by the switching artifacts.

Nonlinear demodulation of an amplitude-modulated signal can be realized with a single diode. The diode rectifies the signal (a nonlinear process) and then the nonlinear products are filtered out before the desired signal is recovered.

## NONLINEAR OPERATORS

All signal processing doesn't have to be linear. Any time that we treat various signal levels differently, the operation is called *nonlinear*. This is not to say that all signals must be treated the same for a circuit to be linear. High frequency signals are attenuated in a low-pass filter while low frequency signals are not, yet the filter can be linear. The distinction is that all voltages of the high-frequency signal are attenuated by the same amount, thus satisfying one of the linearity conditions. What if we do not want to treat all voltage levels the same way? This is commonly desired in analog signal processing for clipping, rectification, compression, modulation and switching.

## Clipping and Rectification

Clipping is the process of limiting the range of signal voltages passing through a circuit (in other words, *clipping* those voltages outside the desired range off of the signals). There are a number of reasons why we would like to do this. Clipping generally refers to the process of limiting the positive and negative peaks of a signal. We might use this technique to avoid overdriving an amplifier, for example. Another type of clipping results in rectification. The rectifier clips off all voltages of one polarity (positive or negative) and allows only the other polarity through, thus changing ac to pulsating dc (see the **Power Supplies and Projects** chapter). Another use of clipping is when only one signal polarity is allowed to drive an

amplifier input; a clipping stage precedes the amplifier to ensure this.

## Logarithmic Amplification

It is sometimes desirable to amplify a signal logarithmically, which means amplifying low levels more than high levels. This type of amplification is often called *signal compression*. Speech compression is sometimes used in audio amplifiers that feed modulators. The voice signal is compressed into a small range of amplitudes, allowing more voice energy to be transmitted without over modulation (see the **Modulation Sources** chapter).

## ANALOG BUILDING BLOCKS

Many types of electronic equipment are developed by combining basic analog signal processing circuits or "building blocks." This section describes several of these building blocks and how they are combined to perform complex functions. Although not all basic electronic functions are discussed here, the characteristics of combining them can be applied generally.

An analog building block can contain any number of discrete components. Since our main concern is the effect that circuitry has on a signal, we often describe the building block by its actions rather than its specific components. For this reason, an analog building block is often referred to as a *two-port network* or a *black box*. Two basic properties of analog networks are of principal concern: the effect that the network has on an analog signal and the interaction that the network has with the circuitry surrounding it. The two network ports are the input and output connections. The signal is fed into the input port, is modified inside the network and then exits from the output port.

An analog network modifies a signal in a specific way that can be described mathematically. The output is related to the input by a *transfer function*. The mathematical operation that combines a signal with a transfer function is pictured symbolically in **Fig 8.4**. The output signal,  $w(t)$ , has a value that changes with time. The output signal is created by the action of an analog transfer function,  $h(t)$ , on the input signal,  $g(t)$ .

While it is not necessary to understand transfer functions mathematically to work

**Fig 8.4 — Linear function block.** The output signal,  $w(t)$  is produced by the action of the transfer function,  $h(t)$  on the input signal  $s(t)$ .

with analog circuits, it is useful to realize that they describe how a signal interacts with other signals in an electronic system. In general, the output signal of an analog system depends not only on the input signal at the same time, but also on past values of the input signal. This is a very important concept and is the basis of such essential functions as analog filtering.

### Cascading Stages

If an analog circuit can be described with a transfer function, a combination of analog circuits can also be described similarly. This description of the combined circuits depends upon the relationship between the transfer functions of the parts and that of the combined circuits. In many cases this relationship allows us to predict the behavior of large and complex circuits from what we know about the parts that make them up. This aids in the design and analysis of analog circuits.

When two analog circuits are cascaded (the output signal of one stage becomes the input signal to the next stage) their transfer functions are combined. The mechanism of the combination depends on the interaction between the stages. The ideal case is when there is no interaction between stages. In other words, the action of the first stage is unchanged, regardless of whether or not the second stage follows it. Just as the signal entering the first stage is modified by the action of the first transfer function, the ideal cascading of analog circuits results in changes produced only by the individual transfer functions. For any number of stages that are cascaded, the combination of their transfer functions results in a new transfer function. The signal that enters the circuit is changed by the composite transfer function, to produce the signal that exits the cascaded circuits.

### Cascaded Buffers

Buffer stages that are made with single active devices can be more effective if cascaded. Two types of such buffers are in common use. The *Darlington pair* is a cascade of two common-collector transistors as shown in Fig 8.5. (The various amplifier configurations will be described later in this chapter.) The input impedance of the Darlington pair is equal to the load impedance times the current gain,  $h_{FE}$ . The current gain of the Darlington pair is the product of the current gains for the two transistors.

$$Z_I = Z_{LOAD} \times h_{FE1} \times h_{FE2} \quad (2)$$

For example, if a typical bipolar transistor has  $h_{FE} = 100$  and a circuit has a  $Z_{LOAD} = 15 \text{ k}\Omega$ , a pair of these transistors

in the Darlington-pair configuration would have:

$$Z_I = 15 \text{ k}\Omega \times 100 \times 100 = 150 \text{ M}\Omega.$$

The shunt capacitance at the input of real transistors can lower the actual impedance as the frequency increases.

A common-emitter amplifier followed by a common-base amplifier is called a *cascode buffer* (see Fig 8.6). Cascodes are also made with FETs by following a common-source amplifier by a common-gate configuration. The input impedance and current gain of the cascode are approximately the same as those of the first stage. The output impedance is much higher than that of a single stage. Cascode amplifiers have excellent input/output isolation (very low unwanted feedback) and this can provide high gain with good stability. An example of a cascode buffer made with bipolar transistors has moderate input impedance,  $Z_I = 1 \text{ k}\Omega$ , high current gain,  $h_{FE} = 50$  and high output impedance,  $Z_O = 1 \text{ M}\Omega$ . There is very little reverse internal feedback in the cascode design, making it very stable, and the amplifier design has little effect on external tuning components. Cascode circuits are often used in tuned amplifier designs for these reasons.

### Interstage Loading and Impedance Matching

If the transfer function of a stage changes when it is cascaded with another stage, we say that the second stage has *loaded* the first stage. This often occurs when an appreciable amount of current passes from one stage to the next.

Every two-port network can be further defined by its input and output impedance. The input impedance is the opposition to current, as a function of frequency, that is seen when looking into the input port of the network. Likewise, the output impedance is similarly defined when looking back into a network through its output port. Interstage loading is related to the relative output impedance of a stage and the input impedance of the stage that is cascaded after it.

In some applications the goal is to transfer a maximum amount of power. In an RF amplifier, the impedance at the input of the transmission line feeding an antenna is transformed by means of a matching network to produce the resistance the amplifier needs in order to efficiently produce RF power.

In contrast, it is the goal of most analog signal processing circuitry to modify a signal rather than to deliver large amounts of energy. Thus, an impedance-matched condition may not be what is desired. Instead,

Fig 8.5 — Darlington pair made with two emitter followers. Input impedance,  $Z_I$ , is far higher than for a single transistor and output impedance,  $Z_O$ , is nearly the same as for a single transistor. DC biasing has been omitted for simplicity.

Fig 8.6 — Cascode pair made with two NPN bipolar transistors has a medium input impedance and high output impedance. DC biasing has been omitted for simplicity.

current between stages can be minimized by having mismatched impedances. Ideally, if the output impedance of a network approaches zero ohms and the input impedance of the following stage is very high, very little current will pass between the stages, and interstage loading will be negligible.

### Noise

Generally we are only interested in specific man-made signals. Nature allows many signals to combine, however, so the desired signal becomes combined with many other unwanted signals, both man-made and naturally occurring. The broadest definition of noise is any signal that is not the one in which we are interested. One of the goals of signal processing is to separate desired signals from noise.

One form of noise that occurs naturally and must be dealt with in low-level processing circuits is called *thermal noise*, or *Johnson noise*. Thermal noise is produced by random motion of free electrons in conductors and semiconductors. This motion increases as temperature increases, hence the name. This kind of noise is present at all frequencies and is proportional to temperature. Naturally occurring noise can be reduced either by decreasing the bandwidth or by reducing the temperature in the system. Thermal noise voltage and

current vary with the circuit impedance, according to Ohm's Law. Low-noise-amplifier-design techniques are based on these relationships (see the **Amplifiers** chapter).

Analog signal processing stages are characterized in part by the noise they add to a signal. A distinction is made between enhancing existing noise (such as amplifying it) and adding new noise. The noise added by analog signal processing is commonly quantified by the *noise factor*,  $f$ . Noise factor is the ratio of the total output noise power (thermal noise plus noise

added by the stage) to the input noise power when the termination is at the standard temperature of 290 K (17°C). When the noise factor is expressed in dB, we often call it *noise figure*,  $NF$ .  $NF$  is calculated as:

$$NF = 10 \log \frac{P_{NO}}{A P_{NTH}} \quad (3)$$

where:

$P_{NO}$  = total noise output power,  
 $A$  = amplification gain, and  
 $P_{NTH}$  = input thermal noise power.

The noise factor can also be calculated as the difference between the input and

output signal-to-noise ratios (SNR), with SNR expressed in dB.

In a system of many cascaded signal processing stages, each stage affects the noise of the system. The noise factor of the first stage dominates the noise factor of the entire system. Designers try to optimize system noise factor by using a first stage with a minimum possible noise factor and maximum possible gain. A circuit that overloads is often as useless as one that generates too much noise. See the **Transceivers** chapter for more information about circuit noise.

## Analog Devices

There are several different kinds of components that can be used to build circuits for analog signal processing. The same processing can be performed with vacuum tubes, bipolar semiconductors, field-effect semiconductors or integrated circuitry, each with its own advantages and disadvantages.

### TERMINOLOGY

A similar terminology is used for most active electronic devices. The letter  $V$  stands for voltages and  $I$  for currents. Voltages generally have two subscripts indicating the terminals the voltage is measured between ( $V_{BE}$  is the voltage between the base and the emitter of a bipolar transistor). Currents have a single subscript indicating the terminal that the current flows into ( $I_P$  is the current into the plate of a vacuum tube). If the current flows out of the device, it is generally indicated with a negative sign. Power supply voltages have two subscripts that are the same, indicating the terminal to which the voltage is applied ( $V_{DD}$  is the power supply voltage applied to the drain of a field-effect transistor). A transfer characteristic is a ratio of an output parameter to an input parameter, such as output current divided by input current. Transfer characteristics are represented with letters, such as  $h$ ,  $s$ ,  $y$  or  $z$ . Resistance is designated with the letter  $r$ , and impedance with the letter  $Z$ . For example,  $r_{DS}$  is resistance between drain and source of an FET and  $Z_i$  is input impedance. In some designators, values differ for dc and ac signals. This is indicated by using capital letters in the subscripts for dc and lower-case subscripts for ac. For example, the common-emitter dc current gain for a bipolar transistor is designated as  $h_{FE}$ , and  $h_{fe}$  is the ac current

gain. Qualifiers are sometimes added to the subscripts to indicate certain operating modes of the device. SS for saturation, BR for breakdown, ON and OFF are all commonly used.

The abbreviations for tubes existed before these standards were adopted so some tube-performance descriptors are different. For example,  $B+$  is usually used for the plate bias voltage. Since integrated circuits are collections of semiconductor components, the abbreviations for the type of semiconductor used also apply to the integrated circuit.  $V_{CC}$  is a power supply voltage for an integrated circuit made with bipolar transistor technology.

### Amplifier Types

Amplifier configurations are described by the *common* part of the device. The word "common" is used to describe the connection of a lead directly to a reference. The most common reference is ground, but positive and negative power sources are also valid references. The type of reference used depends on the type of device (vacuum tube, transistor [NPN or PNP], FET [P-channel or N-channel]), which lead is common and the range of signal levels. Once a common lead is chosen, the other two leads are used for signal input and output. Based on the biasing conditions, there is only one way to select these leads. Thus, there are three possible amplifier configurations for each type of three-lead device.

The operation of an amplifier is specified by its gain. A gain in this sense is defined as the change ( $\Delta$ ) in the output parameter divided by the corresponding change in the input parameter. If a particular device measures its input and output as currents, the gain is called a current gain.

If the input and output are voltages, the amplifier is defined by its voltage gain. If the input is a voltage and the output is a current, the ratio is called the *transconductance*.

### Characteristic Curves

Analog devices are described most completely with their *characteristic curves*. Almost all devices that we deal with are nonlinear over a wide range of operating parameters. We are often interested in using a device only in the region that approximates a linear response. The characteristic curve is a plot of the interrelationships between two or three variables. The vertical ( $y$ ) axis parameter is the output, or result of the device being operated with an input parameter on the horizontal ( $x$ ) axis. Often the output is the result of two input values. The first input parameter is represented along the  $x$  axis and the second input parameter by several curves, each for a different value. For example, a vacuum tube characteristic curve may have the plate current along the  $y$  axis, the grid voltage along the  $x$  axis and several curves, each representing a different value of the plate bias voltage (see **Fig 8.7**).

The parameters plotted in the characteristic curve depend on how the device will be used. The common amplifier configuration defines the input and output leads, and their relationship is diagrammed by the curves. Device parameters are usually derived from the characteristic curve. To calculate a gain, the operating region of the curve is specified, usually a straight portion of the curve if linear operation is desired. Two points along that portion of the curve are selected, each defined by its location along the  $x$  and  $y$  axes. If the two points are defined by  $(x_1, y_1)$  and  $(x_2, y_2)$ ,

**Fig 8.7 — Tube characteristic curve.** Input signal is the grid voltage,  $V_g$ , along the x-axis and the output signal is the plate current,  $I_p$ , along the y-axis. Different curves are plotted for various values of plate bias voltage,  $V_p$  (also called  $B+$ ).

the slope,  $m$ , of the curve, which can be a gain, a resistance or a conductance, is calculated as:

$$m = \frac{\Delta y}{\Delta x} = \frac{y_1 - y_2}{x_1 - x_2} \quad (4)$$

A characteristic curve that plots device output voltage and current along the x and y axes permits the inclusion of an additional curve. The *load line* is a straight line with a slope that is equal to the load impedance. The intersections between the load line and the characteristic curves indicate the operating points for that circuit. Load lines are only applicable to output characteristic plots; they cannot be used with input or transfer (input versus output) characteristic curves.

## BIASING

The operation of an analog signal processing device is greatly affected by which portion of the characteristic curve is used to do the processing. As an example, consider the vacuum tube characteristic curves in Fig 8.8 and Fig 8.9.

The relationship between the input and the output of a tube amplifier is illustrated in Fig 8.8. The input signal (a sine wave in this example) is plotted in the vertical direction and below the graph. For a grid bias level of  $-5$  V, the sine wave causes the grid voltage,  $V_g$ , to deviate between  $-3$  and  $-7$  V. These values correspond to a range of plate currents,  $I_p$ , between  $1.4$  and  $2.6$  mA. With a plate bias of  $200$  V and a load resistance,  $R_p$ , of  $50$  k $\Omega$ , the corresponding change in plate voltage,  $V_p$ , is between  $70$  and  $130$  V. Thus, this triode amplifier configuration changes a range of  $4$  V at the input to  $60$  V at the output. Also there is a change of output-signal voltage polarity; this amplifier both amplifies the signal magnitude  $15$  times and

shifts the phase of the signal by  $180^\circ$ .

In the previous example the signal was biased so that it fell on a linear (straight) portion of the characteristic curve. If a different bias voltage is selected so that the signal does not fall on a linear portion of the curve, the output signal will be a distorted version of the input signal. This is illustrated in Fig 8.9. The input signal is amplified within a curved region of the characteristic curve. The positive part of the signal is amplified more than the negative part of the signal. Proper biasing is crucial to ensure amplifier linearity.

Input biasing serves to modify the relative level (dc offset) of the input signal so that it falls on the desired portion of the characteristic curve. Devices that perform signal processing (vacuum tubes, diodes, bipolar transistors, field-effect transistors and operational amplifiers) usually require appropriate input signal biasing.

## Manufacturers' Data Sheets

Manufacturer's data sheets list device characteristics, along with the specifics of the part type (polarity, semiconductor type), identification of the pins, and the typical use (such as small signal, RF, switching or power amplifier). The pin identification is important because, although common package pinouts are normally used, there are exceptions. Manufacturers may differ slightly in the values reported, but certain basic parameters are listed. Different batches of the same devices are rarely identical, so manufacturers specify the guaranteed limits for the parameters of their device. There are usually three columns of values listed in the data sheet. For each parameter, the columns may list the guaranteed minimum value, the guaranteed maximum value and/or the typical value.

Another section of the data sheet lists ABSOLUTE MAXIMUM RATINGS, beyond which device damage may result. For example, the parameters listed in the ABSOLUTE MAXIMUM RATINGS section for a solid-state device are typically voltages, continuous currents, total device power dissipation ( $P_D$ ) and operating- and storage-temperature ranges.

Rather than plotting the characteristic curves for each device, the manufacturer often selects key operating parameters that describe the device operation for the configurations and parameter ranges that are most commonly used. For example, a bipolar transistor data sheet might include an OPERATING PARAMETERS section. Parameters are listed in an OFF CHARACTERISTICS subsection and an ON CHARACTERISTICS subsection that describe the conduction properties of the device for dc

**Fig 8.8 — Determination of output signal (to the right of the plot) for a given input signal (below the plot, turned on its side) with a tube characteristic curve plotted for a given plate bias. Note that the grid bias voltage,  $-5$  V, causes the entire range of the input signal to be mapped onto the linear (diagonal straight line) portion of the characteristic curve. The output signal has the same shape as the input signal except that it is larger in amplitude.**

**Fig 8.9 — Same characteristic curve and input signal as in Fig 8.8 except the grid bias voltage is now about  $-8.75$  V. The input signal falls on the curved (non-linear) portion of the plot and causes distortion in the output signal. Note how the upper portion of the output sine wave was amplified more than the lower portion.**

voltages. The SMALL-SIGNAL CHARACTERISTICS section often contains the guaranteed minimum Gain-Bandwidth Product ( $f_T$ ), the guaranteed maximum output capacitance, the guaranteed maximum input capacitance and the guaranteed range of the transfer parameters applicable to a given device. Finally, the SWITCHING CHARACTERISTICS section lists absolute maximum ratings for Delay Time ( $t_d$ ),

Rise Time ( $t_r$ ), Storage Time ( $t_s$ ) and Fall Time ( $t_f$ ). Other types of devices list characteristics important to operation of that specific device.

When selecting equivalent parts for replacement of specified devices, the data sheet provides the necessary information to tell if a given part will perform the functions of another. Lists of equivalencies generally only specify devices that have nearly identical parameters. There are usually a large number of additional devices that can be chosen as replacements. Knowledge of the circuit requirements adds even more to the list of possible replacements. The device parameters should be compared individually to make sure that the replacement part meets or exceeds the parameter values of the original part required by the circuit. Be aware that in some applications a far superior part may fail as a replacement, however. A transistor with too much gain could easily oscillate if there were insufficient negative feedback to ensure stability.

## VACUUM TUBES

Current is generally described as the flow of electrons through a conductor, such as metal. The vacuum tube controls the flow of electrons in a vacuum, which is analogous to a faucet that adjusts the flow of a fluid. The British commonly refer to vacuum tubes as *valves*. Although the physics of the operation of vacuum tubes varies greatly from that of semiconductors, there are many similarities in the way that they behave in analog circuits.

### Thermionic Theory

Metals are elements that are characterized by their large number of free electrons. Individual atoms do not hold onto all of their electrons very tightly, and it is relatively easy to dislodge them. This property makes metals good conductors of electricity. Under electrical pressure (voltage), electrons collide with metal atoms, dislodging an equal number of free electrons from the metal. These collide with adjoining metal atoms to continue the process, resulting in a flow of electrons.

It is also possible to cause the free electrons to be emitted into space if enough energy is added to them. Heat is one way of adding energy to metal atoms, and the resulting flow of electrons into space is called *thermionic emission*. It is important to remember that the metal atoms don't permanently lose electrons; the emitted electrons are replaced by others that come from an electrical connection to the heated metal. Thus, an electron that flows into the

**Fig 8.10 — Vacuum tube diode. (A) Schematic symbol detailing heater (H), cathode (C) and plate (P). (B) Power supply circuit using diode as a half wave rectifier.**

heated metal collides with and is captured by a metal atom, knocking loose a highly energized electron that is emitted into space.

In a vacuum, there are no other atoms with which the emitted electron can collide, so it follows a straight path until it collides with another atom. A *vacuum tube* has nearly all of the air evacuated from it, so the emitted electrons proceed unhindered to another piece of metal, where they continue to move as part of the electrical current.

### Components of a Vacuum Tube

A basic vacuum tube contains at least two parts; a *cathode* and a *plate*. The electrons are emitted from the *cathode*. The cathode can either be heated directly by passing a large dc current through it, or it can be located adjacent to a heating element. Although ac currents can also be used to directly heat cathodes, if any of the ac voltage mixes with the signal, ac hum will be introduced into the output. If the ac heater supply voltage can be obtained from a center tapped transformer, and the center tap is connected to the signal ground, hum can be minimized. Cathodes are made of substances that have the highest emission of electrons for the lowest temperatures and voltages. Tungsten, thoriated tungsten and oxide-coated metals are commonly used.

Every vacuum tube needs a receptor for the emitted electrons. After moving through the vacuum, the electrons are absorbed by the *plate*. Since the plate receives electrons, it is also called the

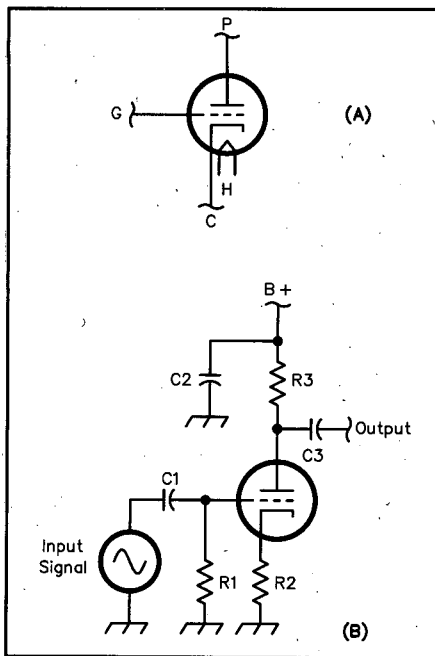

*anode*. Each electron has a negative charge, so a positively biased plate will attract the emitted electrons to it, and a current will result. For every electron that is accepted by the plate, another electron flows into the cathode; the plate and cathode currents must be the same. As the plate voltage is increased, there is a larger electrical field attracting electrons, causing more of them to be emitted from the cathode. This increases the current through the tube. This relationship continues until a limit is reached where further increases to the electrical field do not cause any more electrons to be emitted. This is the *saturation point* of the vacuum tube.

A vacuum tube that contains only a cathode and a plate is called a *diode tube* (di- for two components). See Fig 8.10. The diode tube is similar to a semiconductor diode since it allows current to pass in only one direction; it is used as a rectifier. When the plate voltage becomes negative, the electrical field that is set up repels electrons, preventing them from being emitted from the cathode.

To amplify signals, a vacuum tube must also contain a control *grid*. This name comes from its physical construction. The grid is a mesh of wires located between the cathode and the plate. Electrons from the cathode pass between the grid wires on their way to the plate. The electrical field that is set up by the voltage on these wires affects the electron flow from cathode to plate. A negative grid voltage sets up an electrical field that repels electrons, decreasing emission from the cathode because of the higher energy needed for the electrons to escape from their atoms into the vacuum. A positive grid voltage will have the opposite effect. Since the plate voltage is always positive, however, grid voltages are usually negative. The more negative the grid, the less effective the electrical field from the plate will be at attracting electrons from the cathode.

Vacuum tubes containing a cathode, a grid and a plate are called *triode* tubes (tri- for three components). See Fig 8.11. They are generally used as amplifiers, particularly at frequencies in the HF range and below. Characteristic curves for triodes normally relate grid bias voltage and plate bias voltage to plate current for the triode (Fig 8.7). There are three descriptors of a tube's performance that can be derived from the characteristic curves. The *plate resistance*,  $r_p$ , describes the resistance to the flow of electrons from cathode to plate. The  $r_p$  is calculated by selecting a vertical line in the characteristic curve and dividing the change in plate-to-cathode voltage ( $\Delta V_p$ ) of two of the

**Fig 8.11 — Vacuum tube triode.** (A) Schematic symbol detailing heater (H), cathode (C), grid (G) and plate (P). (B) Audio amplifier circuit using a triode. C1 and C3 are dc blocking capacitors for the input and output signals to isolate the grid and plate bias voltages. C2 is a bypass filter capacitor to decrease noise in the plate bias voltage, B+. R1 is the grid bias resistor, R2 is the cathode bias resistor and R3 is the plate bias resistor. Note that although the cathode and grid bias voltages are positive with respect to ground, they are still negative with respect to the plate.

lines by the corresponding change in plate current ( $\Delta I_p$ ).

$$r_p = \frac{\Delta V_p}{\Delta I_p} \quad (5)$$

The ratio of change in plate voltage ( $\Delta V_p$ ) to the change in grid-to-cathode voltage ( $\Delta V_g$ ) for a given plate current is the *amplification factor* ( $\mu$ ). Amplification factor is calculated by selecting a horizontal line in the characteristic curve and dividing the difference in plate voltage of two of the lines by the difference in grid voltages that corresponds to the same points.

$$\mu = \frac{\Delta V_p}{\Delta V_g} \quad (6)$$

Triode amplification factors range from 10 to about 100.

The plate current flows to the plate bias supply, so the output from a triode amplifier is often expressed as the voltage that is developed as this current passes through a load resistor. The value of the load resistance affects the tube amplification, as

illustrated by the dynamic characteristic curves in **Fig 8.12**, so the tube  $\mu$  does not fully describe its action as an amplifier. *Grid-plate transconductance* ( $g_m$ ) takes into account the change of amplification due to load resistance. The slope of the lines in the characteristic curve represents  $g_m$ . (Since the various lines are nearly parallel in the linear operating region, they have about the same slope.)

$$g_m = \frac{\Delta I_p}{\Delta V_g} \quad (7)$$

This ratio represents a conductance, which is measured in siemens. Triodes have  $g_m$  values that range from about 1000 to several thousand microsiemens, the higher values indicating greater possible amplification.

The input impedance of a vacuum tube amplifier is directly related to the grid current, increasing as the voltage becomes more positive. The normal operation uses a negative grid-bias voltage, and the input impedance can be in the megohm range for very negative grid bias values. This is limited by the desired operating point on the characteristic curve, however, as illustrated in Figs 8.8 and 8.9. The output impedance of the amplifier is a function of the plate resistance,  $r_p$ , in parallel with the output capacitance. Typical output impedance is on the order of hundreds of ohms.

The physical configuration of the components within the vacuum tube appear as conductors that are separated by an insulator (in this case, the vacuum). This description is very similar to that of a capacitor. The capacitance between the cathode and grid, between the grid and plate, and between the cathode and plate can be large enough to affect the operation of the amplifier at high frequencies. These capacitances, which are usually on the order of a few picofarads, can limit the frequency response of a vacuum tube amplifier and can also provide signal feedback paths that may lead to unwanted oscillation. Neutralizing circuits are sometimes used to counteract the effects of internal capacitances and to prevent oscillations.

The grid-to-plate capacitance is the chief source of unwanted signal feedback. A special form of vacuum tube has been developed to deal with the grid-to-plate capacitance. A second grid, called a *screen grid*, is inserted between the original grid (now called a *control grid*) and the plate. The additional tube component leads to the name for this new tube — *tetrode* (tetra- for four components). See **Fig 8.13**. The screen grid reduces the capacitance between the control grid and the plate, but it also reduces the electrical field from

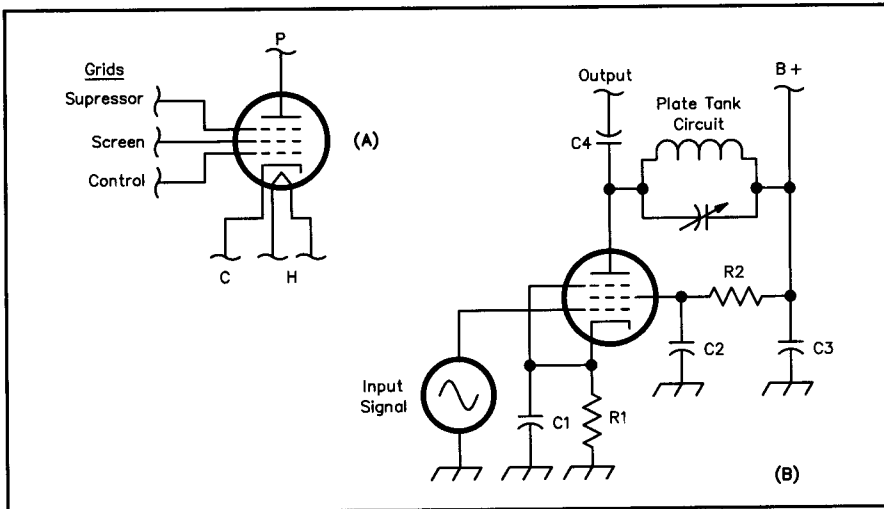

**Fig 8.12 — Vacuum tube dynamic characteristic curve.** This corresponds to the  $V_p = 300$  line in Fig 8.7 with different values of load resistance. This shows how the tube will behave when cascaded to circuits with different input impedances.

**Fig 8.13 — Vacuum tube tetrode.** Schematic symbol detailing heater (H), cathode (C), the two grids: control and screen and plate (P).

the plate that attracts electrons from the cathode. Like the control grid, the screen grid is made of a wire mesh and electrons pass through the spaces between the wires to get to the plate. The bias of the screen grid is positive with respect to the cathode, in order to enhance the attraction of electrons from the cathode. The electrons accelerate toward the screen grid and most of them pass through the spaces and continue to accelerate until they reach the plate. The presence of the screen grid adversely affects the overall efficiency of the tube, since some of the electrons strike the grid wires. A bypass capacitor with a low reactance at the frequency being amplified by the vacuum tube is generally connected between the screen grid and the cathode.

A special form of tetrode concentrates the electrons flowing between the cathode and the plate into a tight beam. The decreased electron-beam area increases the efficiency of the tube. *Beam tetrodes* permit higher plate currents with lower plate voltages and large power outputs with smaller grid driving power. RF power amplifiers are usually made with this type of vacuum tube.

**Fig 8.14 — Vacuum tube pentode.** (A) Schematic symbol detailing heater (H), cathode (C), the three grids: control, screen and suppressor, and plate (P). (B) RF amplifier circuit using a pentode. C1, C2 and C3 are bypass (filter) capacitors and C4 is a dc blocking capacitor to isolate the plate bias voltage from the output signal. R1 is the cathode bias resistor and R2 is the screen voltage dropping resistor. The plate tank circuit is tuned to the desired frequency bandpass. As is common, the heater circuit is not shown.

**Fig 8.15 — Grounded grid amplifier schematic.** The input signal is connected to the cathode, the grid is biased to the appropriate operating point by a dc bias voltage,  $-V_g$ , and the output voltage is obtained by the voltage drop through  $R_L$  that is developed by the plate current,  $I_p$ .

Another unwanted effect in vacuum tubes is the emission of electrons from the plate. The electrons flowing within the tube have so much energy that they are capable of dislodging electrons from the metal atoms in the plate. These *secondary emission* electrons are repelled back to the plate by the negative bias of the grid in a triode and are of no concern. In the tetrode, the screen grid is positively biased and attracts the secondary emission electrons, causing a reverse current from the plate to the screen grid.

A third grid, called the *suppressor grid*,

**Fig 8.16 — Cathode follower schematic.** The input signal is biased by  $-V_g$  and fed into the grid. The plate bias,  $B+$  is fed directly into the plate terminal. The output is derived by the cathode current (which is equal to the plate current,  $I_p$ ) dropping the voltage through the load resistor,  $R_L$ .

can be added between the screen grid and the plate. This overcomes the effects of secondary emission in tetrodes. A vacuum tube with three grids is called a *pentode* (penta- for five components). See Fig 8.14. The suppressor grid is negatively biased with respect to the screen grid and the plate. In some tube designs it is internally connected to the cathode. The suppressor grid repels the secondary emission electrons back to the plate.

As the number of grids is increased between the cathode and the plate, the effect of the electrical field from the positive plate voltage at the cathode is decreased. This limits the number of electrons that can be emitted from the cathode and the

characteristic curves tend to flatten out as the grid bias becomes less negative. This flattening is another nonlinearity of the tube as an amplifier, since the response saturates at a given plate current and will go no higher. Tube saturation can be used advantageously in some circuits if a constant current source is desired, since the current does not change within the saturation region regardless of changes in plate voltage.

## Types of Vacuum Tube Amplifiers

The descriptions of vacuum tube amplifiers up to this point have been for only one configuration, the common cathode, where the cathode is connected to the signal reference point, the grid is the input and the plate is the output. Although this is the most common configuration of the vacuum tube as an amplifier, other configurations exist. If the signal is introduced into the cathode and the grid is at a reference level (still negatively biased but with no ac component), with the output at the plate, the amplifier is called a *grounded-grid* (Fig 8.15). This amplifier is characterized by a very low input impedance, on the order of a few hundred ohms, and a low output impedance, that is mainly determined by the plate resistance of the tube.

The third configuration is called the *cathode follower* (Fig 8.16). The plate is the common element, the grid is the input and the cathode is the output. This type of amplifier is often used as a buffer stage due to its high input impedance, similar to that of the common cathode amplifier, and its very low output impedance. The output impedance ( $Z_o$ ) can be calculated from the tube characteristics as:

$$Z_o = \frac{r_p}{1 + \mu} \quad (8)$$

where:

$r_p$  = tube plate resistance  
 $\mu$  = tube amplification factor.

For a close approximation, we can simplify this equation as:

$$Z_o \approx \frac{r_p}{\mu} = \frac{1}{g_m}$$

## Other Types of Tubes

Vacuum tube identifiers do not generally indicate what type of tube the device is. The format is typically a number, one or two letters and a number (such as 6AU6 or 12AT7). The first number in the identifier indicates the heater voltage (usually either 6 or 12 V). The last number often indicates the number of elements, including the heater. Some tubes also have an

additional letter following the identifier (usually A or B) that indicates a revision of the tube design that represents an improvement in its operating parameters. There are also tubes that do not follow this naming convention, many of which are power amplifiers or military-type tubes (such as 6146 and 811).

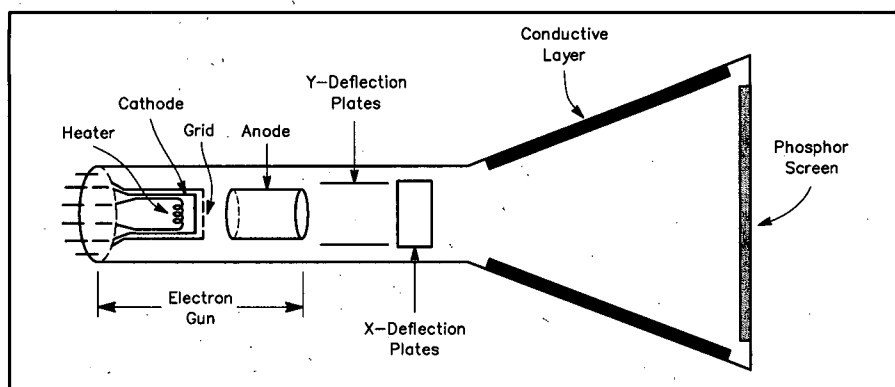

To reduce stray reactances, some tubes do not have the plate connection in the tube base, where all the other connections are located. Rather, a connection is made at the top of the tube through a metallic cap. This requires an additional connector for the plate circuitry.

Tubes may share components in a single envelope to reduce size and incidental power requirements. A very common example of this is the dual triode tube (such as 12AT7 or 12AU7) that contains a single heater circuit and two complete triode tubes in the same device. Other configurations of multiple devices contained in a single vacuum tube also exist. The 6GW8 and 6EA8 tubes each contain both a triode and a pentode. The 6BN8 contains three distinct devices, one triode and two diodes.

Most common vacuum tubes are encased in glass. It is also possible to encase them in metal or ceramic materials to attain higher tube power and smaller size. Since heat dissipation from the plate is one of the major limiting factors for vacuum tube power amplifiers, the alternate materials remove heat more efficiently. These tubes can be cooled by convection, with the casing connected to a large heat sink, or with water flowing past the tube for hydraulic cooling.

A variation of the vacuum tube that is widely used in oscilloscopes and television monitors is the *cathode ray tube (CRT)*, diagrammed in Fig 8.17. The CRT has a cathode and grid much like a triode tube. The plate, usually referred to as the *anode* in this device, is designed to accelerate the electrons to very high velocities, with anode voltages that can be as high as tens of thousands of volts. The anode of the CRT differs from the plates of other vacuum tubes, since it is designed as a set of plates that are parallel to the electron beam. The anode voltage accelerates the electrons but does not absorb them. The electron beam passes by the anode and continues to the face of the tube. The cathode, grid and anode are all located in the neck of the CRT and are collectively referred to as the *electron gun*.

The electron beam is deflected from its path by either magnetic deflectors that surround the yoke of the tube or by electrostatic deflection plates that are built into the tube neck just beyond the electron gun.

**Fig 8.17 — Cross section of CRT.** The electron gun generates a stream of electrons and is made up of a heater, cathode, grid and anode (plate). The electron beam passed by two pairs of deflection plates that deviate the path of the beam in the vertical (y) direction and then the horizontal (x) direction. The deflected electron beam strikes a phosphor screen and causes it to glow at that spot. Any electrons that bounce off the screen are absorbed by the conductive layer along the sides of the tube, preventing spurious luminescence

A CRT typically has two sets of deflectors: vertical and horizontal. When a potential is applied to a set of deflectors, the passing electron beam is bent, altering its path. In an oscilloscope, the time base typically drives the horizontal deflectors and the input signal drives the vertical deflectors, although in many oscilloscopes it is possible to connect another input signal to the horizontal deflectors to obtain an X-Y, or vector, display. In televisions and some computer monitors, the deflectors are typically driven by a raster generator. The horizontal deflectors are driven by a sawtooth pattern that causes the beam to move repeatedly from left to right and then retrace quickly to the left. The vertical deflectors are driven by a slower sawtooth pattern that causes the beam to move repeatedly from top to bottom and then retrace quickly to the top. The relative timing of the two sawtooth patterns is such that the beam scans from left to right, retraces to the left and then begins the next horizontal trace just below the previous one.

Beyond the deflectors, the CRT flares out. The front face is coated with a phosphorescent material that glows when struck by the electron beam. To prevent spurious phosphorescence, a conductive layer along the sides of the tube absorbs any electrons that reflect off the glass.

Vector displays have better resolution than raster scanning. The trace lines are clearer, which is the reason oscilloscope displays use this technique. It is faster to fill the screen using raster scanning, however. This is why TVs use raster scanning.

Some CRT tubes are designed with multiple electron beams. The beams are sometimes generated by different electron guns that are placed next to each other in the neck of the tube. They can also be gen-

erated by splitting the output of a single electron gun into two or more beams. Very high quality oscilloscopes use two electron beams to trace two input channels rather than the more common method of alternating a single beam between the two inputs. Color television tubes use three electron beams for the three primary colors (red, green and blue). Each beam is focused on only one of these colored phosphors, which are interleaved on the face of the tube. A metal shadow mask keeps the colors separate as the beams scan across the tube.

A variation of the CRT is the *vidicon tube*. The vidicon is used in many video cameras and operates in a similar fashion to the CRT. The vidicon absorbs light from the surroundings, which charges the plate at the location of the light. This charge causes the cathode-to-plate current to increase when the raster scan points the electron beam at that location. The current increase is converted to a voltage that is proportional to the amount of light absorbed. This results in an electrical signal that represents the pattern of a visual image.

Standard vacuum tubes work well for frequencies up to hundreds of megahertz. At frequencies higher than this, the amount of time that it takes for the electrons to move between the cathode and the plate becomes a limiting factor. There are several special tubes designed to work at microwave frequencies. The *klystron* tube uses the principle of velocity modulation of the electrons to avoid transit time limitations. The beam of electrons travels down a metal drift tube that has interaction gaps along its sides. RF voltages are applied to the gaps and the electric fields that they generate accelerate or decelerate

the passing electrons. The relative positions of the electrons shift due to their changing velocities causing the electron density of the beam to vary. The modulation of the electron density is used to perform amplification or oscillation. Klystron tubes tend to be relatively large, with lengths ranging from 10 cm to 2 m and weights ranging from as little as 150 g to over 100 kg. Unfortunately, klystrons have relatively narrow bandwidths, and are not retunable by amateurs for operation on different frequencies.

The *magnetron* tube is an efficient oscillator for microwave frequencies. Magnetrons are most commonly found in microwave ovens and high powered radar equipment. The anode of a magnetron is made up of a number of coupled resonant cavities that surround the cathode. The magnetic field causes the electrons to rotate around the cathode and the energy that they give off as they approach the anode adds to the RF electric field. The RF power is obtained from the anode through a vacuum window. Magnetrons are self oscillating with the frequency determined by the construction of their anodes, however they can be tuned by coupling either inductance or capacitance to the resonant anode. The range of frequencies depends on how fast the tuning must be accomplished. The tube may be tuned slowly over a range of approximately 10% of the center frequency. If faster tuning is necessary, such as is required for frequency modulation, the range decreases to about 5%.

A third type of tube capable of operating in the microwave range is the *traveling wave tube*. For wide band amplifiers in the microwave range this is the tube of choice. Either permanent magnets or electromagnets are used to focus the beam of electrons that emerges from an electron gun similar to the one described for the CRT tube. The electron beam passes through a helical *slow-wave structure*, in which electrons are accelerated or decelerated, providing density modulation due to the applied RF signal, similar to that in the klystron. The modulated electron beam induces voltages in the helix that provides an amplified tube output whose gain is proportional to the length of the slow-wave structure. After the RF energy is extracted from the electron beam by the helix, the electrons are collected and recycled to the cathode. Traveling wave tubes can often be operated outside their designed frequencies by carefully optimizing the beam voltage.

## PHYSICAL ELECTRONICS OF SEMICONDUCTORS

Every atom of matter consists of, among other things, an equal number of protons

and electrons. These two subatomic particles must match in number to neutralize the electric charge: one positive charge for a proton and one negative charge for an electron.

Electrons orbit the nucleus, which contains the protons, at different energy levels. The binding of the electrons to the nucleus determines how an atom will behave electrically. Loosely bound electrons are easily liberated from their nuclei; atoms with this property are called *conductors*. In contrast, tightly bound electrons require considerable energy to be dislodged from their atoms; these atoms are called *insulators*. In between these two extremes is a class of elements called *semiconductors*, or partial conductors. As energy is added to a semiconductor atom, electrons are more easily freed. This property leads to many potential applications for this type of material.

In a conductor, such as a metal, the outer, or *valence*, electrons of each atom are shared with the adjacent atoms so there are many electrons that can move about freely between atoms. The moving free electrons are the constituents of electrical current. In a good conductor, the concentration of these free electrons is very high, on the order of  $10^{22}$  electrons /  $\text{cm}^3$ . In an insulator, nearly all the electrons are tightly held by their atoms; the concentration of free electrons is very small, on the order of 10 electrons /  $\text{cm}^3$ .

Semiconductor atoms (germanium — Ge and silicon — Si) share their valence electrons in a chemical bond that holds adjacent atoms together. The electrons are not free to leave their atom in order to move into the sphere of the adjacent atom, as in a conductor. They can be shared by the adjacent atom, however. The sharing of electrons means that the adjacent atoms are attracted to each other, forming a bond that gives the semiconductor its physical structure.

When energy is added to a semiconductor lattice, generally in the form of heat, some electrons are liberated from their bonds and move freely throughout the structure. The bond that loses an electron is then unbalanced and the space that the electron came from is referred to as a *hole*. Electrons from adjacent bonds can leave their positions and fill the holes, thus creating new holes in the adjacent bonds. Two opposite movements can be said to occur: negatively charged electrons move from bond to bond in one direction and positively charged holes move from bond to bond in the opposite direction. Both of these movements represent forms of electrical current, but this is very different from the current in a conductor. While the conductor has *free electrons* that flow re-

gardless of the crystalline structure, the current in a semiconductor is constrained to move only along the crystalline lattice between adjacent bonds.

Crystals formed from pure semiconductor atoms (Ge or Si) are called *intrinsic* semiconductors. In these materials the number of free electrons is equal to the number of holes. Each atom has four valence electrons that form bonds with adjacent atoms. Impurities can be added to the semiconductor material to enhance the formation of electrons or holes. These are *extrinsic* semiconductors. There are two types of impurities that can be added: one kind with five valence electrons *donates* free electrons to the crystalline structure; this is called an *N-type* impurity, for the negative charge that it adds. Some examples are antimony (Sb), phosphorus (P) and arsenic (As). N-type extrinsic semiconductors have more electrons and fewer holes than intrinsic semiconductors. Impurities with three valence electrons accept free electrons from the lattice, adding holes to the overall structure. These are called P-type impurities, for the net positive charge; some examples are boron (B), gallium (Ga) and indium (In).

Intrinsic semiconductor material can be formed by combining equal amounts of N-type and P-type impurity materials. Some examples of this include gallium-arsenide (GaAs), gallium-phosphate (GaP) and indium-phosphide (InP). To make an N-type compound semiconductor, a slightly higher amount of N-type material is used in the mixture. A P-type compound semiconductor has a little more P-type material in the mixture.

The conductivity of an extrinsic semiconductor depends on the charge density (in other words, the concentration of free electrons in N-type, and holes in P-type, semiconductor material). As the energy in the semiconductor increases, the charge density also increases. This is the basis of how all semiconductor devices operate: the major difference is the way in which the energy level is increased. Variations are: The *transistor*, where conductivity is altered by injecting current into the device via a wire; the *thermistor*, where the level of heat in the device is detected by its conductivity, and the *photoconductor*, where light energy that is absorbed by the semiconductor material increases the conductivity.

## The PN Semiconductor Junction

If a piece of N-type semiconductor material is placed against a piece of P-type semiconductor material, the location at which they join is called a *PN semiconductor junction*. The junction has characteristics that make it possible to develop

diodes and transistors. The action of the junction is best described by a diode operating as a rectifier. Initially, when the two types of semiconductor material are placed in contact, each type of material will have only its majority carriers: P-type will have only holes and N-type will have only free electrons. The net positive charge of the P-type material attracts free electrons from across the junction and the opposite is true in the N-type material. These attractions lead to diffusion of some of the majority carriers across the junction, which neutralize the carriers immediately on the other side. The region close to the junction is then *depleted* of carriers, and, as such, is named the *depletion region* (or the *space-charge region* or the *transition region*). The width of the depletion region is very small, on the order of 0.5  $\mu\text{m}$ .

If the N-type material is placed at a more negative voltage than the P-type material, current will pass through the junction because electrons are attracted from the lower potential to the higher potential and holes are attracted in the opposite direction. When the polarity is reversed, current does not flow because the electrons that are trying to enter the N-type material are repelled, as are the holes trying to enter the P-type material. This unidirectional current is what allows a semiconductor diode to act as rectifier.

Diodes are commonly made of silicon or germanium. Although they act similarly, they have slightly different characteristics. The *junction threshold voltage*, or *junction barrier voltage*, is the forward bias voltage at which current begins to pass through the device. This voltage is different for the two kinds of diodes. In the diode response curve of Fig 8.18, this value corresponds to the voltage at which the positive portion of the curve begins to rise sharply from the x axis. Most silicon diodes have a junction threshold voltage of about 0.7 V, while the value for germanium diodes typically is 0.3 V. The reverse biased leakage current is much lower for silicon diodes (in the nanoamp range) than for germanium diodes (in the microamp range). The forward resistance of a diode is typically very low and varies with the amount of forward current.

### Multiple Junctions

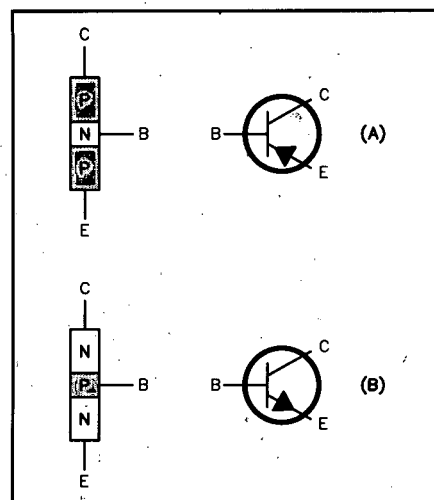

A bipolar transistor is formed when two PN junctions are placed next to each other. If N-type material is surrounded by P-type material, the result is a PNP transistor. Alternatively, if P-type material is in the middle of two layers of N-type material, the NPN transistor is formed (Fig 8.19).

Physically, we can think of the transistor as two PN junctions back-to-back, such as two diodes connected at their *anodes*

**Fig 8.18 — Semiconductor diode (PN junction) response curve. (A) Forward biased (anode voltage higher than cathode) response for Germanium — Ge and Silicon — Si devices. Each curve breaks away from the x-axis at its junction threshold voltage. The slope of each curve is its forward resistance. (B) Reverse biased response. Very small reverse current increases until it reaches the reverse saturation current ( $I_0$ ). The reverse current increases suddenly and drastically when the reverse voltage reaches the reverse breakdown voltage,  $V_{BR}$ .**

(the positive terminal) for an NPN transistor or two diodes connected at their *cathodes* (the negative terminal) for a PNP transistor. The connection point is the base of the transistor. (You can't actually *make* a transistor this way.) A transistor conducts when the base-emitter junction is forward biased and the base-collector is reverse biased. Under these conditions, the emitter region emits majority carriers into the base region, where they are minority carriers because the materials of the emitter and base regions have opposite polarity. The excess minority carriers in the base are attracted across the base-collector junction, where they are collected and are once again considered majority carriers. The flow of majority carriers from emitter to collector can be modified by the application of a bias current to the base terminal. If the bias cur-

**Fig 8.19 — Bipolar transistors. (A) A layer of N-type semiconductor sandwiched between two layers of P-type semiconductor makes a PNP device, the schematic symbol has three leads: collector (C), base (B) and emitter (E), with the arrow pointing in toward the base. (B) A layer of P-type semiconductor sandwiched between two layers of N-type semiconductor makes an NPN device, the schematic symbol has three leads: collector (C), base (B) and emitter (E), with the arrow pointing out away from the base.**

rent has the same polarity as the base material (for example holes flowing into a P-type base) the emitter-collector current increases. A transistor allows a small base current to control a much larger collector current.

As in a semiconductor diode, the forward biased base-emitter junction has a threshold voltage ( $V_{BE}$ ) that must be exceeded before the emitter current increases.

### PNPN Diode

If four alternate layers of P-type and N-type material are placed together, a PNPN (usually pronounced like *pinpin*) diode with three junctions is obtained (see Fig 8.20). This device, when the anode is at a higher potential than the cathode, has its first and third junctions forward biased and its center junction reverse biased. In this state, there is little current, just as in the reverse biased diode. As the forward bias voltage is increased, the current through the device increases slowly until the *breakover* (or *firing*) voltage,  $V_{BO}$ , is reached and the flow of current abruptly increases. The PNPN diode is often considered to be a switch that is off below  $V_{BO}$  and on above it.

### Bilateral Diode Switch

A semiconductor device similar to two

PNPN diodes facing in opposite directions and attached in parallel is the *bilateral diode switch* or *diac*. This device has the characteristic curve of the PNPN diode for both positive and negative bias voltages. Its construction, schematic symbol and characteristic curve are shown in Fig 8.21.

### Silicon Controlled Rectifier

Another device with four alternate layers of P-type and N-type semiconductor is the *silicon controlled rectifier (SCR)*, or *thyristor*. In addition to the connections to the outer two layers, two other terminals can be brought out for the inner two layers. The connection to the P-type material near the cathode is called the *cathode gate* and the N-type material near the anode is called the *anode gate*. In nearly all commercially available SCRs, only the cathode gate is connected (Fig 8.22).

Like the PNPN diode switch, the SCR is

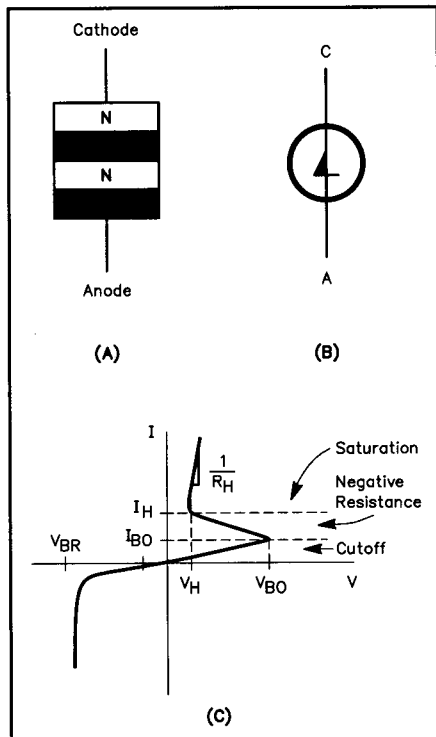

Fig 8.20 — PNP diode. (A) Alternating layers of P-type and N-type semiconductor. (B) Schematic symbol with cathode (C) and anode (A) leads. (C) Voltage-current response curve. Reverse biased response is the same as normal PN junction diodes. Forward biased response acts as a hysteresis switch. Resistance is very high until the bias voltage reaches  $V_{BO}$  and exceeds the cutoff current,  $I_{BO}$ . The device exhibits a negative resistance with the current increases as the bias voltage decreases until a voltage of  $V_H$  and saturation current of  $I_H$  is reached. After this the resistance is very low, with large increases in current for small voltage increases.

used to abruptly start conducting when the voltage exceeds a given level. By biasing the gate terminal appropriately, the breakover voltage can be adjusted. The SCR is highly efficient and is used in power control applications. SCRs are available that can handle currents of greater than 100 A and voltage differentials of greater than 1000 V, yet can be switched with gate currents of less than 50 mA.

### Triac

A five layered semiconductor whose operation is similar to a bidirectional SCR is the *triac* (Fig 8.23). This is also similar to a bidirectional diode switch with a bias control gate. The gate terminal of the triac can control both positive and negative breakover voltages and the devices can pass both polarities of voltage.

SCRs and triacs are often used to modify ac power sources. A sine wave with a given RMS value can be switched on and off at preset points during the cycle to decrease the RMS voltage. When conduction is delayed until after the peak (as Fig 8.24 shows) the peak-to-peak voltage is re-

Fig 8.21 — Bilateral switch. (A) Alternating layers of P-type and N-type semiconductor. (B) Schematic symbol. (C) Voltage-current response curve. The right-hand side of the curve is identical to the PNP diode response in Fig 8.20. The device responds identically for both forward and reverse bias so the left-hand side of the curve is symmetrical to the right-hand side.

duced. If conduction starts before the peak, the RMS voltage is reduced, but the peak-to-peak value remains the same. This method is used to operate light dimmers and 240 V ac to 120 V ac converters. The

(B) Schematic symbol with anode (A), cathode (C), anode gate ( $G_A$ ) and cathode gate ( $G_C$ ). Many devices are constructed without  $G_A$ . (C) Voltage-current response curve with different responses for various gate currents.  $I_G = 0$  has the same response as the PNP diode.

Fig 8.23 — Triac. (A) Alternating layers of P-type and N-type semiconductor. This behaves as two SCR devices facing in opposite directions with the anode of one connected to the cathode of the other and the cathode gates connected together. (B) Schematic symbol.

**Fig 8.24 — Triac operation on sine wave.** The dashed line is the original sine wave and the solid line is the portion that conducts through the triac. The relative delay and conduction period times are controlled by the amount or timing of gate current,  $I_G$ . The response of an SCR is the same as this for positive voltages (above the x-axis) and with no conduction for negative voltages.

sharp switching transients created when these devices switch are common sources of RF interference. SCRs are used as “crowbars” in power supply circuits, to short the output to ground and blow a fuse when an overvoltage condition exists.

## FIELD-EFFECT TRANSISTORS

The *field-effect transistor (FET)* controls the current between two points but does so differently than the bipolar transistor. The FET operates by the effects of an electric field on the flow of electrons through a single type of semiconductor material. This is why the FET is sometimes called a *unipolar* transistor. Also, unlike bipolar semiconductors that can be arranged in many configurations to provide diodes, transistors, photoelectric devices, temperature sensitive devices and so on, the field effect is usually only used to make transistors, although FETs are also available as special-purpose diodes, for use as constant current sources.

Current moves within the FET in a channel, from the source connection to the drain connection. A gate terminal generates an electric field that controls the current (see **Fig 8.25**). The channel is made of either N-type or P-type semiconductor material; an FET is specified as either an N-channel or P-channel device. Majority carriers flow from source to drain. In N-channel devices, electrons flow so the drain potential must be higher than that of the source ( $V_{DS} > 0$ ). In P-channel devices, the flow of holes requires that  $V_{DS} < 0$ . The polarity of the electric field that controls current in the channel is determined by the majority carriers of the channel, ordinarily positive for P-channel FETs and negative for N-channel FETs.

Variations of FET technology are based on different ways of generating the elec-

**Fig 8.25 — JFET devices with terminals labeled: source (S), gate (G) and drain (D).** A) Pictorial of N-type channel embedded in P-type substrate and schematic symbol. B) P-channel embedded in N-type substrate and schematic symbol.

tric field. In all of these, however, electrons at the gate are used only for their charge in order to create an electric field around the channel, and there is a minimal flow of electrons through the gate. This leads to a very high dc input resistance in devices that use FETs for their input circuitry. There may be quite a bit of capacitance between the gate and the other FET terminals, however. The input impedance may be quite low at RF.

The current through an FET only has to pass through a single type of semiconductor material. There is very little resistance in the absence of an electric field (no bias voltage). The drain-source resistance ( $r_{DS\ ON}$ ) is between a few hundred ohms to less than an ohm. The output impedance of devices made with FETs is generally quite low. If a gate bias voltage is added to operate the transistor near cut off, the circuit output impedance may be much higher.

FET devices are constructed on a *substrate* of doped semiconductor material. The channel is formed within the substrate and has the opposite polarity (a P-channel FET has N-type substrate). Most FETs are constructed with silicon. In order to achieve a higher gain-bandwidth product, other materials have been used. Gallium Arsenide (GaAs) has electron mobility and drift velocities that are far higher than the standard doped silicon. Amplifiers designed with *GaAs FET* devices have much higher frequency response and lower noise factor at VHF and UHF than those made with standard FETs.

## JFET

There are two basic types of FET. In the

*junction FET (JFET)*, the gate material is made of the opposite polarity semiconductor to the channel material (for a P-channel FET the gate is made of N-type semiconductor material). The gate-channel junction is similar to a diode's PN junction. As with the diode, current is high if the junction is forward biased and is extremely small when the junction is reverse biased. The latter case is the way that JFETs are used, since any current in the gate is undesirable. The magnitude of the reverse bias at the junction is proportional to the size of the electric field that “pinches” the channel. Thus, the current in the channel is reduced for higher reverse gate bias voltage.

Because the gate-channel junction in a JFET is similar to a bipolar junction diode, this junction must never be forward biased; otherwise large currents will pass through the gate and into the channel. For an N-channel JFET, the gate must always be at a lower potential than the source ( $V_{GS} < 0$ ). The channel is as fully open as it can get when the gate and source voltages are equal ( $V_{GS} = 0$ ). The prohibited condition is when  $V_{GS} > 0$ . For P-channel JFETs these conditions are reversed (in normal operation  $V_{GS} = 0$  and the prohibited condition is when  $V_{GS} < 0$ ).

## MOSFET

Placing an insulating layer between the gate and the channel allows for a wider range of control (gate) voltages and further decreases the gate current (and thus increases the device input resistance). The insulator is typically made of an oxide (such as silicon dioxide,  $SiO_2$ ). This type of device is called a *metal-oxide-semiconductor FET (MOSFET)* or *insulated-gate FET (IGFET)*. The substrate is often connected to the source internally. The insulated gate is on the opposite side of the channel from the substrate (see **Fig 8.26**). The bias voltage on the gate terminal either attracts or repels the majority carriers of the substrate across the PN junction with the channel. This narrows (depletes) or widens (enhances) the channel, respectively, as  $V_{GS}$  changes polarity. For N-channel MOSFETs, positive gate voltages with respect to the substrate and the source ( $V_{GS} > 0$ ) repel holes from the channel into the substrate, thereby widening the channel and decreasing channel resistance. Conversely,  $V_{GS} < 0$  causes holes to be attracted from the substrate, narrowing the channel and increasing the channel resistance. Once again, the polarities discussed in this example are reversed for P-channel devices. The common abbreviation for an N-channel MOSFET is *NMOS*, and for a P-channel MOSFET, *PMOS*.

## Semiconductor Failure

There are several common failure modes for semiconductors that are related to heat. The semiconductor material is connected to the outside world through metallic leads. The point at which the metal and the semiconductor are connected is one common place for the semiconductor device to fail. As the device heats up and cools down, the materials expand and contract. The rate of expansion and contraction of semiconductor material is different from that of metal. Over many cycles of heating and cooling the bond between the semiconductor and the metal can break. Some experts have suggested that the lifetime of semiconductor equipment can be extended by leaving the devices on all the time. While this would decrease the type of failure just described, inadequate cooling can lead to another type of semiconductor failure.

Impurities are introduced into intrinsic semiconductors by diffusion, the same physical property that lets you smell cookies baking from several rooms away. Smells diffuse through air much faster than molecules diffuse through solids. Once the impurities diffuse into the semiconductor, they tend to stay in place. Rates of diffusion are proportional to temperature, and semiconductors are doped with impurities at high temperature to save time. Once the doped semiconductor material is cooled, the rate of diffusion of the impurities is so low that they are essentially immobile for many years to come.

A common failure mode of semiconductors is due to the heat generated during semiconductor use. If the temperatures at the junctions rise to high enough levels for long enough periods of time, the impurities start to diffuse across the PN junctions. When enough of these atoms get across the junction, it stops functioning properly and the semiconductor device fails.

## Thermistors

The effect of temperature on current in semiconductors is put to use in a controlled fashion in a *thermistor*. The temperature coefficients of silicon and germanium are highly dependent on the amount of doping. For stability, thermistors are made of oxides such as nickel oxide (NiO), dimanganese trioxide ( $\text{Mn}_2\text{O}_3$ ) or dicobalt trioxide ( $\text{Co}_2\text{O}_3$ ). If the doping concentration of a semiconductor is high enough, it will start to take on some of the properties of a metal and the temperature coefficient becomes positive. A device made from this type of material is sometimes called a *sensistor*.

**Fig 8.26 — MOSFET devices with terminals labeled: source (S), gate (G) and drain (D). N-channel devices are pictured. P-channel devices have the arrows reversed in the schematic symbols and the opposite type semiconductor material for each of the layers. (A) N-channel depletion mode device schematic symbol and pictorial of P-type substrate, diffused N-type channel, SiO<sub>2</sub> insulating layer and aluminum gate region and source and drain connections. The substrate is connected to the source internally. A negative gate potential narrows the channel. (B) N-channel enhancement mode device schematic and pictorial of P-type substrate, N-type source and drain wells, SiO<sub>2</sub> insulating layer and aluminum gate region and source and drain connections. Positive gate potential forms a channel between the two N-type wells.**

Because of the insulating layer next to the gate, input resistance of a MOSFET is usually greater than  $10^{12} \Omega$  (a million megohms). Since MOSFETs can both deplete the channel, like the JFET, and also enhance it, the construction of MOSFET devices differs based on the channel size in the resting state,  $V_{GS} = 0$ . A *depletion mode device* (also called a *normally on MOSFET*) has a channel in resting state that gets smaller as a reverse bias is applied; this device conducts current with no bias applied (see Fig 8.26 A and B). An *enhancement mode device* (also called a *normally off MOSFET*) is built without a channel and does not conduct current when  $V_{GS} = 0$ ; increasing forward bias forms a channel that conducts current (see Fig 8.26 C and D).

## Semiconductor Temperature Effects

The number of excess holes and electrons is increased as the temperature of a semiconductor increases. Since the

conductivity of a semiconductor is related to the number of excess carriers, this also increases with temperature. With respect to resistance, semiconductors have a negative temperature coefficient. The resistance of silicon *decreases* by about  $8\% / ^\circ\text{C}$  and by about  $6\% / ^\circ\text{C}$  for germanium. Semiconductor temperature properties are the opposite of most metals, which *increase* their resistance by about  $0.4\% / ^\circ\text{C}$ . These opposing temperature characteristics permit the design of circuits with opposite temperature coefficients that cancel each other out, making a temperature insensitive circuit. Left by itself, the semiconductor can experience an effect called *thermal runaway* as the current causes an increase in temperature. The increased temperature decreases resistance and may lead to a further increase in current (depending on the circuit) that leads to an additional temperature increase. This sequence of events can continue until the semiconductor destroys itself.

# Practical Semiconductors

## SEMICONDUCTOR DIODES

Although many types of semiconductor diodes are available, there are not many differences between them. The diode is made of a single PN junction that affects current differently depending on its direction. This leads to a large number of applications in electronic circuitry.

The diode symbol is shown in Fig 8.27. Current passes most easily from anode to cathode, in the direction of the arrow. This is often referred to as the *forward* direction and the opposite is the *reverse* direction. Remember that *current* refers to the flow of electricity from higher to lower potentials and is in the opposite direction to the flow of electrons (current moves from anode to cathode and electrons flow from cathode to anode, as based on the definitions of the words, *anode* and *cathode*). The anode of a semiconductor junction diode is made of P-type material and the cathode is made of N-type material, as indicated in Fig 8.27. Most diodes are marked with a band on the cathode end (Fig 8.27). The ideal diode would have zero resistance in the forward direction and infinite resistance in the reverse direction. This is not the case for actual devices, which behave as shown in the plot of a diode response in Fig 8.18. Note that the scales of the two parts of the graph are drastically different. The inverse of the slope of the line (the change in voltage between two points on a straight portion of the line divided by the corresponding change in current) on the upper right is the resistance of the diode in the forward direction. The range of voltages is small and the range of currents is large since the forward resistance is very small (in this example, about 2  $\Omega$ ). The lower left portion of the curve illustrates a much higher resistance that increases from tens of kilohms to thousands of megohms as the reverse voltage gets larger, and then decreases to near zero (a nearly vertical line) very suddenly at the peak inverse voltage (PIV = 100 V in this example).

There are four major characteristics that distinguish standard junction diodes from one another: the PIV, the current or power handling capacity, the response speed and the junction barrier voltage. Each of these characteristics can be manipulated during manufacture to produce special purpose diodes.

The most common application of a diode is to perform rectification; that is, allowing positive voltages to pass and stopping negative voltages. Rectification is used in power supplies that convert ac to dc and in amplitude demodulation. The

most important diode parameters to consider for power rectification are the PIV and current ratings. The peak negative voltages that are stopped by the diode must be smaller in magnitude than the PIV and the peak current through the diode when it is forward biased must be less than the maximum amount for which the device was designed. Exceeding the current rating in a diode will cause excessive heating (based on  $P = I \times V_F$ ) that leads to PN junction failure as described earlier.

### Fast Diodes

The speed of a diode affects the frequencies that it can act on. The diode response in Fig 8.18 is a steady state response, showing how that diode will act at dc. As the frequency increases, the diode may not be able to keep up with the changing polarity of the signal and its response will not be as expected. Diode speed mainly depends on charge storage in the depletion region. Under reverse bias, excess charges move away from the junction, forming a larger space-charge region that is the equivalent of a dielectric. The diode thus exhibits capacitance, which is inversely proportional to the width of the dielectric and directly proportional to the cross-sectional surface area of the junction.

One way to decrease charge storage time in the depletion region is to form a metal-semiconductor junction. This can be accomplished with a point-contact diode, where a thin piece of aluminum wire, often called a *whisker*, is placed in contact with one face of a piece of lightly doped N-type material. In fact, the original diodes used for detecting radio signals ("cat's whisker diodes") were made this way. A more recent improvement to this technology, the *hot-carrier diode*, is like a point-contact diode with more ideal characteristics attained by using more efficient metals, such as platinum and gold, that act to lower forward resistance and increase PIV. This type of contact is known as a *Schottky barrier*, and diodes made this way are called *Schottky diodes*.

The PIN diode, shown in Fig 8.27C is a *slow response* diode that is capable of passing microwave signals when it is forward biased. This device is constructed with a layer of intrinsic (undoped) semiconductor placed between very highly doped P-type and N-type material (called P<sup>+</sup>-type and N<sup>+</sup>-type material to indicate the high level of doping), creating a PIN junction. These devices provide very effective switches for RF signals and are often used in TR switches in transceivers. PIN diodes have longer than normal carrier lifetimes,

**Fig 8.27 — Practical semiconductor diodes.** All devices are aligned with anode on the left and cathode on the right. (A) Standard PN junction diode. (B) Point-contact or "cat's whisker" diode. (C) PIN diode formed with heavily doped P-type (P<sup>+</sup>), undoped (intrinsic) and heavily doped N-type (N<sup>+</sup>) semiconductor material. (D) Diode schematic symbol. (E) Diode package with marking stripe on the cathode end.

resulting in a slow switching process that causes them to act more like resistors than diodes at high radio frequencies.

### Varactors

If the PN junction capacitance is controlled rather than reduced, a diode can be made to act as a variable capacitor. As the reverse bias voltage on a diode increases, the width of the junction increases, which decreases its capacitance. A *varactor* is a diode whose junction is specially formulated to have a relatively large range of capacitance values for a modest range of reverse bias voltages (Fig 8.28). Although special forms of varactors are available from manufacturers, other types of diodes may be used as inexpensive varactor diodes, but the relationship between reverse voltage and capacitance is not always reliable. When designing with varactor diodes, the reverse bias voltage must be absolutely free of noise since any variations in the bias voltage will cause changes in capacitance. Unwanted frequency shifts or instability will result if the reverse bias voltage is noisy. It is possible to frequency modulate a signal by adding the audio signal to the reverse bias on a varactor diode used in the carrier oscillator.

### Zener Diodes

When the PIV of a reverse biased diode is exceeded, the diode begins to conduct current as it does when it is forward biased. This current does not destroy the diode if it is limited to less than the device's maximum allowable value. When the PIV is controlled during manufacture to be at

desired levels, the device is called a *Zener diode*. Zener diodes (named after the American physicist Clarence Zener) provide accurate voltage references and are often used for this purpose in power supply regulators.

When the reverse breakdown voltage is exceeded, the reverse voltage drop across the Zener diode remains constant. With an appropriate current limiting resistor in series with it, the Zener diode provides an accurate voltage reference (Fig 8.29).

Zener diodes are rated by their reverse breakdown voltage and their power handling capacity. The power is a product of the current passing through the reverse biased Zener diode "in breakdown" (that is, in the breakdown mode of operation)

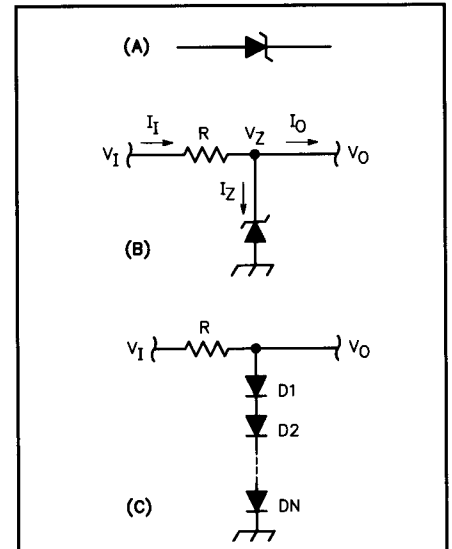

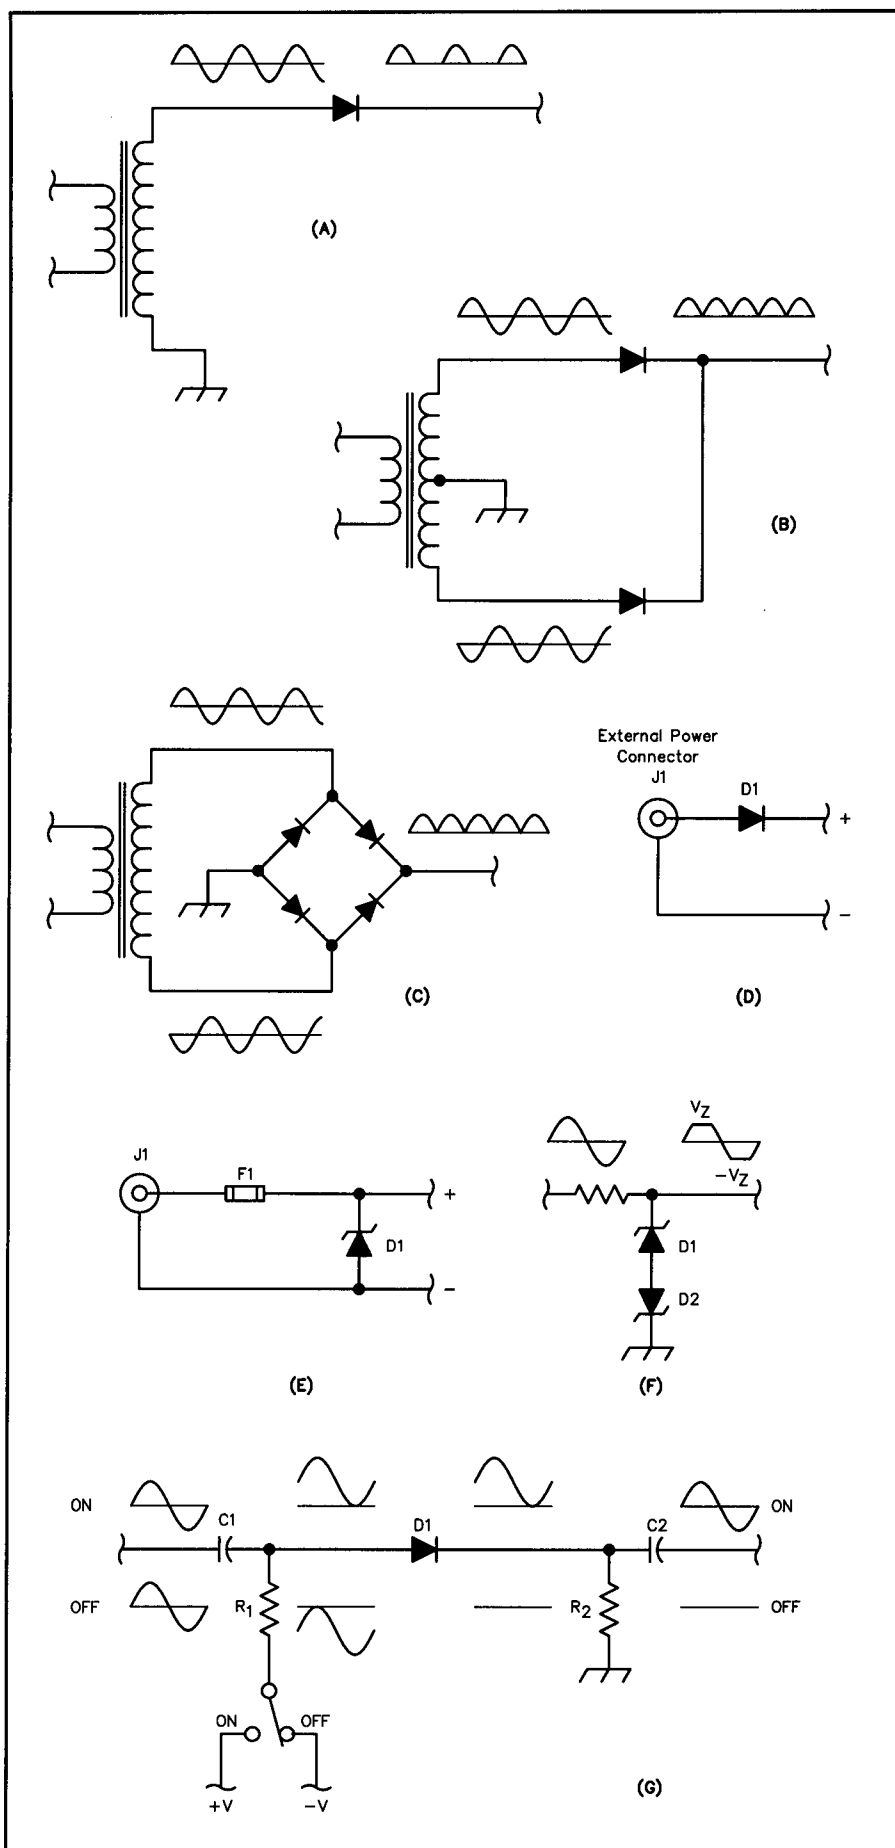

Fig 8.29 — Zener diode. (A) Schematic symbol. (B) Basic voltage regulating circuit.  $V_Z$  is the Zener reverse breakdown voltage. The Zener diode draws more current until  $V_I - I_I R = V_Z$ . The circuit design should select  $R$  so that when the maximum current is drawn,  $R < (V_I - V_Z) / I_O$ . The diode should be capable of passing the same current when there is no output current drawn. (C) For small voltages, several forward biased diodes can be used in place of Zener diodes. Each diode will drop the voltage by about 0.7 V for silicon or 0.3 V for germanium.

Fig 8.28 — Varactor diode. (A) Schematic symbol. (B) Equivalent circuit of the reverse biased varactor diode.  $R_s$  is the junction resistance,  $R_j$  is the leakage resistance and  $C_j$  is the junction capacitance, which is a function of the magnitude of the reverse bias voltage. (C) Plot of junction capacitance,  $C_j$ , as a function of reverse voltage,  $V_R$ , for three different varactor devices. Both axes are plotted on a logarithmic scale. (D) Oscillator circuit with varactor tuning. D1-L1 is a tuned circuit with a dual varactor diode that is controlled by the voltage from potentiometer R2. C1 is a filter capacitor to insure that the varactor bias voltage is clean dc. C2 and C6 are dc blocking capacitors. Q1 is an N-channel JFET in common drain configuration with feedback to the gate through C3. R3 is the gate bias resistor. R4 is the drain voltage resistor with filter capacitor C5.

**Fig 8.30 — Current regulator diode.** (A) Schematic symbol and package with line marking cathode end. (B) Diode characteristic curve (1N5283 device). When forward bias voltage exceeds about 4 V the current passing through the device is held constant regardless of the voltage across the device.

**Fig 8.31 — Diode circuits.** (A) Half wave rectifier circuit. Only when the ac voltage is positive does current pass through the diode. Current flows only during half of the cycle. (B) Full-wave center-tapped rectifier circuit. Center-tap on the transformer secondary is grounded and the two ends of the secondary are 180° out of phase. During the first half of the cycle the upper diode conducts and during the second half of the cycle the lower diode conducts. There is conduction during the full cycle with only positive voltages appearing at the output. (C) Full-wave bridge rectifier circuit. In each half of the cycle two diodes conduct capacity. (D) Polarity protection for external power connection. J1 is the connector that power is applied to. If polarity is correct, the diode will conduct and if reversed the diode will block current, protecting the circuit that is being powered. (E) Over-voltage protection circuit. If excessive voltage is applied to J1, D1 will conduct current until fuse, F1, is blown. (F) Bipolar voltage clipping circuit. In the positive portion of the cycle, D2 is forward biased but no current is shunted to ground because D1 is reverse biased. D1 starts to conduct when the voltage exceeds the Zener breakdown voltage and the positive peak is clipped. When the negative portion of the cycle is reached, D1 is forward biased but no current is shunted to ground because D2 is reverse biased. When the voltage exceeds the Zener breakdown voltage of D2, it also begins to conduct and the negative peak is clipped. (G) Diode switch. The signal is ac coupled to the diode by C1 at the input and C2 at the output. R2 provides a reference for the bias voltage. When switch S1 is in the ON position, a positive dc voltage is added to the signal so it is forward biased and is passed through the diode. When S1 is in the OFF position, the negative dc voltage added to the signal reverse biases the diode and the signal does not get through.

**Fig 8.32 — Transistor response curve.** The x-axis is the output voltage and the y-axis is the output current. Different curves are plotted for various values of input current. The three regions of the transistor are its cutoff region, where no current flows in any terminal, its active region, where the output current is nearly independent of the output voltage and there is a linear relationship between the input current and the output current, and the saturation region, where the output current has large changes for small changes in output voltage.

and the breakdown voltage. Since the same current must always pass through the resistor to drop the source voltage down to the reference voltage, with that current divided between the Zener diode and the load, this type of power source is very wasteful of current. The Zener diode does make an excellent and efficient voltage reference in a larger voltage regulating circuit where the load current is provided from another device whose voltage is set by the reference. (See the **Power Supplies and Projects** chapter for more information about using Zener diodes as voltage regulators.) The major sources of error in Zener-diode derived voltages are the variation with load current and the variation due to heat. Temperature compensated Zener diodes are available with temperature coefficients as low as  $0.0005\% / ^\circ\text{C}$ . If this is unacceptable, voltage reference integrated circuits based on Zener diodes have been developed that include additional circuitry to counteract temperature effects.

### Constant Current Diodes

A form of diode, called a *field-effect regulator diode*, provides a constant current over a wide range of forward biased voltages. The schematic symbol and characteristic curve for this type of device are shown in **Fig 8.30**. Constant current diodes are very useful in any application where a constant current is desired. Some part numbers are 1N5283 through 1N5314.

### Common Diode Applications

Standard semiconductor diodes have many uses in analog circuitry. Several examples of diode circuits are shown in **Fig 8.31**. Rectification has already been described. There are three basic forms of rectification using semiconductor diodes: half wave (1 diode), full-wave center-tapped (2 diodes) and full-wave bridge (4 diodes). These are more fully described in the **Power Supplies and Projects** chapter.

Diodes are commonly used to protect circuits. In battery powered devices a forward biased series diode is often used to protect the circuitry from the user inadvertently inserting the batteries backwards. Likewise, when a circuit is powered from an external dc source, a diode is often placed in series with the power connector in the device to prevent incorrectly wired power supplies from destroying the equipment. Diodes are commonly used to protect analog meters from both reverse voltage and over voltage conditions that would destroy the delicate needle movement.

Zener diodes are sometimes used to protect low-current (a few amps) circuits from over-voltage conditions. A reverse biased Zener diode connected between the positive power lead and ground will conduct excessive current if its breakdown voltage is exceeded. Used in conjunction with a fuse in series with the power lead, the Zener diode will cause the fuse to blow when an over-voltage condition exists.

Very high, short-duration voltage spikes can destroy certain semiconductors, particularly MOS devices. Standard Zener diodes can't handle the high pulse powers found in these voltage spikes. Special Zener diodes are designed for this purpose, such as the *mosorb*. (General Semiconductor Industries, Inc calls these devices *TransZorbs*.) A reverse biased TransZorb with a low-value series resistor can decrease the voltage reaching the sensitive device. Since the polarity of the spike can be positive, negative, or both, over voltage transient suppressor circuits can be designed with two devices wired back-to-back. They protect a circuit over a range of voltages rather than just suppressing positive peaks.

Diodes can be used to clip signals, similar to rectification. If the signal is appropriately biased it can be clipped at any level. Two Zener diodes placed back-to-back can be used to clip both the positive and negative peaks of a signal. Such an arrangement is used to convert a sine wave to an approximate square wave.

Care must be taken when using Zener diodes to process signals. The Zener diode is a relatively noisy device and can add excessive noise to the signals if it operates in breakdown. The Zener diode is often specified for use in circuits that intentionally generate noise, such as the noise bridge (see the **Test Procedures and Projects** chapter). The reverse biased Zener diode in breakdown generates wide band (nearly white) noise levels as high as  $2000\ \mu\text{V} / \sqrt{\text{Hz}}$ . (The noise voltage is determined by multiplying this value by the square root of the circuit bandwidth in Hz.)

Diodes are used as switches for ac coupled signals when a dc bias voltage can be added to the signal to permit or inhibit the signal from passing through the diode. In this case the bias voltage must be added to the ac signal and be of sufficient magnitude so that the entire envelope of the ac signal is above or below the junction barrier voltage, with respect to the cathode, to pass through the diode or inhibit the signal. Special forms of diodes, such as the PIN diode described earlier, which are capable of passing higher frequencies, are used to switch RF signals.

### BIPOLAR TRANSISTORS

The bipolar transistor is a *current-controlled device*. The current between the emitter and the collector is governed by the current that enters the base. The convention when discussing transistor operation is that the three currents into the device are positive ( $I_C$  into the collector,  $I_B$  into the base and  $I_E$  into the emitter).

Kirchhoff's current law applies to transistors just as it does to passive electrical networks: the total current entering the device must be zero. Thus, the relationship between the currents into a transistor can be generalized as

$$0 = I_c + I_b + I_e \quad (9)$$

which can be rearranged as necessary. For example, if we are interested in the emitter current,

$$I_e = -(I_c + I_b) \quad (10)$$

The back-to-back diode model is appropriate for visualization of transistor construction. In actual transistors, however, the relative sizes of the collector,

base and emitter regions differ. A common transistor configuration that spans a distance of 3 mm between the collector and emitter contacts typically has a base region that is only 25  $\mu\text{m}$  across.

Current conduction between collector and emitter is described by regions in the common-base response curves of the transistor device (see Fig 8.32). The transistor is in its *active region* when the base-collector junction is reverse biased and the base-emitter junction is forward biased. The slope of the output current ( $I_O$ ) versus the output voltage ( $V_O$ ) is virtually flat, indicating that the output current is nearly independent of the output voltage. The slight slope that does exist is due to base-

width modulation (known as the "Early effect"). Under these conditions, there is a linear relationship between the input current ( $I_I$ ) and  $I_O$ . When both the junctions in the transistor are forward biased, the transistor is said to be in its *saturation region*. In this region,  $V_O$  is nearly zero and large changes in  $I_O$  occur for very small changes in  $V_O$ . The *cutoff region* occurs when both junctions in the transistor are reverse biased. Under this condition, there is very little current in the output, only the nanoamperes or microamperes that result from the very small leakage across the input-to-output junction. These descriptions of junction conditions are the basis for the use of

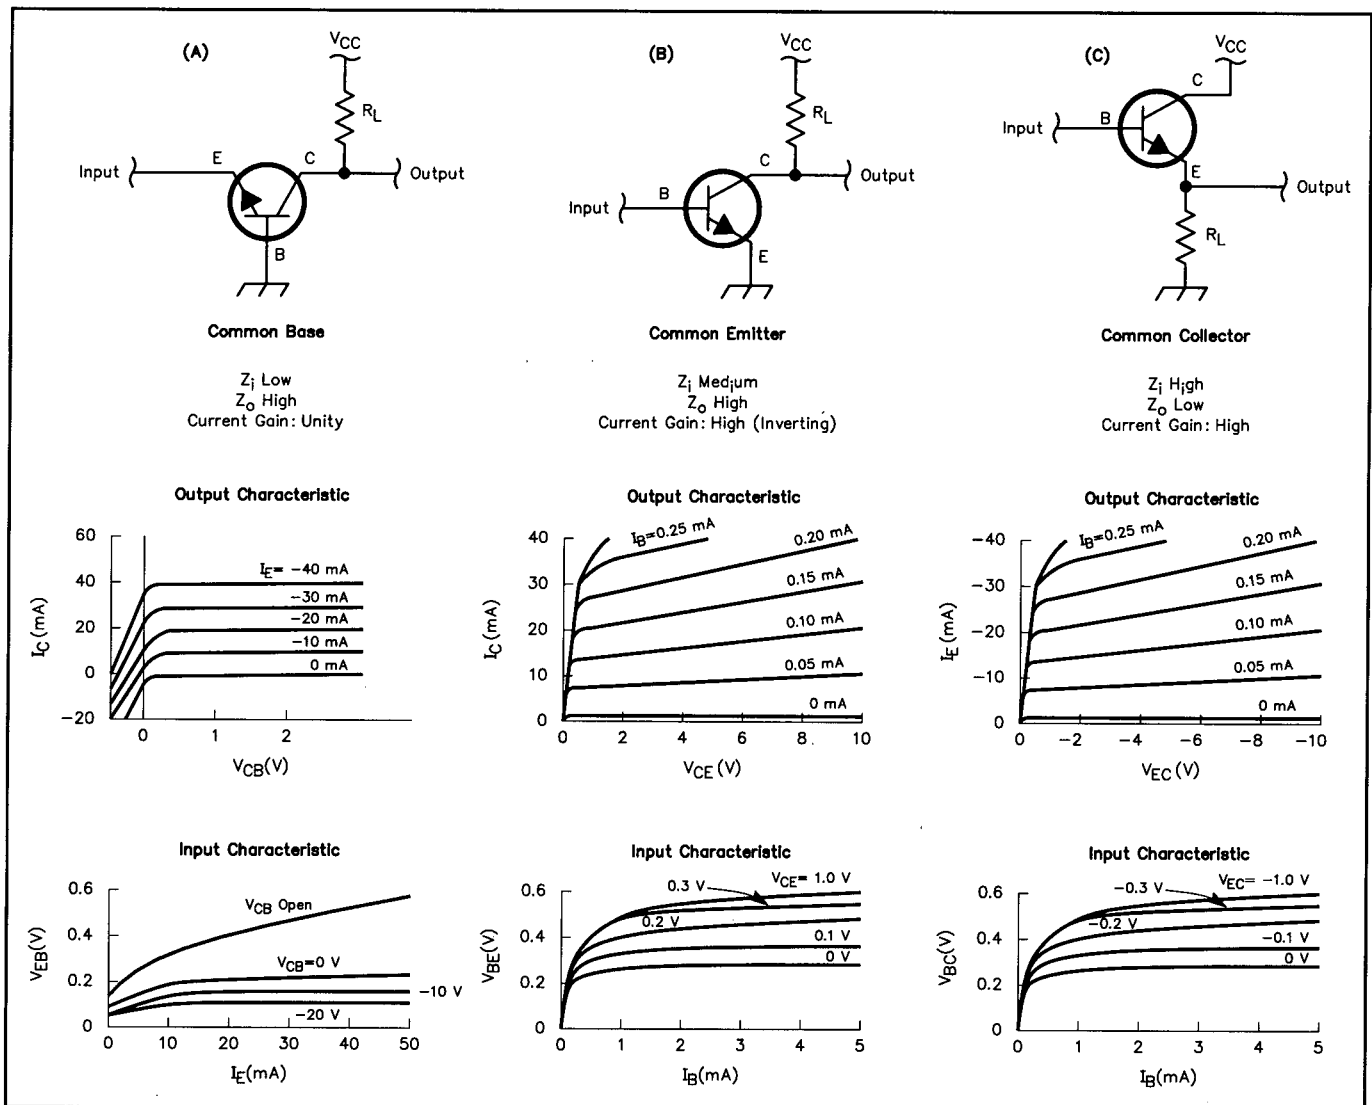

Fig 8.33 — The three configurations of transistor amplifiers. Each has a table of its relative impedance and current gain. The output characteristic curve is plotted for each, with the output voltage along the x-axis, the output current along the y-axis and various curves plotted for different values of input current. The input characteristic curve is plotted for each configuration with input current along the x-axis, input voltage along the y-axis and various curves plotted for different values of output voltage. (A) Common base configuration with input terminal at the emitter and output terminal at the collector. (B) Common emitter configuration with input terminal at the base and output terminal at the collector. (C) Common collector with input terminal at the base and output terminal at the emitter.

transistors. Various configurations of the transistor in circuitry make use of the properties of the junctions to serve different purposes in analog signal processing.

In the common base configuration, where the input is at the emitter and the output is at the collector, the current gain is defined as

$$\alpha = -\frac{\Delta I_C}{\Delta I_E} \approx 1 \quad (11)$$

In the common emitter configuration, with the input at the base and the output at the collector, the current gain is

$$\beta = \frac{\Delta I_C}{\Delta I_B} \quad (12)$$

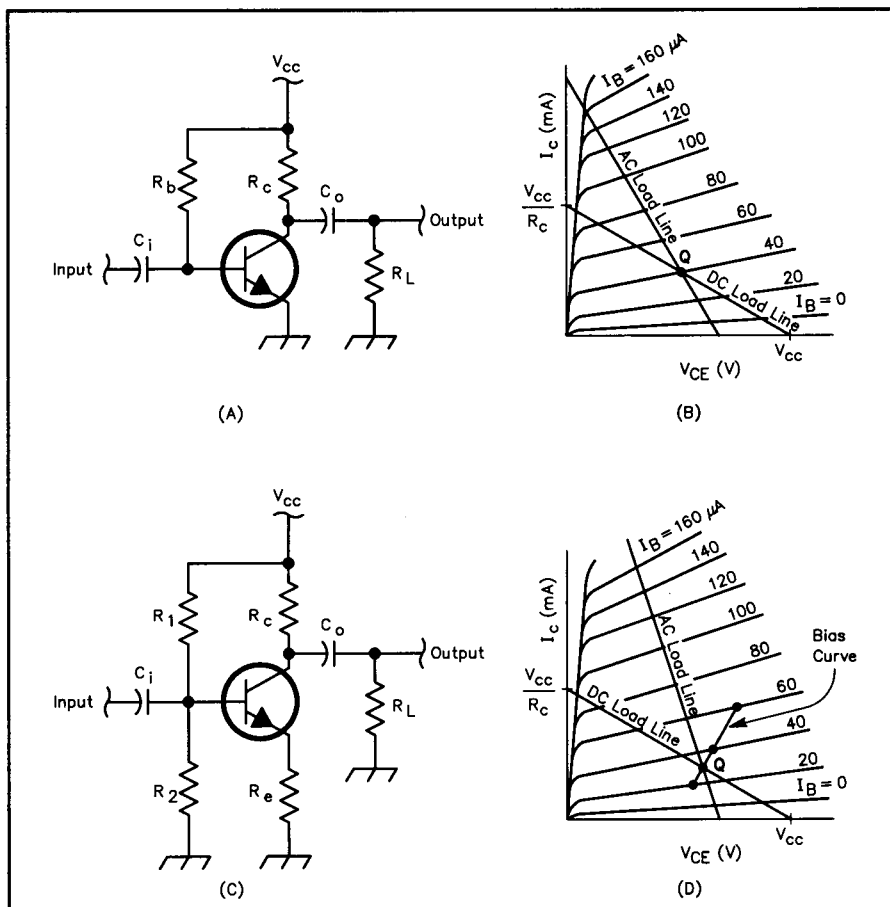

and the relationship between  $\alpha$  and  $\beta$  is defined as

$$\alpha = \frac{\beta}{1 + \beta} \quad (13)$$

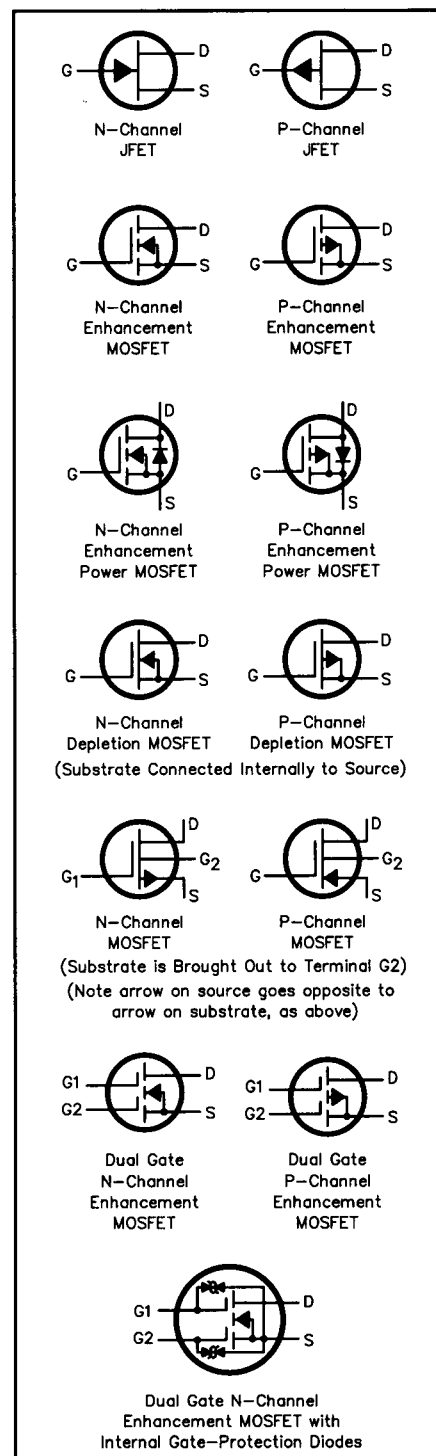

Since the common-emitter configuration is the most used transistor-amplifier configuration, another designation for  $\beta$  is often used:  $h_{FE}$ , the forward dc current gain. (The "h" refers to "h parameters," a set of parameters for describing a two-port network.) The symbol,  $h_{fe}$ , is used for the forward current gain of ac signals. Other transistor transfer function relationships that are measured are  $h_{ie}$ , the input impedance,  $h_{oe}$ , the output admittance (reciprocal of impedance) and  $h_{re}$ , the

voltage feedback ratio.

The behavior of a transistor can be defined in many ways, depending on which type of amplifier it is wired to be. A complete description of a transistor must include characteristic curves for each configuration. Typically, two sets of characteristic curves are presented: one describing the input behavior and the other describing the output behavior in each amplifier configuration. Different transistor

**Fig 8.34 — Transistor biasing circuits.** (A) Fixed bias. Input signal is ac coupled through  $C_i$ . The output has a voltage that is equal to  $V_{CC} - I_C \times R_C$ . This signal is ac coupled to the load,  $R_L$ , through  $C_o$ . For dc signals, the entire output voltage is based on the value of  $R_C$ . For ac signals, the output voltage is based on the value of  $R_C$  in parallel with  $R_L$ . (B) Characteristic curve for the transistor amplifier pictured in (A). The slope of the dc load line is equal to  $-1/R_C$ . For ac signals, the slope of the ac load line is equal to  $-1/(R_C \parallel R_L)$ . The quiescent operating point, Q, is based on the base bias current with no input signal applied and where this characteristic line crosses the dc load line. The ac load line must also pass through point Q. (C) Self-bias. Similar to fixed bias circuit with the base bias resistor split into two:  $R_1$  connected to  $V_{CC}$  and  $R_2$  connected to ground. Also an emitter bias resistor,  $R_E$ , is included to compensate for changing device characteristics. (D) This is similar to the characteristic curve plotted in (B) but with an additional "bias curve" that shows how the base bias current varies as the device characteristics change with temperature. The operating point, Q, moves along this line and the load lines continue to intersect it as it changes.

**Fig 8.35 — FET schematic symbols.**

amplifier configurations have different gains, input and output impedances. At low frequencies, where parasitic capacitances aren't a factor, the common emitter configuration has a high current gain (about - 50, with the negative sign indicating a 180° phase shift), medium to high input impedance (about 50 k $\Omega$ ) and a medium to low output impedance (about 1 k $\Omega$ ). The common collector has a high current gain (about 50), a high input impedance (about 150 k $\Omega$ ) and a low output impedance (about 80  $\Omega$ ). The common base amplifier has a low current gain (about 1), a low input impedance (about 25  $\Omega$ ) and a very high output impedance (about 2 M $\Omega$ ). Depending on the intended use of the transistor amplifier in an analog circuit, one configuration will be more appropriate than others. Once the common lead of the transistor amplifier configuration is chosen, the input and output impedance are functions of the device bias levels and circuit loading (Fig 8.33). The actual input and output impedances of a transistor amplifier are highly dependent on the input, biasing and load resistors that are used in the circuit.

A typical general-purpose bipolar-transistor data sheet lists important device specifications. Parameters listed in the ABSOLUTE MAXIMUM RATINGS section are the three junction voltages ( $V_{CEO}$ ,  $V_{CBO}$  and  $V_{EBO}$ ), the continuous collector current ( $I_C$ ), the total device power dissipation ( $P_D$ ) and the operating and storage temperature range. In the OPERATING PARAMETERS section, the three guaranteed minimum junction breakdown voltages are listed —  $V_{(BR)CEO}$ ,  $V_{(BR)CBO}$  and  $V_{(BR)EBO}$  — along with the two guaranteed maximum collector cutoff currents —  $I_{CEO}$  and  $I_{CBO}$  — under OFF CHARACTERISTICS. Under ON CHARACTERISTICS are the guaranteed minimum dc current gain ( $h_{FE}$ ), guaranteed maximum collector-emitter saturation voltage —  $V_{CE(sat)}$  — and the guaranteed maximum base-emitter on voltage —  $V_{BE(on)}$ . The next section is SMALL-SIGNAL CHARACTERISTICS, where the guaranteed minimum current gain-bandwidth product —  $f_T$ , the guaranteed maximum output capacitance —  $C_{obo}$ , the guaranteed maximum input capacitance —  $C_{ibo}$ , the guaranteed range of input impedance —  $h_{ie}$ , the small-signal current gain —  $h_{fe}$ , the guaranteed maximum voltage feedback ratio —  $h_{re}$  and output admittance —  $h_{oe}$  are listed. Finally, the SWITCHING CHARACTERISTICS section lists absolute maximum ratings for delay time —  $t_d$ , rise time —  $t_r$ , storage time —  $t_s$  and fall time —  $t_f$ .

### Transistor Biasing

Biasing in a transistor adds or subtracts

**Fig 8.36 — JFET output and transconductance response curves for common source amplifier configuration. (A) Output voltage ( $V_{DS}$ ) on the x-axis versus output current ( $I_D$ ) on the y-axis, with different curves plotted for various values of input voltage ( $V_{GS}$ ). (B) Transconductance curve has the same three variables rearranged,  $V_{GS}$  on the x-axis,  $I_D$  on the y-axis and curves plotted for different values of  $V_{DS}$ .**

a fixed amount of current from the signal at the input port. This differs from vacuum tube, FET and operational amplifier biasing where a bias voltage is added to the input signal. Fixed bias is the simplest form, as shown in Fig 8.34A. The operating point is determined by the intersection between the characteristic curves, the load line and the quiescent current bias line (Fig 8.34B). The problem with fixing the bias current is that if the transistor parameters drift due to heat, the operating point will change. The operating point can be stabilized by self biasing, also called emitter biasing, as pictured in Fig 8.34C. If  $I_C$  increases due to temperature changes, the current in  $R_E$  increases. The larger current through  $R_E$  increases the voltage drop across that resistor, causing a decrease in the base current,  $I_B$ . This, in turn, leads to a decreasing  $I_C$ , minimizing its variation due to heat. The operating point for this type of biasing is plotted in Fig 8.34D.

### FIELD-EFFECT TRANSISTORS

FET devices are more closely related to vacuum tubes than are bipolar transistors. Both the vacuum tube and the FET are controlled by the voltage level of the input rather than the input current, as in the bipolar transistor. FETs have three basic terminals, the gate, the source and the drain. These are related to both vacuum tube and bipolar transistor terminals: the gate to the grid and the base, the source to the cathode and the emitter, and the drain to the plate and the collector. Different forms of FET devices are pictured in Fig 8.35.

The characteristic curves for FETs are similar to those of vacuum tubes. The two most useful relationships are called the

**Fig 8.37 — JFET input leakage curves for common source amplifier configuration. Input voltage ( $V_{GS}$ ) on the x-axis versus input current ( $I_G$ ) on the y-axis, with two curves plotted for different operating temperatures, 25°C and 125°C. Input current increases greatly when the gate voltage exceeds the junction breakpoint voltage.**

transconductance and output curves (Fig 8.36). Transconductance curves give the drain current,  $I_D$ , due to different gate-source voltage differences,  $V_{GS}$ , for various drain-source voltages,  $V_{DS}$ . The same parameters are interrelated in a different way in the output curve. For different values of  $V_{GS}$ ,  $I_D$  is plotted against  $V_{DS}$ . In both of these representations, the device output is the drain current and these curves describe the FET in the common-source configuration. The action of the FET channel is so nearly ideal that, as long as the JFET gate does not become forward biased, the drain and source currents are virtually identical. For JFETs the gate leakage current,  $I_G$ , is a function of  $V_{GS}$  and this is often expressed with an input curve (Fig 8.37). The point at which there is a great increase in  $I_G$  is called the

## Transistor Amplifier Design—a Practical Approach

The design of a transistorized amplifier is a straightforward process. Just as you don't need a degree in mechanical engineering to drive an automobile, neither do you need detailed knowledge of semiconductor physics in order to design a transistor amplifier with predictable and repeatable properties.

This sidebar will describe how to design a small-signal "Class A" transistor amplifier, following procedures detailed in one of the best books on the subject—*Solid State Design for the Radio Amateur*, by Wes Hayward, W7ZOI, and Doug DeMaw, W1FB. For many years, both hams and professional engineers have used this classic ARRL book to design untold numbers of working amplifiers.

### How Much Gain?

One of the simple, yet profound, observations made in *Solid State Design for the Radio Amateur* is that a designer should *not* attempt to extract every last bit of gain from a single amplifier stage. Trying to do so virtually guarantees that the circuit will be "touchy"—it may end up being more oscillator than amplifier! While engineers might debate the exact number, modern semiconductor circuits are inexpensive enough that you should try for no more than 25 dB of gain in a single stage.

For example, if you are designing a high-gain amplifier system to follow a direct-conversion receiver mixer, you will need a total of about 100 dB of audio amplification. We would recommend a conservative approach where you use four stages, each with 25 dB of gain. But you might risk oscillation and instability by using only two stages, with 50 dB gain each. The component cost will not be greatly different between these approaches, but the headaches and lack of reproducibility of the "simpler" two-stage design will very likely far outweigh any small cost advantages!

### Biasing the Transistor Amplifier

The first step in amplifier design is to *bias* the transistor properly. A small-signal linear amplifier is biased properly when there is current at all times. Once you have biased the stage, you can then use several simple rules of thumb to determine all the major properties of the resulting amplifier.

*Solid State Design for the Radio Amateur* introduces several elegant transistor models. We won't get into that much detail here, except to say that the most fundamental property of a transistor is this: When there is current in the base-emitter junction, a larger current will flow in the collector-emitter junction. When the base-emitter junction is thus *forward biased*, the voltage across the base and emitter leads of a silicon transistor will be relatively constant, at 0.7 V. For most modern transistors, the dc current in the collector-emitter junction will be at least 50 to 100 times greater than the base-emitter current. This dc current gain is called the transistor's *Beta* ( $\beta$ ).

See Fig A, which shows a simple capacitively coupled low-frequency amplifier suitable for use at 1 MHz. Resistors R1 and R2 form a voltage divider feeding the base of the transistor. The amount of current in the resistive voltage divider is purposely made large enough so the base current is small in comparison, thus creating a "stiff" voltage supply for the base. As stated above, the voltage at the emitter will be 0.7 V less than the base voltage for this NPN transistor. The emitter voltage  $V_E$  appears across the series combination of R4 and R5. Note that R5 is bypassed by capacitor C4 for ac current.

By Ohm's Law, the emitter current is equal to the emitter voltage  $V_E$  divided by the sum of R4 plus R5.

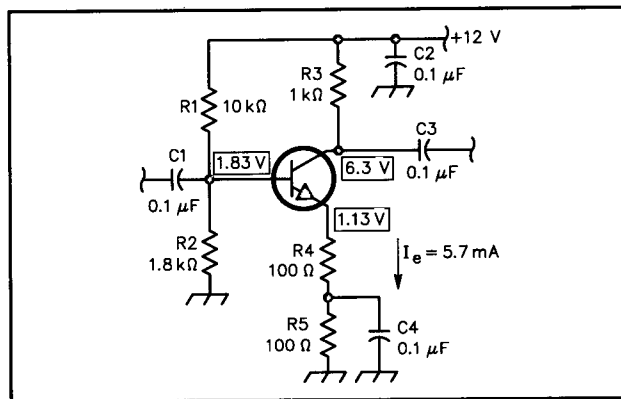

Now, the emitter current is made up of both the base-emitter and the collector-emitter current, but since the base current is much smaller than the collector current, the amount of collector current is essentially equal to the emitter current, at  $V_E / (R4 + R5)$ .

Our design process starts by specifying the amount of current we want to flow in the collector, with the dc collector voltage equal to half the supply voltage. For good bias stability with temperature variation, the total emitter resistor should be at least 100  $\Omega$  for a small-signal amplifier. Let's choose a collector current of 5 mA, and use a total emitter resistance of 200  $\Omega$ , with  $R4 = R5 = 100 \Omega$  each. The voltage across 200  $\Omega$  for 5 mA of current is 1.0 V. This means that the voltage at the base must be 1.0 V + 0.7 V = 1.7 V, provided by the voltage divider R1 and R2.

The dc base current requirements for a collector current of 5 mA is approximately 5 mA / 50 = 0.1 mA if the transistor's dc Beta is at least 50, a safe assumption for modern transistors. To provide a "stiff" base voltage, we want the current through the voltage divider to be about five to ten times greater than the base current. For convenience then, we choose the current through R1 to be 1 mA. This is a convenient current value, because the math is simplified—we don't have to worry about decimal points for current or resistance: 1 mA  $\times$  1.8 k $\Omega$  = 1.8 V. This is very close to the 1.7 V we are seeking. We thus choose a standard value of 1.8 k $\Omega$  for R2. The voltage drop across R1 is 12 V – 1.8 V = 10.2 V. With 1 mA in R1, the necessary value is 10.2 k $\Omega$ , and we choose the closest standard value, 10 k $\Omega$ .

Let's now look at what is happening in the collector part of the circuit. The collector resistor R3 is 1 k $\Omega$ , and the 5 mA of collector current creates a 5 V drop across R3. This means that the collector dc voltage must be 12 V – 5 V = 7 V. The dc power dissipated in the transistor will be essentially all in the collector-emitter junction, and will be the collector-emitter voltage (7 V – 1 V = 6 V) times the collector current of 5 mA = 0.030 W, or 30 mW. This dissipation is well within the 0.5 W rating typical of small-signal transistors.

Now, let's calculate more accurately the result from using standard values for R1 and R2. The actual base voltage will be 12 V  $\times$  [1.8 k $\Omega$  / (1.8 k $\Omega$  + 10 k $\Omega$ )] = 1.83 V,

**Fig A—Example of a simple low-frequency capacitively coupled transistorized small-signal amplifier. The voltages shown are the preliminary values desired for a collector current of 5 mA. The ac voltage gain is the ratio of the collector load resistor, R3, divided by the unbypassed portion of the emitter resistor, R4.**

rather than 1.7 V. The resulting emitter voltage is  $1.83 \text{ V} - 0.7 \text{ V} = 1.13 \text{ V}$ , resulting in  $1.13 \text{ V} / 200 \Omega = 5.7 \text{ mA}$  of collector current, rather than our desired 5 mA. We are close enough—we have finished designing the bias circuitry!

### Performance: Voltage Gain

Now we can analyze how our little amplifier will work. The use of the unbypassed emitter resistor R4 results in *emitter degeneration*—a fancy word describing a form of negative feedback. The bottom line for us is that we can use several handy rules of thumb. The first is for the ac voltage gain of an amplifier:  $A_v = R_3 / R_4$ , where  $A_v$  is shorthand for *voltage gain*. The ac voltage gain of such an amplifier is simply the ratio of the collector load resistor and the unbypassed emitter resistor. In this case, the gain is  $1000 / 100 = 10$ , which is 20 dB of voltage gain. This expression for gain is true virtually without regard for the exact kind of transistor used in the circuit, provided that we design for moderate gain in a single stage, as we have done.

### Performance: Input Resistance

Another useful rule of thumb stemming from use of an unbypassed emitter resistor is the expression for the ac input resistance:  $R_{in} = \beta \times R_4$ . If the ac  $\beta$  at low frequencies is about 50, then the input resistance of the transistor is  $50 \times 100 \Omega = 5000 \Omega$ . The actual input resistance includes the shunt resistance of voltage divider R2 and R1, about 1.5 k $\Omega$ . Thus the biasing resistive voltage divider essentially sets the input resistance of the amplifier.

### Performance: Overload

We can accurately predict how this amplifier will perform. If we were to supply a peak positive 1 V signal to the base, the voltage at the collector will try to fall by the voltage gain of 10. However, since the dc voltage at the collector is only 7 V, it is clear that the collector voltage cannot fall 10 V. In theory, the collector voltage could fall as low as the 1.13 V dc level at the emitter. This amplifier will “run out of voltage” at a negative collector voltage swing of about  $6.3 \text{ V} - 1.13 \text{ V} = 5.17 \text{ V}$ , when the input voltage is 5.17 divided by the gain of 10 = 0.517 V.

When a negative-going ac voltage is supplied to the base, the collector current falls, and the collector voltage will rise by the voltage gain of 10. The maximum amount of voltage possible is the 12 V supply voltage, where the transistor is cut off with no collector current. The maximum positive collector swing is from the standing collector dc voltage to the supply voltage:  $12 \text{ V} - 6.3 \text{ V} = 5.7 \text{ V}$  positive swing. This occurs with a peak negative input voltage of  $5.7 \text{ V} / 10 = 0.57 \text{ V}$ . Our amplifier will overload rather symmetrically on both negative and positive peaks. This is no accident—we biased it to have a collector voltage halfway

between ground and the supply voltage.

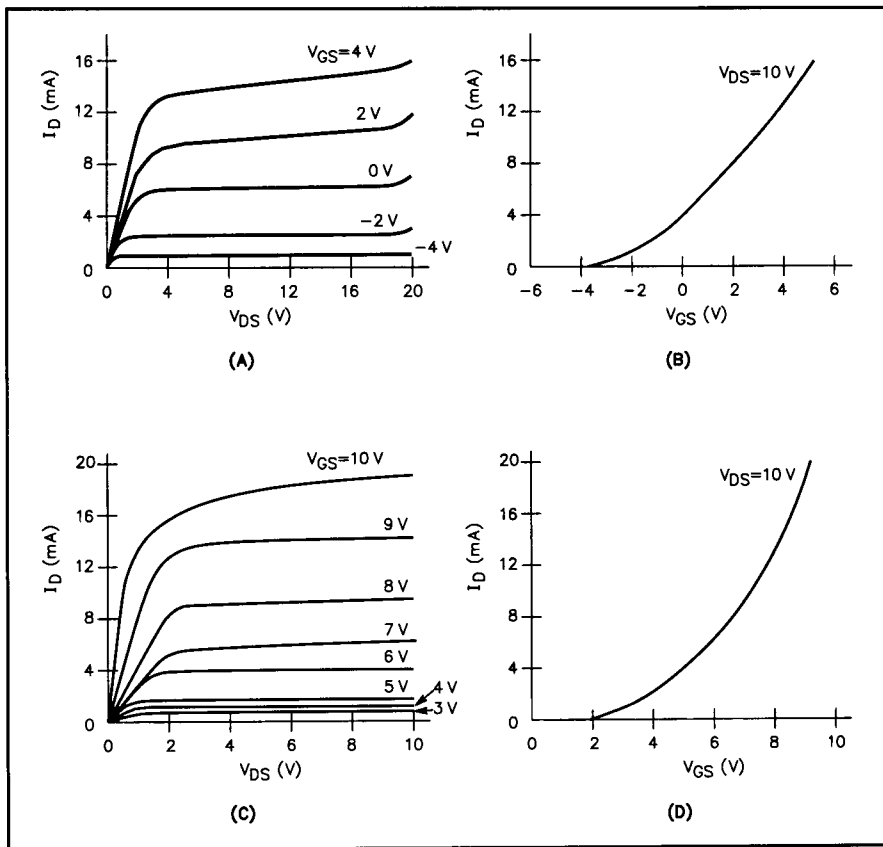

When the amplifier “runs out of output voltage” in either direction, another useful rule of thumb is that this is the *1 dB compression point*. This is where the amplifier just begins to depart from linearity, where it can no longer provide any more output for further input. For our amplifier, this is with a peak-to-peak output swing of approximately  $5.1 \text{ V} \times 2 = 10.2 \text{ V}$ , or 3.6 V rms. The output power developed in output resistor R3 is  $(3.6)^2 / 1000 = 0.013 \text{ W} = 13 \text{ mW}$ , which is +11.1 dBm (referenced to 1 mW on 50  $\Omega$ ).

At the 1 dB compression point, the third-order IMD (intermodulation distortion) will be roughly 25 dB below the level of each tone. **Fig B** shows a graph of output versus input levels for both the desired signal and for third-order IMD products. The rule of thumb for IMD is that if the input level is decreased by 10 dB, the IMD will decrease by 30 dB. Thus, if input is restricted to be 10 dB below the 1 dB compression point, the IMD will be  $25 \text{ dB} + 30 \text{ dB} = 55 \text{ dB}$  below each output tone.

With very simple math we have thus designed and characterized a simple amplifier. This amplifier will be stable for both dc and ac under almost any thermal and environmental conditions conceivable. That wasn't too difficult, was it?—*R. Dean Straw, N6BV, ARRL Senior Assistant Technical Editor*

**Fig B**—Output IMD (intermodulation distortion) as a function of input. In the region below the 1 dB compression point, a decrease in input level of 10 dB results in a drop of IMD products by 30 dB below the level of each output tone in a two-tone signal.

**Fig 8.38 — MOSFET output [(A) and (C)] and transconductance [(B) and (D)] response curves. Plots (A) and (B) are for an N-channel depletion mode device. Note that  $V_{GS}$  varies from negative to positive values. Plots (C) and (D) are for an N-channel enhancement mode device.  $V_{GS}$  has only positive values.**

*junction break point voltage.* The insulated gates in MOSFET devices do away with any appreciable gate leakage current. MOSFETs do not need input and reverse transconductance curves. Their output curves (Fig 8.38) are similar to those of the JFET.

The parameters used to describe a FET's performance are also similar to those of vacuum tubes. The dc channel resistance,  $r_{DS}$ , is specified in data sheets to be less than a maximum value when the device is biased on ( $r_{DS(on)}$ ). For ac signals,  $r_{ds(on)}$  is not necessarily the same as  $r_{DS(on)}$ , but it is not very different as long as the frequency is not so high that capacitive reactance becomes significant. The common source forward transconductance,  $g_{fs}$ , is obtained as the slope of one of the lines in the forward transconductance curve,

$$g_{fs} = \frac{\Delta I_D}{\Delta V_{GS}} \quad (14)$$

When gate voltage is maximum ( $V_{GS} = 0$  for a JFET)  $r_{DS(on)}$  is minimum. This describes the effectiveness of the device as an analog switch.

A typical FET data sheet gives

ABSOLUTE MAXIMUM RATINGS for  $V_{DS}$ ,  $V_{DG}$ ,  $V_{GS}$  and  $I_D$ , along with the usual device dissipation ( $P_D$ ) and storage temperature range. The OFF CHARACTERISTICS listed are the gate-source breakdown voltage,  $V_{GS(BR)}$ , the reverse gate current,  $I_{GSS}$  and the gate-source cutoff voltage,  $V_{GS(OFF)}$ . The ON CHARACTERISTIC is the zero-gate-voltage drain current ( $I_{DSS}$ ). The SMALL SIGNAL CHARACTERISTICS include the forward transfer admittance,  $y_{fs}$ , the output admittance,  $y_{os}$ , the static drain-source on resistance,  $r_{ds(on)}$  and various capacitances such as input capacitance,  $C_{iss}$ , reverse transfer capacitance,  $C_{rss}$ , the drain-substrate capacitance,  $C_{d(sub)}$ . FUNCTIONAL CHARACTERISTICS include the noise figure, NF and the common source power gain  $G_{ps}$ .

The relatively flat regions in the MOSFET output curves are often used to provide a constant current source. As is plotted in these curves, the drain current,  $I_D$ , changes very little as the drain-source voltage,  $V_{DS}$ , varies in this portion of the curve. Thus, for a fixed gate-source voltage,  $V_{GS}$ , the drain current can be considered to be constant over a wide

range of drain-source voltages.

Multiple gate MOSFETs are also available (MFE130, MPF201, MPF211, MPF521). Due to the insulating layer, the two gates are isolated from each other and allow two signals to control the channel simultaneously with virtually no loading of one signal by the other. A common application of this type of device is an automatic gain control (AGC) amplifier. The signal is applied to one gate and a rectified, low-pass filtered form of the output (the AGC voltage) is fed back to the other gate. Another common application is for mixers.

## FET Biasing

There are two ways to bias an FET, with and without feedback. Source self biasing for an N-channel JFET is pictured in Fig 8.39A. In this common-drain amplifier circuit, bias level is determined by the current through  $R_S$ , since  $I_G$  is very small and there is essentially no voltage drop across  $R_G$ . The characteristic curve for this configuration is plotted in Fig 8.39B. The operating points of the amplifier are where the load line intersects the curves. An example of feedback biasing is shown in Fig 8.39C.  $R_1$  is generally much larger than  $R_S$  and the load line is determined by the sum of these resistors, as shown in Fig 8.39D. Feedback biasing increases the input impedance of the amplifier, but is rarely required, since input resistance ( $R_G$ ) can be made very large.

## MOSFET Gate Protection

The MOSFET is constructed with a very thin layer of  $SiO_2$  for the gate insulator. This layer is extremely thin in order to improve the gain of the device but this makes it susceptible to damage from high voltage levels. If enough charge accumulates on the gate terminal, it can punch through the gate insulator and destroy it. The insulation of the gate terminal is so good that virtually none of this potential is eased by leakage of the charge into the device. While this condition makes for nearly ideal input impedance (approaching infinity), it puts the device at risk of destruction from even such seemingly innocuous electrical sources as static electricity in the air.

Some MOSFET devices contain an internal Zener diode with its cathode connected to the gate and its anode to the substrate. If the voltage at the gate rises to a damaging level the Zener junction breaks down and bleeds the excess charges off to the substrate. When voltages are within normal operating limits the Zener has little effect on the signal at the gate, although it may decrease the input impedance of the

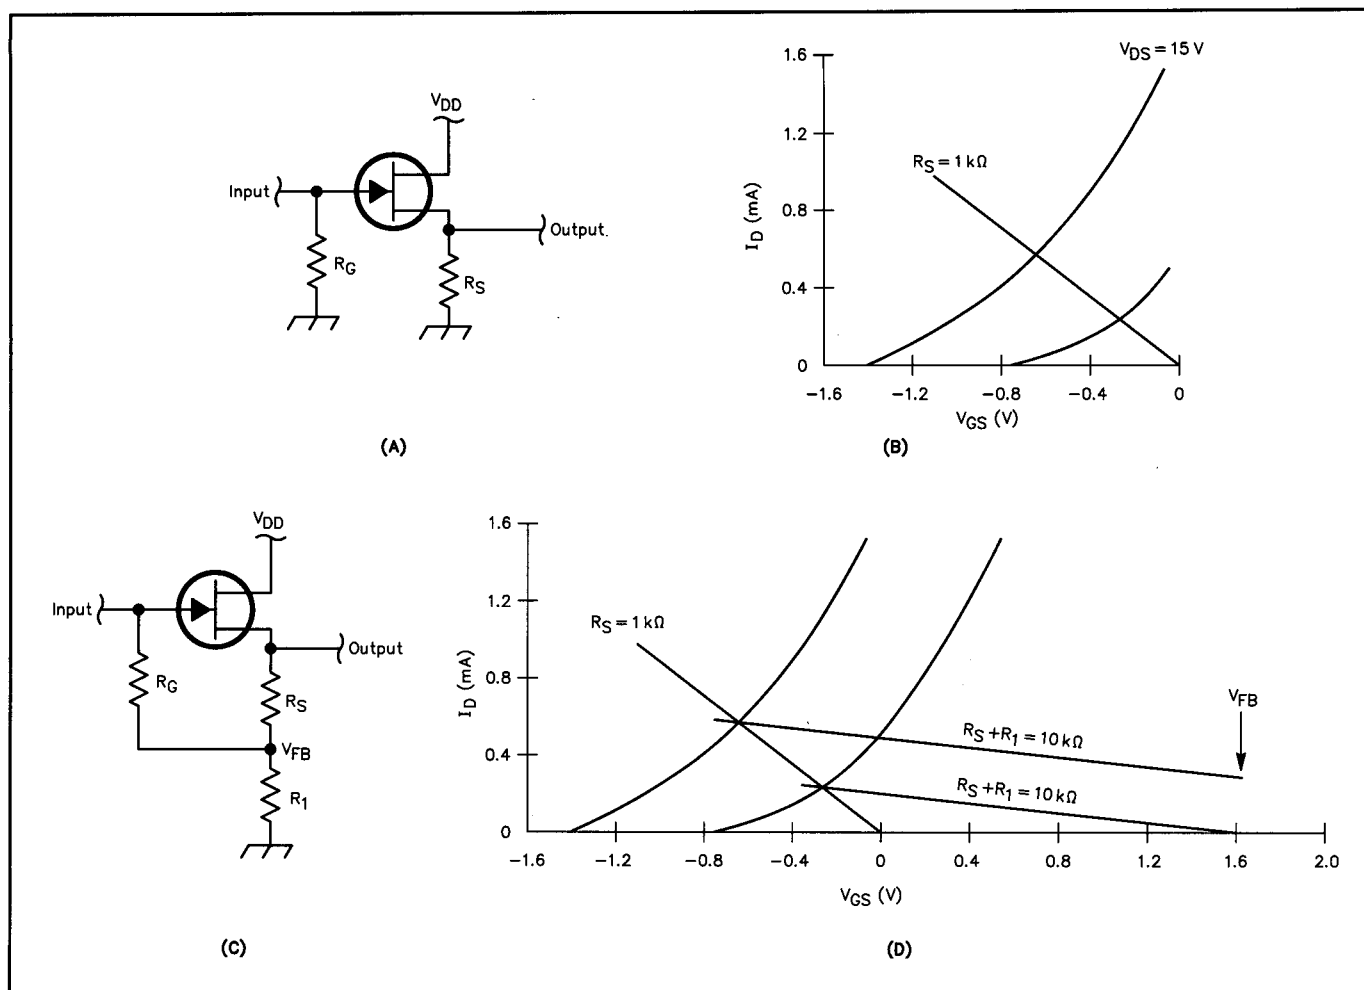

Fig 8.39 — FET biasing circuits. (A) Self biased common drain JFET circuit. (B) Transconductance curve for self biased JFET in (A). Gate bias is determined by current through  $R_S$ . Load line has a slope of  $-1/R_S$  and gate bias voltage can vary between where the load line crosses the characteristic curves. (C) Feedback bias common drain JFET circuit.

MOSFET. This solution will not work for all MOSFETs. The Zener diode must always be reverse biased to be effective. In the enhancement mode MOSFET,  $V_{GS} > 0$  for all valid uses of the part. In depletion mode devices  $V_{GS}$  can be both positive and negative; when negative, a protection Zener diode would be forward biased and the MOSFET would not work properly. In some depletion mode MOSFET devices, back-to-back Zener diodes are used to protect the gate.

MOSFET devices are at greatest risk of damage from static electricity when they are out of circuit. Even though static electricity is capable of delivering little current, it can generate thousands of volts. When storing MOSFETs, the leads should be placed into conductive foam. When working with MOSFETs, it is a good idea to minimize static by wearing a grounded wrist strap and working on a grounded table. A humidifier may help to decrease

the static electricity in the air. Before inserting a MOSFET into a circuit board it helps to first touch the device leads with your hand and then touch the circuit board. This serves to equalize the excess charge so that when the device is inserted into the circuit board little charge will flow into the gate terminal.

### OPTICAL SEMICONDUCTORS

In addition to electrical energy and heat energy, light energy also affects the behavior of semiconductor materials. If a device is made to allow light to fall on the surface of the semiconductor material, the light energy will break covalent bonds and increase the number of electron-hole pairs, decreasing the resistance of the material.

#### Photoconductors

In commercial *photoconductors* (also called *photoresistors*) the resistance can

change by as much as several kilohms for a light intensity change of 100 ft-candles. The most common material used in photoconductors is cadmium sulfide (CdS), with a resistance range of more than  $2\text{ M}\Omega$  in total darkness to less than  $10\text{ }\Omega$  in bright light. Other materials used in photoconductors respond best at specific colors. Lead sulfide (PbS) is most sensitive to infrared light and selenium (Se) works best in the blue end of the visible spectrum.

A similar effect is used in some diodes and transistors so that their operation can be controlled by light instead of electrical current biasing. These devices are called *photodiodes* and *phototransistors*. The flow of minority carriers across the reverse biased PN junction is increased by light falling on the doped semiconductor material. In the dark, the junction acts the same as any reverse biased PN junction, with a very low current (on the order of  $10\text{ }\mu\text{A}$ )

**Fig 8.40 — Photodiode response curve.** Reverse voltage is plotted on the x-axis and current through diode is plotted on the y-axis. Various response lines are plotted for different illumination. Except for the zero illumination line, the response does not pass through the origin since there is current generated at the PN junction by the light energy. A load line is shown for a 50 k $\Omega$  resistor in series with the photodiode.

that is nearly independent of reverse voltage. The presence of light not only increases the current but also provides a resistance-like relationship (reverse current increases as reverse voltage increases). See Fig 8.40 for the characteristic response of a photodiode. Even with no reverse voltage applied, the presence of light causes a small reverse current, as indicated by the points at which the lines in Fig 8.40 intersect the left side of the graph. Photoconductors and photodiodes are generally used to produce light-related analog signals that require further processing. The phototransistor can often be used to serve both purposes, acting as an amplifier whose gain varies with the amount of light present. It is also more sensitive to light than the other devices. Phototransistors have lots of gain, but photodiodes normally have less noise, so they make sensitive detectors.

### Photovoltaic Effect

When illuminated, the reverse biased photodiode has a reverse current due to excess minority carriers. As the reverse voltage is reduced, the potential barrier to the forward flow of majority carriers is also reduced. Since light energy leads to the generation of both majority and minority carriers, when the resistance to the flow of majority carriers is decreased these carriers form a forward current. The voltage at which the forward current equals the reverse current is called the *photovoltaic potential* of the junction. If the illuminated PN junction is not connected to a load, a voltage equal to the photovoltaic potential can be measured across it. Devices that use light from the sun to produce electricity in this way are

called *solar cells* or *solar batteries*. Common operating characteristics of silicon photovoltaic cells are an open circuit voltage of about 0.6 V and a conversion efficiency of about 10 to 15%.

### Light Emitting Diodes

In the photodiode, energy from light falling on the semiconductor material is absorbed to make additional electron-hole pairs. When the electrons and holes recombine, the same amount of energy is given off. In normal diodes the energy from recombination of carriers is given off as heat. In certain forms of semiconductor material, the recombination energy is given off as light with a mechanism called *electroluminescence*. Unlike the incandescent light bulb, electroluminescence is a cold light source that typically operates with low voltages and currents (such as 1.5 V and 10 mA). Devices made for this purpose are called *light emitting diodes (LEDs)*. They have the advantages of low power requirements, fast switching times (on the order of 10 ns) and narrow spectra (relatively pure color). The LED emits light when it is forward biased and excess carriers are present. As the carriers recombine, light is produced with a color that depends on the properties of the semiconductor material used. Gallium arsenide (GaAs) generates light in the infrared region, gallium phosphide (GaP) gives off red light when doped with oxygen or green light when doped with nitrogen. Orange light is attained with a mixture of GaAs and GaP (GaAsP). Silicon doped with carbon gives off yellow light but does not produce much illumination. Other colors are also possible with different types and concentrations of dopants but usually have

lower illumination efficiencies.

The LED is very simple to use. It is connected across a voltage source with a series resistor that limits the current to the desired level for the amount of light to be generated. The cathode lead is connected to the lower potential, and is usually specially marked (flattening of the lead near the package, a dot of paint next to the lead, and a flat portion of the round device located next to the lead are all common methods).

### Optoisolators

An interesting combination of optoelectronic components proves very useful in many analog signal processing applications. An *optoisolator* consists of an LED optically coupled to a phototransistor, usually in an enclosed package. The optoisolator, as its name suggests, isolates different circuits from each other. Typically, isolation resistance is on the order of  $10^{11} \Omega$  and isolation capacitance is less than 1 pF. Maximum voltage isolation varies from 1,000 to 10,000 V ac. The most common optoisolators are available in 6 pin DIP packages.

Optoisolators are used for voltage level shifting and signal isolation. The isolation has two purposes: to protect circuitry from excessive voltage spikes and to isolate noisy circuitry from noise sensitive circuitry. A disadvantage of an optoisolator is that it adds a finite amount of noise and is not appropriate for use in many applications with low level signals. Optoisolators also cannot transfer signals with high power levels. The power rating of the LED in a 4N25 device is 120 mW. Optoisolators have a limited frequency response due to the high capacitance of the LED. A typical bandwidth for the 4N25 series is 300 kHz.

As an example of voltage level shifting, the input to an optoisolator can be derived from a tube amplifier that has a signal varying between 0 and 150 V by using a series current limiting resistor. In order to drive a semiconductor circuit that operates in the -1 to 0 V range, the output of the optoisolator can be biased to operate in that range. This conversion of voltage levels, without a common ground connection between the circuits, is not easily performed in any other way.

A 1000 V spike that is high enough to destroy a semiconductor circuit will only saturate the LED in the optoisolator and will not propagate to the next stage. The worst that will happen is the LED will be destroyed, but very often it is capable of surviving even very high voltage spikes.

Optoisolators are also useful for isolating different ground systems. The input

and output signals are totally isolated from each other, even with respect to the references for each signal. A common application for optoisolation is when a computer is used to control radio equipment. The computer signal, and even its ground reference, typically contains considerable wide band noise due to the digital circuitry. The best way to keep this noise out of the radio is to isolate both the signal and its reference; this is easily done with an optoisolator.

The design of circuits with optoisolators is not different from the design of circuits with LEDs and with transistors. The LED is forward biased and usually driven with a series current limiting resistor whose value is set so that the forward current will be less than the maximum value for the device (such as 60 mA in a 4N25). Signals must be appropriately dc shifted so that the LED is always forward biased. The phototransistor typically has all three leads available for connection. The base lead is used for biasing, since the signal is usually derived from the optics, and the collector and emitter leads are used as they would be in any transistor amplifier circuit.

### Fiber Optics

An interesting variation of the optoisolator is the *fiber optic* connection. Like the optoisolator, the signal is introduced to an LED device that modulates light. The signal is recovered by a photodetecting device (photoresistor, photodiode, or phototransistor). Instead of locating the input and output devices next to each other, the light is transmitted in a fiber optic cable, an extruded glass fiber that efficiently carries light over long distances and around fairly sharp bends. The fiber optic cable isolates the two circuits and provides an interesting transmission line. Fiber optics generally have far less loss than coaxial cable transmission lines. They do not leak RF energy, nor do they pick up electrical noise. Special forms of LEDs and phototransistors are available with the appropriate optical couplers for connecting to fiber optic cables. These devices are typically designed for higher frequency operation with bandwidths in the tens and hundreds of megahertz.

### LINEAR INTEGRATED CIRCUITS

If you look into a transistor, the actual size of the semiconductor is quite small compared to the size of the packaging. For most semiconductors, the packaging takes considerably more space than the actual semiconductor device. Thus, an obvious way to reduce the physical size of circuitry is to combine more of the circuit

inside a single package.

### Hybrid Integrated Circuits

It is easy to imagine placing several small semiconductor chips in the same package. This is known as *hybrid circuitry*, a technology in which several semiconductor chips are placed in the same package and miniature wires are connected between them to make complete circuits.

Hybrid circuits miniaturize analog electronic circuits by replacing much of the packaging that is inherent in discrete electronics. The term *discrete* refers to the use of individual components to make a circuit, each in its own package. One application that still exists for hybrid circuitry is microwave amplifiers. The components of the amplifier are placed in a standard TO-39 package that is only 1 cm in diameter. The small dimensions of these circuits permit operation at VHF. For example, the Motorola MWA5157 can provide over 23 dB of gain at 1 GHz.

Both discrete and hybrid circuitry require that connections be made between the leads of the components. This takes space, is relatively expensive to construct and is the source of most failures in electronic circuitry. If multiple components could be placed on a single piece of semiconductor with the connections between them as part of the semiconductor chip, these three disadvantages would be overcome.

### Monolithic Integrated Circuits

In order to build entire circuits on a single piece of semiconductor, it must be possible to fabricate other devices, such as resistors and capacitors, as well as transistors and diodes. The entire circuit is combined into a single unit, or chip, that is called a *monolithic integrated circuit*.

An integrated circuit (IC) is fabricated in layers. An example of a semiconductor circuit schematic and its implementation in an IC is pictured in **Fig 8.41**. The base layer of the circuit, the *substrate*, is made of P-type semiconductor material. Although less common, the polarity of the substrate can also be N-type material. Since the mobility of electrons is about three times higher than that of holes, bipolar transistors made with N-type collectors and FETs made with N-type channels are capable of higher speeds and power handling. Thus, P-type substrates are far more common. For devices with N-type substrates, all polarities in the ensuing discussion would be reversed. Other substrates have been used, one of the most successful of which is the silicon-on-sapphire (SOS) construction that has been

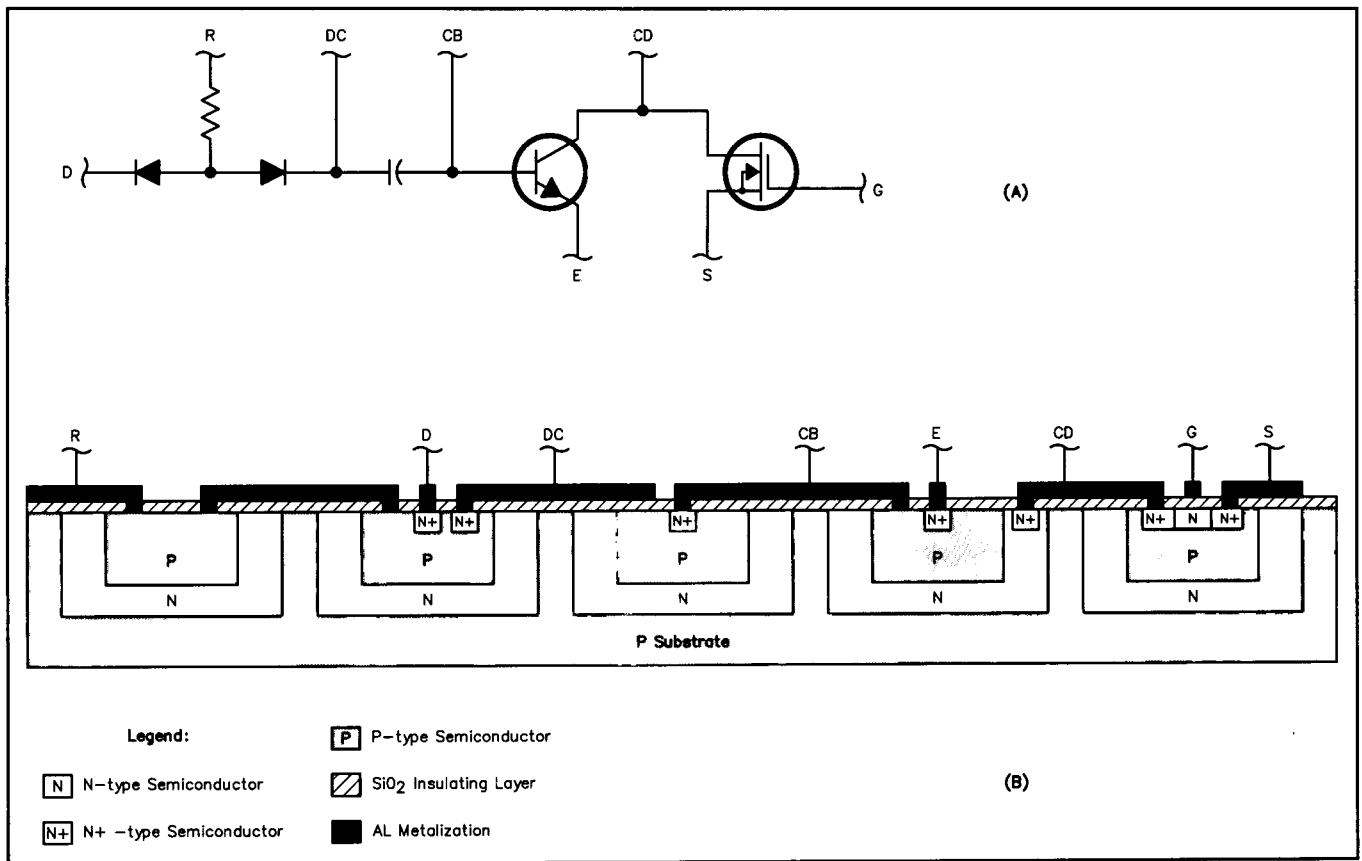

used to increase the bandwidth of integrated circuitry. Its relatively high manufacturing cost has impeded its use, however.

On top of the P-type substrate is a thin layer of N-type material in which the active and passive components are built. Impurities are diffused into this layer to form the appropriate component at each location. To prevent random diffusion of impurities into the N-layer, its upper surface must be protected. This is done by covering the N-layer with a layer of silicon dioxide ( $\text{SiO}_2$ ). Wherever diffusion of impurities is desired, the  $\text{SiO}_2$  is etched away. The precision of placing the components on the semiconductor material depends mainly on the fineness of the etching. The fourth layer of an IC is made of metal (usually aluminum) and is used to make the interconnections between the components.

Different components are made in a single piece of semiconductor material by first diffusing a high concentration of acceptor impurities into the layer of N-type material. This process creates P-type semiconductor — often referred to as P<sup>+</sup>-type semiconductor because of its high concentration of acceptor atoms—that isolates regions of N-type material. Each of these regions is then further processed to form single components. A component is produced by the diffusion of a lesser concentration of acceptor atoms into the middle of each isolation region. This results in an N-type *isolation well* that contains P-type material, is surrounded on its sides by P<sup>+</sup>-type material and has P-type material (substrate) below it. The cross sectional view in **Fig 8.41B** illustrates the various layers. Contacts to the metal layer are often made by diffusing high concentrations of donor atoms into small regions of the N-type well and the P-type material in the well. The material in these small regions is N<sup>+</sup>-type and facilitates electron flow between the metal contact and the semiconductor. In some configurations, it is necessary to connect the metal directly to the P-type material in the well.

An isolation well can be made into a resistor by making two contacts into the P-type semiconductor in the well. Resistance is inversely proportional to the cross-sectional area of the well. An alternate type of resistor that can be integrated in a semiconductor circuit is a *thin film resistor*, where a metallic film is deposited on the  $\text{SiO}_2$  layer, masked on its upper surface by more  $\text{SiO}_2$  and then etched to make the desired geometry, thus adjusting the resistance.

There are two ways to form capacitors in a semiconductor. One is to make use of

**Fig 8.41 — Integrated circuit layout. (A) Circuit containing two diodes, a resistor, a capacitor, an NPN transistor and an N-channel MOSFET. Labeled leads are D for diode, R for resistor, DC for diode-capacitor, E for emitter, S for source, CD for collector-drain and G for gate. (B) Integrated circuit that is identical to circuit in (A). Same leads are labeled for comparison. Circuit is built on a P-type semiconductor substrate with N-type wells diffused into it. An insulating layer of SiO<sub>2</sub> is above the semiconductor and is etched away where aluminum metal contacts are made with the semiconductor. Most metal-to-semiconductor contacts are made with heavily doped N-type material (N<sup>+</sup>-type semiconductor).**

the PN junction between the N-type well and the P-type material that fills it. Much like a varactor diode, when this junction is reverse biased a capacitance results. Since a bias voltage is required, this type of capacitor is polarized, like an electrolytic capacitor. Nonpolarized capacitors can also be formed in an integrated circuit by using thin film technology. In this case, a very high concentration of donor ions is diffused into the well, creating an N<sup>+</sup>-type region. A thin metallic film is deposited over the SiO<sub>2</sub> layer covering the well and the capacitance is created between the metallic film and the well. The value of the capacitance is adjusted by varying the thickness of the SiO<sub>2</sub> layer and the cross-sectional size of the well. This type of thin film capacitor is also known as a metal oxide semiconductor (MOS) capacitor.

Unlike resistors and capacitors, it is very difficult to create inductors in integrated circuits. Generally, RF circuits that need inductance require external inductors to be connected to the IC. In some cases, particularly at lower frequencies, the behavior of an inductor can be

mimicked by an amplifier circuit. In many cases the appropriate design of IC amplifiers can obviate the need for external inductors.

Transistors are created in integrated circuitry in much the same way that they are fabricated in their discrete forms. The NPN transistor is the easiest to make since the wall of the well, made of N-type semiconductor, forms the collector, the P-type material in the well forms the base and a small region of N<sup>+</sup>-type material formed in the center of the well becomes the emitter. A PNP transistor is made by diffusing donor ions into the P-type semiconductor in the well to make a pattern with P-type material in the center (emitter) surrounded by a ring of N type material that connects all the way down to the well material (base), and this is surrounded by another ring of P-type material (collector). This configuration results in a large base width separating the emitter and collector, causing these devices to have much lower current gain than the NPN form. This is one reason why integrated circuitry is designed to use many more NPN tran-

sistors than PNP transistors.

The simplest form of diode is generated by connecting to an N<sup>+</sup>-type connection point in the well for the cathode and to the P-type well material for the anode. Diodes are often converted from NPN transistor configurations. Integrated circuit diodes made this way can either short the collector to the base or leave the collector unconnected. The base contact is the anode and the emitter contact is the cathode.

FETs can also be fabricated in IC form. Due to its many functional advantages, the MOSFET is the most common form used for digital ICs. MOSFETs are made in a semiconductor chip much the same way as MOS capacitors, described earlier. In addition to the signal processing advantages offered by MOSFETs over other transistors, the MOSFET device can be fabricated in 5% of the physical space required for bipolar transistors. MOSFET ICs can contain 20 times more circuitry than bipolar ICs with the same chip size. Just as discrete MOSFETs are at risk of gate destruction, IC chips made with MOSFET devices have a similar risk. They should

be treated with the same care to protect them from static electricity as discrete MOSFETs. Integrated circuits need not be made exclusively with MOSFETs or bipolar transistors. It is common to find IC chips designed with both technologies, taking advantage of the strengths of each.

### Complementary Metal Oxide Semiconductors

Power dissipation in a circuit can be reduced to very small levels (on the order of a few nW) by using the MOSFET devices in complementary pairs (CMOS). Each amplifier is constructed of a series circuit of MOSFET devices, as in Fig 8.42. The gates are tied together for the input signal, as are the drains for the output signal. In saturation and cutoff, only one of the devices conducts. The current drawn by the circuit under no load is equal to the OFF leakage current of either device and the voltage drop across the pair is equal to  $V_{DD}$ , so the steady state power used by the circuit is always equal to  $V_{DD} \times I_{D(off)}$ . For ac signals, power consumption is proportional to frequency.

CMOS circuitry could be built with discrete components, however the number of extra parts and the need for the complementary components to be matched has made it an unusual design technique. Although CMOS is most commonly used in digital integrated circuitry, its low power consumption has been put to advantage by several manufacturers of analog ICs.

### Integrated Circuit Advantages

There are many advantages of monolithic integrated circuitry over similar circuitry implemented with discrete components. The integration of the interconnections is one that has already been mentioned. This procedure alone serves to greatly decrease the physical size of the circuit and to improve its reliability. In fact, in one study performed on failures of electronic circuitry, it was found that the failure rate is not necessarily related to the complexity of the circuit, as had been previously thought, but is more closely a function of the number of interconnections between packages. Thus, the more circuitry that can be integrated onto a single piece of semiconductor material, the more reliable the circuit should be.

The amount of circuitry that can be placed onto a single semiconductor chip is a function of two factors: the size of the chip and how closely the various components are spaced. A revolution in IC manufacture occurred when semiconductor material was created in the laboratory rather than found in nature. The man-made semiconductor wafers are more pure and

**Fig 8.42 — Complementary metal oxide semiconductor (CMOS).** (A) CMOS device is made from a pair of enhancement mode MOS transistors, the upper is a P-channel device and the lower is an N-channel device. When one transistor is biased on, the other is biased off so there is minimal current from  $V_{DD}$  to ground. (B) Implementation of a CMOS pair as an integrated circuit.

allow for larger wafer sizes. This, along with the steady improvement of the etching resolution on the chips, has caused an exponential increase over the past two decades in the amount of circuitry that can be placed in a single IC package. Currently, it is not unusual to find chips with more than one million transistors on them.

Decreased circuit size and improved reliability are only two of the advantages of monolithic integrated circuitry. The uncertainty of the exact behavior of the integrated components is the same as it is for discrete components, as discussed earlier. The relative properties of the devices on a single chip are very predictable, however. Since adjacent components on a semiconductor chip are made simultaneously (the entire N-type layer is grown at once, a single diffusion pass isolates all the wells and another pass fills them), the characteristics of identically formed components on a single chip of silicon should be identical. Even if the exact characteristics of the components are unknown, very often in analog circuit design the major concern is how components interact. For instance, push-pull amplifiers require perfectly matched transistors, and the gain of many amplifier configurations is governed by the ratio between two resistors and not their absolute values of resistance.

Integrated circuits often have an advantage over discrete circuits in their temperature behavior. The variation of performance of the components on an integrated circuit due to heat is no better than that of discrete components. While a discrete circuit may be exposed to a wide range of temperature changes, the entire semiconductor chip generally changes temperature

by the same amount; there are fewer “hot spots” and “cold spots.” Thus, integrated circuits can be designed to better compensate for temperature changes.

A designer of analog devices implemented with integrated circuitry has more freedom to include additional components that could improve the stability and performance of the implementation. The inclusion of components that could cause a prohibitive increase in the size, cost or complexity of a discrete circuit would have very little effect on any of these factors in an integrated circuit.

Once an integrated circuit is designed and laid out, the cost of making copies of it is very small, often only pennies per chip. Integrated circuitry is responsible for the incredible increase in performance with a corresponding decrease in price of electronics over the last 20 years. While this trend is most obvious in digital computers, analog circuitry has also benefited from this technology.

The advent of integrated circuitry has also improved the design of high frequency circuitry. One problem in the design and layout of RF equipment is the radiation and reception of spurious signals. As frequencies increase and wavelengths approach the dimensions of the wires in a circuit board, the interconnections act as efficient antennas. The dimensions of the circuitry within an IC are orders of magnitude smaller than in discrete circuitry, thus greatly decreasing this problem and permitting the processing of much higher frequencies with fewer problems of interstage interference. Another related advantage of the smaller interconnections in an IC is the lower in-

herent inductance of the wires, and lower stray capacitance between components and traces.

### Integrated Circuit Disadvantages

Despite the many advantages of integrated circuitry, disadvantages also exist. ICs have not replaced discrete components, even tubes, in some applications. There are some tasks that ICs cannot perform, even though the list of these continues to decrease over time as IC technology improves.

Although the high concentration of components on an IC chip is considered to be an advantage of that technology, it also leads to a major limitation. Heat generated in the individual components on the IC chip is often difficult to dissipate. Since there are so many heat generating components so close together, the heat can build up and destroy the circuitry. It is this limitation that currently causes many power amplifiers to be designed with discrete components.

Integrated circuits, despite their short interconnection lengths and lower stray inductance, do not have as high a frequency response as similar circuits built with appropriate discrete components. (There are exceptions to this generalization, of course. Monolithic microwave integrated circuits—MMICs—are available for operation on frequencies up through 10 GHz.) The physical architecture of an integrated circuit is the cause of this limitation. Since the substrate and the walls of the isolation wells are made of opposite types of semiconductor material, the PN junction between them must be reverse biased to prevent current from passing into the substrate. Like any other reverse biased PN junction, a capacitance is created at the junction and this limits the frequency response of the devices on the IC. This situation has improved over the years as isolation wells have gotten smaller, thus decreasing the capacitance between the well and the substrate, and techniques have been developed to decrease the PN junction capacitance at the substrate. One such technique has been to create an  $N^+$ -type layer between the well and the substrate, which decreases the capacitance of the PN junction as seen by the well. As an example, in the 1970s the LM324 operational amplifier IC package was developed by National Semiconductor and claimed a gain-bandwidth product of 1 MHz. In the 1990s the HFA1102 operational amplifier IC, developed by Harris Semiconductor, was introduced with a gain-bandwidth product of 600 MHz.

A major impediment to the introduction of new integrated circuits, particularly

with special applications, is the very high cost of development of new designs. The masking cost alone for a designed and tested integrated circuit can exceed \$100,000. Adding the design, layout and debugging costs motivates IC manufacturers to produce devices that will be widely used so that they can recoup the development costs by volume of sales. While a particular application would benefit from customization of circuitry on an IC, the popularity of that application may not be wide enough to compel an IC manufacturer to develop that design. A designer who wishes to use IC chips must often settle for circuits that do not behave exactly as desired for the specific application. This trade-off between the advantages afforded by the use of integrated circuitry and the loss of performance if the available IC products do not exactly meet the desired specifications must be considered by equipment designers. It often leads to the use of discrete circuitry in sensitive applications. Once again, the improvements afforded by technology have mitigated this problem somewhat. The design and layout of ICs has been made more affordable by computer-based aids. Interaction between the computer aided design (CAD) software and modern chip masking hardware has also decreased the masking costs. As these development costs decrease, we are seeing an increase in the number of specialty chips that are being marketed and also of small companies that are created to fill the needs of the niche markets.

### Common Types of Linear Integrated Circuits

The three main advantages of designing a circuit into an IC are to take advantage of the matched characteristics of like components, to make highly complex circuitry more economical, and to miniaturize the circuit. As a particular technology becomes popular, a rash of integrated circuitry is developed to service that technology. A recent example is the cellular telephone industry. Cellular phones have become so pervasive that IC manufacturers have developed a large number of devices targeted toward this technology. Space limitations prohibit a comprehensive listing of all analog special function ICs but a sampling of those that are more useful in the radio field is presented.

#### Component Arrays

The most basic form of linear integrated circuit is the component array. The most common of these are the resistor, diode and transistor arrays. Though capacitor arrays are also possible, they are used less

often. Component arrays usually provide space saving but this is not the major advantage of these devices. They are the least densely packed of the integrated circuits, limited mainly by the number of off-chip connections needed. While it may be possible to place over a million transistors on a single semiconductor chip, individual access to these would require a total of three million pins and this is beyond the limits of practicability. More commonly, resistor and diode arrays contain from five to 16 individual devices and transistor arrays contain from three to six individual transistors. The advantage of these arrays is the very close matching of component values within the array. In a circuit that needs matched components, the component array is often a good method of obtaining this feature. The components within an array can be internally combined for special functions, such as termination resistors, diode bridges and Darlington pair transistors. A nearly infinite number of possibilities exists for these combinations of components and many of these are available in arrays.

#### Multivibrators

A *multivibrator* is a circuit that oscillates, usually with a square wave output in the audio frequency range. The frequency of oscillation is accurately controlled with the addition of appropriate values of external resistance and capacitance. The most common multivibrator in use today is the 555 (NE555 by Signetics [now Philips] or LM555 by National Semiconductor). This very simple eight-pin DIP device has a frequency range from less than one hertz to several hundred kilohertz. Such a device can also be used in *monostable* operation, where an input pulse generates an output pulse of a different duration, or in *astable* operation, where the device freely oscillates. Some other applications of a multivibrator are as a frequency divider, a delay line, a pulse width modulator and a pulse position modulator.

#### Operational Amplifiers

An *operational amplifier*, or *op amp*, is one of the most useful linear devices that has been developed in integrated circuitry. While it is possible to build an op amp with discrete components, the symmetry of this circuit requires a close match of many components and is more effective, and much easier, to implement in integrated circuitry. **Fig 8.43** shows a basic op-amp circuit. The op amp approaches a perfect analog circuit building block.

Ideally, an op amp has an infinite input impedance ( $Z_i$ ), a zero output impedance

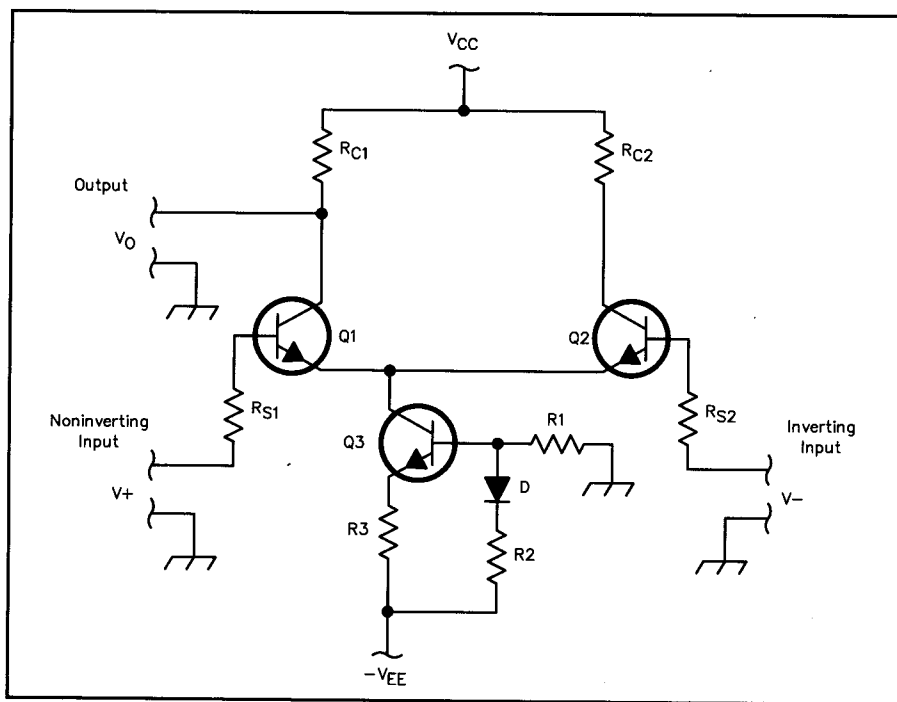

( $Z_O$ ) and an open loop voltage gain ( $A_V$ ) of infinity. Obviously, practical op amps do not meet these specifications, but they do come closer than most other types of amplifiers. An older op amp that is based on bipolar transistor technology, the LM324, has the following characteristics: guaranteed minimum CMRR of 65 dB, guaranteed minimum  $A_V$  of 25000, an input bias current (related to  $Z_i$ ) guaranteed to be below 250 nA ( $2.5 \times 10^{-7}$  A), output current capability (which determines  $Z_O$ )

guaranteed to be above 10 mA and a gain-bandwidth product of 1 MHz. The TL084, which is a pin compatible replacement for the LM324 but is made with both JFET and bipolar transistors, has a guaranteed minimum CMRR of 80 dB, an input bias current guaranteed to be below 200 pA ( $2.0 \times 10^{-10}$  A, almost 1000 times smaller than the LM324) and a gain-bandwidth product of 3 MHz. Philips has recently introduced the LMC6001 op amp with an input bias current of 25 fA ( $2.5 \times 10^{-14}$  A,

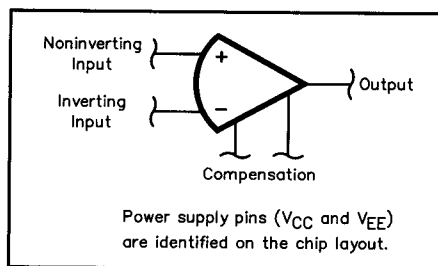

almost 10000 times smaller than the TL084). This is equivalent to 156 electrons entering the device every millisecond and corresponds to nearly infinite input impedance. Op amps can be customized to perform a large variety of functions by the addition of external components.

The typical op amp has three signal terminals (see Fig 8.44). There are two input terminals, the noninverting terminal marked with a + sign and the inverting terminal marked with a - sign. The output of the amplifier has a single terminal and all signal levels within the op amp float, which means they are not tied to a specific reference. Rather, the reference of the input signals becomes the reference for the output signal. In many circuits this reference level is ground. Older operational amplifiers have an additional two connections for *compensation*. To keep the amplifier from going into oscillation at very high gains (increase its stability) it is often necessary to place a capacitor across the compensation terminals. This also decreases the frequency response of the op amp. Most modern op amps are internally compensated and do not have separate pins to add compensation capacitance. Additional compensation can be attained by connecting a capacitor between the op amp output and the inverting input.

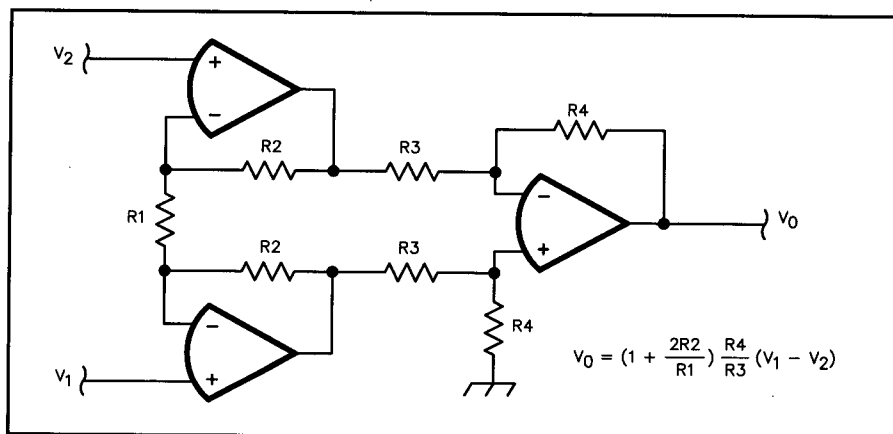

One of the major advantages of using an op amp is its very high common mode rejection ratio (CMRR). Since there are two input terminals to an op amp, anything that is common to both terminals will be subtracted from the signal during amplification. The CMRR is a measure of the effectiveness of this removal. High CMRR results from the symmetry between the circuit halves. The rejection of power-supply noise is also an important parameter of an op amp. This is attained similarly, since

**Fig 8.43** — Schematic of the components that make up an operational amplifier. Q1 and Q2 are matched emitter-coupled amplifiers. Q3 provides a constant current source. The symmetry of this device makes the matching of the components critical to its operation. This is why this circuit is usually implemented only in integrated circuitry. This simple op amp design has a large dc offset voltage at the output. Most practical designs include a level-shifting circuit, so the output voltage can exist near ground potential.

**Fig 8.44** — Operational amplifier schematic symbol. The terminal marked with a + sign is the noninverting input. The terminal marked with a - sign is the inverting input. The output is to the right. On some op amps, external compensation is needed and leads are provided, pictured here below the device. Usually, the power supply leads are not shown on the op amp itself but are specified in the data sheet.

**Fig 8.45** — Operational amplifiers arranged as an instrumentation amplifier. The balanced and cascaded series of op amps work together to perform differential amplification with good common-mode rejection and very high input impedance (no load resistor required) on both the inverting ( $V_1$ ) and noninverting ( $V_2$ ) inputs.

the power supply is connected equally to both symmetrical halves of the op amp circuit. Thus, the power supply rejection ratio (PSRR) is similar to the CMRR and is often specified on the device data sheets.

Just as the symmetry of the transistors making up an op amp leads to a device with high values of  $Z_i$ ,  $A_v$  and CMRR and a low value of  $Z_o$ , a symmetric combination of op amps is used to further improve these parameters. This circuit, shown in Fig 8.45, is called an instrumentation amplifier.

The op amp is capable of amplifying signals to levels limited mainly by the power supplies. Two power supplies are required, thus defining the range of signal voltages that can be processed. In most op amps the signal levels that can be handled are less than the power supply limits (rails), usually one or two diode drops (0.7 V or 1.4 V) away from each rail. Thus, if an op amp has 15 V connected as its upper rail (usually denoted  $V^+$ ) and ground connected as its lower rail ( $V^-$ ), input signals can be amplified to be as high as 13.6 V and as low as 1.4 V in most amplifiers. Any values that would be amplified beyond those limits are clamped (output voltages that should be 1.4 V or less appear as 1.4 V and those that should be 13.6 V or more appear as 13.6 V). This clamping action is illustrated in Fig 8.1. Recently, op amps have been developed to handle signals all the way out to the power supply rails (for example, the MAX406, from Maxim Integrated Products).

If a signal is connected to the input terminals of an op amp, it will be amplified as much as the device is able (up to  $A_v$ ), and

will probably grow so large that it clamps, as described above. Even if such large gains are desired,  $A_v$  varies from one device to the next and cannot be guaranteed. In most applications the op amp gain is limited to a more reasonable value and this is usually realized by providing a negative feedback path from the output terminal to the inverting input terminal. The *closed loop gain* of an op amp depends solely on the values of the passive components used to form the loop (usually resistors and, for frequency-selective circuits, capacitors). Some examples of different circuit configurations that manipulate the loop gain follow.

The op amp is often used as either an inverting or a noninverting amplifier. Accurate amplification can be achieved with just two resistors: the feedback resistor,  $R_f$ , and the input resistor,  $R_i$  (see Fig 8.46). If connected in the noninverting configuration, the input signal is connected to the noninverting terminal. The feedback resistor is connected between the output and the inverting terminal. The inverting terminal is connected to  $R_i$ , which is connected to ground. The gain of this configuration is:

$$\frac{V_o}{V_n} = \left( 1 + \frac{R_f}{R_i} \right) \quad (15)$$

where:

$V_o$  is the output voltage, and

$V_n$  is the input voltage to the noninverting terminal.

In the inverting configuration, the input signal ( $V_i$ ) is connected through  $R_i$  to the inverting terminal. The feedback resistor is again connected between the inverting terminal and the output. The noninverting terminal can be connected to ground or to a dc offset voltage. The gain of this circuit is:

$$\frac{V_o}{V_i} = - \frac{R_f}{R_i} \quad (16)$$

where  $V_i$  represents the voltage input to  $R_i$ .

The negative sign in equation 16 indicates that the signal is inverted. For ac signals, inversion represents a  $180^\circ$  phase shift. The gain of the noninverting op amp can vary from a minimum of  $\times 1$  to the maximum of which the device is capable. The gain of the inverting op amp configuration can vary from a minimum of  $\times 0$  (gains from  $\times 0$  to  $\times 1$  attenuate the signal while gains of  $\times 1$  and higher amplify the signal) to the maximum that the device is capable of, as indicated by  $A_v$  for dc signals, or the gain-bandwidth product for ac signals. Both parameters are usually specified in the manufacturer's data sheet.

A voltage follower is a type of op amp that is commonly used as a buffer stage. The voltage follower has the input connected directly to the noninverting terminal and the output connected directly to the inverting terminal (Fig 8.47). This configuration has unity gain and provides the maximum possible input impedance and the minimum possible output impedance of which the device is capable.

A *differential amplifier* is a special application of an operational amplifier (see Fig 8.48). It amplifies the difference between two analog signals and is very useful to cancel noise under certain conditions. For instance, if an analog signal and a reference signal travel over the same cable they may pick up noise, and it is likely that both signals will have the same amount of noise. When the differential amplifier subtracts them, the signal will be unchanged but the noise will be completely removed, within the limits of the CMRR. The equation for differential amplifier operation is

$$V_o = \frac{R_f}{R_i} \left[ \frac{1}{\frac{R_n}{R_g} + 1} \left( \frac{R_i}{R_f} + 1 \right) V_n - V_i \right] \quad (17)$$

**Fig 8.47 — Voltage follower.** This operational amplifier circuit makes a nearly ideal buffer with a voltage gain of about one, extremely high input impedance and extremely low output impedance.

**Fig 8.48 — Differential amplifier.** This operational amplifier circuit amplifies the difference between the two input signals.

**Fig 8.46 — Operational amplifier circuits.** (A) Noninverting configuration. (B) Inverting configuration.

which, if the ratios  $\frac{R_i}{R_f}$  and  $\frac{R_n}{R_g}$  are equal, simplifies to

$$V_o = \frac{R_f}{R_i} (V_n - V_i) \quad (18)$$

Note that the differential amplifier response is identical to the inverting op amp response (equation 16) if the voltage source to the noninverting terminal is equal to zero. If the voltage source to the inverting terminal ( $V_i$ ) is set to zero, the analysis is a little more complicated but it is possible to derive the noninverting op amp response (equation 15) from the differential amplifier response by taking into account the influence of  $R_n$  and  $R_g$ .

DC offset is an important consideration in op amps for two reasons. Actual op amps have a slight mismatch between the inverting and noninverting terminals that can become a substantial dc offset in the output, depending on the amplifier gain. The op amp output must not be too close to the clamping limits or distortion will occur. Introduction of a small dc correction voltage to the noninverting terminal is sometimes used to apply an offset voltage that counteracts the internal mismatch and centers the signal in the rail-to-rail range.

The high input impedance of an op amp makes it ideal for use as a *summing amplifier*. In either the inverting or noninverting configuration, the single input signal can be replaced by multiple input signals that are connected together through series resistors, as shown in Fig 8.49. For the inverting summing amplifier, the gain of each input signal can be calculated individually using equation 16 and, because of the superposition property, the output becomes the sum of each input signal multiplied by its gain. In the noninverting configuration, the output is the gain times the weighted sum of the  $m$  different input signals:

$$V_n = V_{n1} \frac{R_{p1}}{R_1 + R_{p1}} + V_{n2} \frac{R_{p2}}{R_2 + R_{p2}} + \dots + V_{nm} \frac{R_{pm}}{R_m + R_{pm}} \quad (19)$$

where  $R_{pm}$  is the parallel resistance of all  $m$  resistors excluding  $R_m$ . For example, with three signals being summed,  $R_{p1}$  is the parallel combination of  $R_2$  and  $R_3$ .

Other combinations of summing and difference amplification can be realized with a single op amp. The analyses of such circuits use the standard op amp equations coupled with the principle of superposition.

A *voltage comparator* is another special form of an operational amplifier. It takes in two analog signals and provides a binary output that is true if the voltage of one signal is bigger than that of the other, and false if not. A standard operational amplifier can be made to act as a comparator by connecting the two voltages to the noninverting and inverting inputs with no input or feedback resistors. If the voltage of the noninverting input is higher than that of the inverting input, the output voltage will be clamped to the positive clamping limit. If the inverting input is at a higher potential than the noninverting input, the output voltage will be clamped to the negative clamping limit (although this is not necessarily a negative voltage, depending on the value of the lower rail). Some applications of a voltage comparator are a zero crossing detector, a signal squarer (which turns other cyclical wave forms into square waves) and a peak detector.

### Charge Coupled Devices

As the speed of integrated circuitry increases, it becomes possible to process some of the signals digitally while other processing occurs in analog form, all of this on the same IC chip. Such a chip is often called a *mixed modality* or *hybrid* chip (not to be confused with the hybrid circuitry discussed earlier). An example of this is the *charge coupled device (CCD)*. Pure digital analysis of signals requires digitization in two domains, namely the time sampling of a signal into individual packets and the amplitude sampling of each time packet into digital levels. CCDs perform time sampling but the time packets remain in analog form; they can take on any voltage value rather than a fixed number of discrete values. The CCD is often used to produce a delay filter. While most analog filters introduce some phase shift or delay into the signal, the relationship between the phase shift and the frequency is not always linear; different frequencies are delayed by different amounts of time. The goal of an ideal delay filter is to delay all parts of the signal by the same time. The CCD is used to realize this by sampling the signal, shifting the time packets through a series of capacitors and then reconstructing the continuous signal at the other end. The rate of shifting the time packets and the number of stages determines the amount of the delay. When originally introduced in the late 1970s, CCDs were described as bucket brigade devices (after the old fire fighting technique), where the buckets filled with signal packets are passed along the line until they are dumped at the end and recombined into an analog

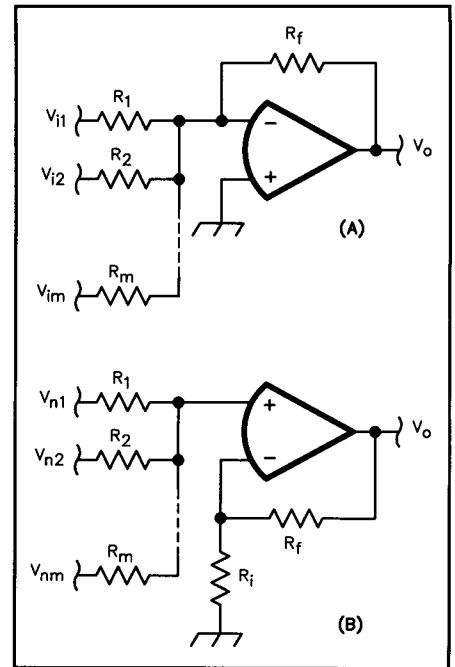

Fig 8.49 — Summing operational amplifier circuits. (A) Inverting configuration. (B) Noninverting configuration.

signal. These devices are simply constructed in an IC where each bucket is a MOS capacitor that is surrounded by two MOSFETs. When the transistors are biased to conduct, the charge moves from one bucket to the next and, while biased off, the charges are held in their capacitors. Very accurate filters, called *switched capacitor filters*, can be made with CCDs (see the **Filters** chapter).

A special form of CCD has also become quite popular in recent years, replacing the vidicon in modern camera circuitry. A two dimensional array of CCD elements has been developed with light sensitive semiconductor material; the charge that enters the capacitors is proportional to the amount of light incident on that location of the chip. The charges are held in their array of capacitors until shifted out, one horizontal line at a time, in a raster format. The CCD array mimics the operation of the vidicon camera and has many advantages. CCD response linearity across the field is superior to that of the vidicon. Very bright light at one location saturates the CCD elements only at that location rather than the blooming effect in vidicons where bright light spreads radially from the original location. CCD imaging elements do not suffer from image retention, which is another disadvantage of vidicon tubes.

### Balanced Mixers

The *balanced mixer* is a device with

many applications in modern radio transceivers (see the **Mixers, Modulation and Demodulation** chapter). Audio signals can be modulated onto a carrier or demodulated from the carrier with a balanced mixer. RF signals can be downconverted to intermediate frequency (IF) or IF can be upconverted to RF with a balanced mixer. This device is made with a bridge of four matched Schottky diodes and the necessary transformers packaged in a small metal, plastic or ceramic container. The consequence of unmatched diodes is poor isolation between the local oscillator (LO) and the two signals. IC mixers often use a "Gilbert cell" to provide LO isolation as high as  $-30$  dB at 500 MHz. The isolation improves with decreasing frequency.

### Receiver Subsystems

High performance ICs have been designed that make up complete receivers with the addition of only a few external components. Two examples that are very similar are the Motorola MC3363 and the Philips NE627. Both of these chips have all the active RF stages necessary for a double conversion FM receiver. The MC3363 has an internal local oscillator (LO) with varactor diodes that can generate frequencies up to 200 MHz,

although the rest of the circuit is capable of operating at frequencies up to 450 MHz with an external oscillator. The RF amplifier has a low noise factor and gives this chip a 0.3 mV sensitivity. The intermediate frequency stages contain limiter amplifiers and quadrature detection. The necessary circuitry to implement receiver squelch and zero crossing detection of FSK modulation is also present. The circuit also contains received signal strength ("S-meter") circuitry (RSSI). The input and output of each stage are also brought out of the chip for versatility. The audio signal out of this chip must be appropriately amplified to drive a low-impedance speaker. This chip can be driven with a dc power source from 2 to 7 V and it draws only 3 mA with a 2 V supply.

The Philips NE627 is a newer chip than the MC3363 and has better performance characteristics even though it has essentially the same architecture. Its LO can generate frequencies up to 150 MHz and external oscillator frequencies up to 1 GHz can be used. The chip has a 4.6 dB noise figure and 0.22 mV sensitivity. The circuit can be powered with a dc voltage between 4.5 and 8 V and it draws between 5.1 and 6.7 mA. This chip is also ESD hardened so it resists damage from elec-

trostatic discharges, such as from nearby lightning strikes.

The various stages in the receiver subsystem ICs are made available by connections on the package. There are two reasons that this is done. Filtering that is added between stages can be performed more effectively with inductors and crystal or ceramic filters, which are difficult to fabricate in integrated circuitry, so the output of one stage can be filtered externally before being fed to the next stage. It also adds to the versatility of the device. Filter frequencies can be customized for different intermediate frequencies. Stages can be used individually as well, so these devices can be made to perform direct conversion or single conversion reception or other forms of demodulation instead of FM.

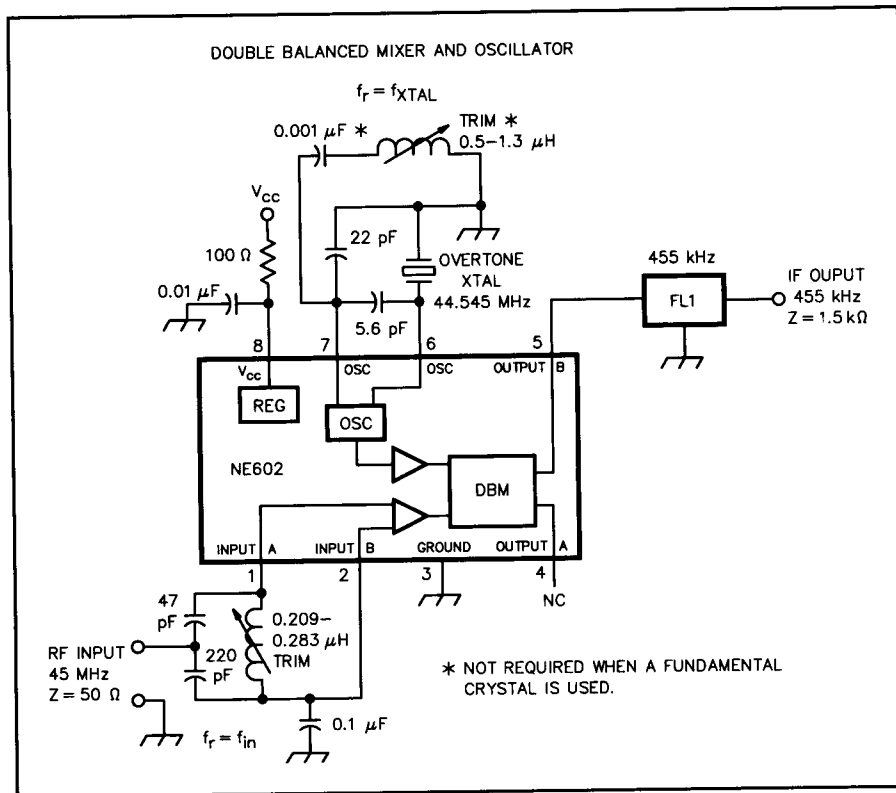

Older integrated circuits that are subsets of the receiver subsystems are popular. The NE602 contains one double balanced mixer and a local oscillator, along with voltage regulation and buffering (Fig 8.50). It contains almost everything required to construct a direct conversion receiver. Its small size, an 8 pin DIP, makes it more desirable for this purpose than using part of an MC3363, which is in a 24 pin DIP and is more expensive. The NE604 contains the IF amplifiers and quadrature detector that, together with two NE602s and an RF amplifier, could almost duplicate the functions of the MC3363 or the NE367.

### Transmitter Subsystems

Single chips are available to implement FM transmitters. One implementation is the Motorola MC2831A. This chip contains a mike preamplifier with limiting, a tone generator for CTCSS or AFSK, and a frequency modulator. It has an internal voltage controlled oscillator that can be controlled with a crystal or an LC circuit. This chip also contains circuitry to check the power supply voltage and produce a warning if it falls too low. Together with an FM receiver IC, an entire transceiver can be fabricated with very few parts.

### Monolithic Microwave Integrated Circuit

A class of bipolar IC that is capable of higher frequency responses is the *monolithic microwave integrated circuit* (MMIC). There is no formal definition of when an IC amplifier becomes an MMIC and, as the performance of IC devices improves, particularly MOS based devices, the distinction is becoming blurred. MMIC devices typically have predefined operating characteristics and require few external components. An example of an

**Fig 8.50 — The NE602 functional block diagram in circuit. This device contains a doubly balanced mixer, a local oscillator, buffers and a voltage regulator. This application uses the NE602 to convert an RF signal in a receiver to IF.**

MMIC is a fixed gain amplifier, the MSA0204 (Fig 8.51), which can deliver 12 dB of gain up to 1 GHz. More modern MMIC devices are being developed with bandwidths in the tens of GHz.

### Comparison of Analog Signal Processing Components

Analog signal processing deals with changing a signal to a desired form. Vacuum tubes, bipolar transistors, field-effect transistors and integrated circuitry perform similar functions, each with specific advantages and disadvantages. These are summarized here.

Of the four component types, vacuum tubes are physically the largest and require the most operating power. They have more limited life spans, usually because the heater filament burns out just as a light bulb does. Regardless of its use, a vacuum tube always generates heat. Miniaturization is difficult with vacuum tubes both because of their size and because of the need for air space around them for cooling. Vacuum tubes do have advantages, however. They are electrically robust. You need not be as concerned about static charges destroying vacuum tubes. A transmitter with vacuum tube finals usually has a variable matching network built in, and can be loaded into a higher SWR than one with semiconductor finals. Tubes are generally able to withstand the high voltages generated by reflections under high SWR conditions. They are not as easily damaged by short-term overloads or the electromagnetic pulses generated by lightning. The relatively high plate voltages mean that the plate current is lower for a given power output; thus power supplies do not need as high a current handling capability. Vacuum tubes are capable of considerable heat dissipation and many high power applications still use them. Special forms of vacuum tubes are also still used. Most video displays use CRTs, and microwave transmitting tubes are still common.

Bipolar transistors have many advantages over vacuum tubes. When treated properly they can have virtually unlimited life spans. They are relatively small and, if they do not handle high currents, do not generate much heat, improving miniaturization. They make excellent high-frequency amplifiers. Compared to MOSFET devices they are less susceptible to damage from electrostatic discharge. RF amplifiers designed with bipolar transistors in their finals generally include circuitry to protect the transistors from the high voltages generated by reflections under

high SWR conditions. Lightning strikes in the area (not direct hits) have been known to destroy all kinds of semiconductors, including bipolar transistors. Semiconductors have replaced almost all small-signal applications of tubes.

There are many performance advantages to FET devices, particularly MOSFETs. The extremely low gate currents allow the design of analog stages with nearly infinite input resistance. Signal distortion due to loading is minimized in this way. As these characteristics are improved by technology, we are seeing an increase in FET design at the expense of bipolar transistors.

The current trend in electronics is portability. Transceivers are decreasing in size and in their power requirements. Integrated circuitry has played a large part in this trend. Extremely large circuits have been designed with microscopic proportions. It is more feasible to use MOSFETs within an IC chip than as discrete components since the devices at risk are usually those that are connected to the outside world. It is not necessary to use electrostatic discharge protection circuitry on the gate of every MOSFET in an IC; only the ones that connect to the pins on the chip need this protection. This arrangement both improves the performance of the internal MOSFETs and decreases the circuit size even further. Semiconductors are slowly replacing the last tube applications. CCD chips have been so successful in video cameras that it is difficult to find an application for vidicon tubes. The liquid crystal displays (LCDs) in laptop computers have given considerable competition

to the CRT tube.

An important consideration in the use of analog components is the future availability of parts. At an ever increasing rate, as new components are developed to replace older technology, the older components are discontinued by the manufacturers and become unavailable for future use. This tends to be a fairly long term process but it is not unusual for a manufacturer to stop offering a component when demand for it falls. This has become evident with vacuum tubes, which are becoming more difficult to find and more expensive as fewer manufacturers produce them.

The major disadvantages of IC technology have been power handling capability, frequency response and noncustomized circuitry. These characteristics have improved at an amazing pace over recent years; it is a process that feeds itself. As ICs are improved they are used to make more powerful tools (such as computers and electronic test equipment) that are used in the design of further IC improvements. Entire transceivers are designed with just a few IC chips and the appropriate transistors for power amplification. The quiescent current draw of these devices has been reduced to the microampere level so they can operate effectively from small battery packs. The improved noise performance of circuitry has also decreased the need for high transmitter power, further decreasing the current requirements for these devices. If this trend continues, we should eventually see a near total switch to IC components with few discrete semiconductors and no vacuum tubes.

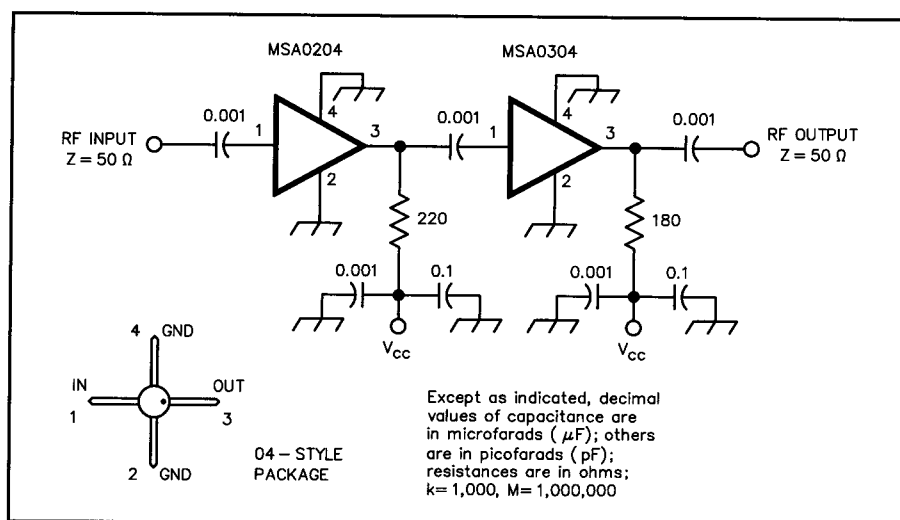

Fig 8.51 — The MSA0204 and MSA0304 MMICs in circuit. Both amplifiers have both input and output impedance of 50  $\Omega$  and a bandwidth of more than 2.5 GHz.

# Safety 9

**T**his chapter, written by James N. Woods, KC7FG, will focus on how to avoid potential hazards as we explore Amateur Radio and its many facets. We need to learn as much as possible about what could *go wrong* so we can avoid factors that might result in accidents. Amateur Radio activities are not inherently hazardous, but like many things in modern life, it pays to be informed. Stated another way, while we long to be creative and innovative, there is still the need to act responsibly. Safety begins with our attitude. Make it a habit to plan work carefully. Don't be the one to say, "I didn't think it could happen to me."

Having a good attitude about safety is not enough, however. We must be knowledgeable about common safety guidelines and follow them faithfully. Safety guidelines cannot possibly cover all situations, but if we approach each task with a measure of common sense, we should be able to work safely.

This chapter will address some of the most popular ham radio activities: building and erecting antennas, constructing radio equipment, and the testing and troubleshooting of our radios. Safety associated with emergency disaster opera-

tions are covered best by the agencies and organizations affected.

Although the RF, ac and dc voltages in most amateur stations pose a potentially grave threat to life and limb, common sense and knowledge of safety practices will help you avoid accidents. Building and operating an Amateur Radio station can be, and is for almost all amateurs, a perfectly safe pastime. Carelessness can lead to severe injury, or even death, however. The ideas presented here are only guidelines; it would be impossible to cover all safety precautions. *Remember: There is no substitute for common sense.*

Fires in well-designed electronic equipment are not common but are known to occur. Proper use of a suitable fire extinguisher can make the difference between a small fire with limited damage and loss of an entire home. Make sure you know the limitations of your extinguisher and the importance of reporting the fire to your local fire department immediately.

Several types of extinguishers are suitable for electrical fires. The multipurpose dry chemical or "ABC" type units are relatively inexpensive and contain a solid powder that is nonconductive. Avoid buying the smallest size; a 5-pound capac-

ity will meet most requirements in the home. ABC extinguishers are also the best choice for kitchen fires (the most common location of home fires). One disadvantage of this type is the residue left behind that might cause corrosion in electrical connectors. Another type of fire extinguisher suitable for energized electrical equipment is the carbon dioxide unit. CO<sub>2</sub> extinguishers require the user to be much closer to the fire, are heavy and difficult to handle, and are relatively expensive. For obvious reasons, water extinguishers are not suitable for fires in or near electronic equipment.

Involve your family in Amateur Radio. Having other people close by is always beneficial in the event that you need immediate assistance. Take the valuable step of showing family members how to turn off the electrical power to your equipment safely. Additionally, cardiopulmonary resuscitation (CPR) training can save lives in the event of electrical shock. Classes are offered in most communities. Take the time to plan with your family members exactly what action should be taken in the event of an emergency, such as electrical shock, equipment fire or power outage.

## Antenna and Tower Safety

Many amateurs enjoy building and installing their antennas and consider this one of the most enjoyable aspects of their hobby. Since antennas are generally outdoors, they are affected by such potentially hazardous weather as wind, ice and lightning. Learning about the potential hazards and how to do antenna work safely will pay dividends.

It is not feasible to discuss each type of antenna and tower in detail, so this section will include highlights you should

be aware of. For a full understanding of the specific hardware you will be working with, consult the manufacturer or supplier. If this is not feasible, discuss your antenna plans with a qualified engineer. The ARRL Volunteer Consulting Engineer program can steer you to a knowledgeable engineer. In addition, you may be required to obtain a building permit to erect a tower or antenna. This is a way to help ensure that the installation follows good practices and that the instal-

lation is safe. Wise amateurs realize that a review of drawings and site inspections are beneficial and can result in fewer problems in the future.

Towers must have a properly engineered support, both for the tower sections themselves as well as guy wire attachments. Sometimes towers are braced to buildings for added support. The Antenna Supports chapter of *The ARRL Antenna Book* covers this subject in greater detail. Towers are available commercially in both

guyed and self-supporting styles, and constructed of both steel and aluminum materials. Masts may be wood or metal. One popular and inexpensive mast used to support small antennas is the tubular mast often sold for TV antenna use. These come in telescoping sections, in heights from 20 to 50 ft.

Aluminum extension ladders are sometimes used for temporary antenna supports, such as at Field Day sites. One problem with this approach is the difficulty in holding down the bottom section while “walking up” the ladder. Do *not* try to erect this type of support alone.

Trees are sometimes pressed into service for holding one end of a wire antenna. When using slingshots or arrows to string up the antenna, be sure no one is in range before you launch.

### FACTORS TO CONSIDER WHEN SELECTING A TOWER

- A tower should not be installed in a position where it could fall onto a neighbor’s property.
- Towers have design load limitations. Make sure the tower you consider has the capacity to safely handle the antenna(s) you intend to install.
- The antenna must be located in such a position that *it cannot possibly tangle with power lines, both during normal operation or if the structure should fall.*
- Sufficient yard space must be available to position a guyed tower properly. A rule of thumb is that the guy anchors should be between 60% and 80% of the tower height in distance from the base of the tower.
- Provisions must be made to keep children from climbing the support.
- Always write to the manufacturer of the tower before purchasing and ask for installation specifications including guying data.
- Soil conditions at the tower site should

be investigated. The footings need to be designed around actual soil conditions, particularly on a rocky site.

### TOWER TIPS

- Beware of used towers. Have them professionally inspected and contact the manufacturer for installation criteria.
- Always follow manufacturer’s instructions, using only parts that are designed for the model you have.
- Never rush into projects. Consult the most experienced amateurs in your community for assistance, especially if you are new to tower installation.
- Check with your local building officials.
- Liability may be increased with a tower installation. Check with your insurer to ensure your coverage is adequate.
- Consider your neighbors and any hazards your antennas may present to them.
- Don’t let your installation become an “attractive nuisance.” Take steps to install positive barriers so your tower cannot easily be climbed by others.
- Use only the highest quality materials in your system.
- Make sure you have all the tools needed before starting. Some specialized tools (such as a gin pole) may be required.
- Never erect an antenna, tower or rotor during an electrical storm or rainstorm, or when lightning is a possibility.
- The assembly crew as well as those climbing the tower during erection must wear hard hats and use appropriate personal protective equipment including gloves, boots, climbing belt or harness. Don’t forget that lifelines are needed when the belt is unattached from the tower while moving.
- Be careful not to over-stress the tower when it is being assembled. The tower manufacturer can offer suggestions that will avoid jeopardizing the tower.
- Assign someone in the erection crew to monitor the use of safety equipment.

- After the tower is installed, keep the installation safe. Inspection and maintenance recommended by the tower’s manufacturer should be carefully followed.

- If making attachments to houses or installations on roofs, have a qualified person determine that the method is adequate and the loading conditions are satisfactory.
- Avoid metal ladders if there are any utility lines in the vicinity. Assume that any line is energized—including cable television and telephone lines.

### POWER LINES

Hundreds of people have been killed or seriously injured when attempting to install or dismantle antennas. In virtually all cases, the victim was aware of the hazards, including electrocution, but did not take the necessary steps to eliminate the risks. Never install antennas, towers and masts near power lines. How far away is considered safe? Towers and masts should be installed twice the height of the installation away from power lines. Every electrical wire must be considered dangerous. If the installation should contact power lines, you or those around you could be killed! If you have any questions about power lines, contact your electrical utility, city inspector or a qualified professional.

If, for some reason your tower starts to fall, get away from it immediately. If it touches energized lines it may be a lethal hazard if you are in contact with the antenna. If a coworker becomes energized, do not touch the person. Instead, use an insulated wooden pole to knock the energized conductor away from them. Don’t become a victim yourself! If the person is not breathing, immediately start CPR and call for emergency assistance.

Further information about tower safety appears in *The ARRL Antenna Book*.

# RF Radiation Safety

Although Amateur Radio is basically a safe activity, in recent years there has been considerable discussion and concern about the possible hazards of electromagnetic radiation (EMR), including both RF energy and power frequency (50-60 Hz) electromagnetic fields. Extensive research on this topic is underway in many countries. This section was prepared by members of the ARRL Committee of the Biological Effects on RF Energy ("Bio Effects" Committee) and coordinated by Wayne Overbeck, N6NB. It summarizes what is now known and offers safety precautions based on the research to date.

All life on Earth has adapted to survive in an environment of weak, natural low-frequency electromagnetic fields (in addition to the Earth's static geomagnetic field). Natural low-frequency EM fields come from two main sources: the sun, and thunderstorm activity. But in the last 100 years, man-made fields at much higher intensities and with a very different spectral distribution have altered this natural EM background in ways that are not yet fully understood. Much more research is needed to assess the biological effects of EMR.

Both RF and 60-Hz fields are classified as *nonionizing radiation* because the frequency is too low for there to be enough photon energy to ionize atoms. Still, at sufficiently high power densities, EMR poses certain health hazards. It has been known since the early days of radio that RF energy can cause injuries by heating body tissue. In extreme cases, RF-induced heating can cause blindness, sterility and other serious health problems. These heat-related health hazards are called *thermal effects*. But now there is mounting evidence that even at energy levels too low to cause body heating, EMR has observable biological effects, some of which may be harmful. These are *athermal effects*.

In addition to the ongoing research, much else has been done to address this issue. For example, the American National Standards Institute, among others, has recommended voluntary guidelines to limit human exposure to RF energy. And the ARRL has established the Bio Effects Committee, a committee of concerned medical doctors and scientists, serving voluntarily to monitor scientific research in the fields and to recommend safe practices for radio amateurs.

## THERMAL EFFECTS OF RF ENERGY

Body tissues that are subjected to very

high levels of RF energy may suffer serious heat damage. These effects depend upon the frequency of the energy, the power density of the RF field that strikes the body, and even on factors such as the polarization of the wave.

At frequencies near the body's natural resonant frequency, RF energy is absorbed more efficiently, and maximum heating occurs. In adults, this frequency usually is about 35 MHz if the person is grounded, and about 70 MHz if the person's body is insulated from the ground. Also, body parts may be resonant; the adult head, for example is resonant around 400 MHz, while a baby's smaller head resonates near 700 MHz. Body size thus determines the frequency at which most RF energy is absorbed. As the frequency is increased above resonance, less RF heating generally occurs. However, additional longitudinal resonances occur at about 1 GHz near the body surface.

Nevertheless, thermal effects of RF energy should not be a major concern for most radio amateurs because of the relatively low RF power we normally use and intermittent nature of most amateur transmissions. Amateurs spend more time listening than transmitting, and many amateur transmissions such as CW and SSB use low-duty-cycle modes. (With FM or RTTY, though, the RF is present continuously at its maximum level during each transmission.) In any event, it is rare for radio amateurs to be subjected to RF fields strong enough to produce thermal effects unless they are fairly close to an energized antenna or unshielded power amplifier. Specific suggestions for avoiding excessive exposure are offered later.

## ATHERMAL EFFECTS OF EMR

Nonthermal effects of EMR, on the other hand, may be of greater concern to most amateurs because they involve lower-level energy fields. In recent years, there have been many studies of the health effects of EMR, including a number that suggest there may be health hazards of EMR even at levels too low to cause significant heating of body tissue. The research has been of two basic types: epidemiological research, and laboratory research into biological mechanisms by which EMR may affect animals or humans.

Epidemiologists look at the health patterns of large groups of people using statistical methods. A series of epidemiological studies has shown that persons likely to have been exposed to higher lev-

els of EMR than the general population (such as persons living near power lines or employed in electrical and related occupations) have higher than normal rates of certain types of cancers. For example, several studies have found a higher incidence of leukemia and lymphatic cancer in children living near certain types of power transmission and distribution lines and near transformer substations than in children not living in such areas. These studies have found a risk ratio of about 2, meaning the chance of contracting the disease is doubled.

Parental exposures may also increase the cancer risk of their offspring. Fathers in electronic occupations who are also exposed to electronic solvents have children with an increased risk of brain cancer, and children of mothers who slept under electric blankets while pregnant have a 2.5 risk ratio for brain cancer.

Adults whose occupations expose them to strong 60-Hz fields (for example, telephone line splicers and electricians) have been found to have about four times the normal rate of brain cancer and male breast cancer. Another study found that microwave workers with 20 years of exposure had about 10 times the normal rate of brain cancer if they were also exposed to soldering fumes or electronic solvents. Typically, these chemical factors alone have risk ratios around 2.

Dr. Samuel Milham, a Washington state epidemiologist, conducted a large study of the mortality rates of radio amateurs, and found that they had statistically significant excess mortality from one type of leukemia and lymphatic cancer. Milham suggested that this could result from the tendency of hams to work in electrical occupations or from their hobby.

However, epidemiological research by itself is rarely conclusive. Epidemiology only identifies health patterns in groups—it does not ordinarily determine their cause. And there are often confounding factors: Most of us are exposed to many different environmental hazards that may affect our health in various ways. Moreover, not all studies of persons likely to be exposed to high levels of EMR have yielded the same results.

There has also been considerable laboratory research about the biological effects of EMR in recent years. For example, it has been shown that even fairly low levels of EMR can alter the human body's circadian rhythms, affect the manner in which cancer-fighting T lymphocytes function in the immune system, and alter the nature of the electrical and chemical signals com-

municated through the cell membrane and between cells, among other things.

Much of this research has focused on low-frequency magnetic fields, or on RF fields that are keyed, pulsed or modulated at a low audio frequency (often below 100 Hz). Several studies suggested that humans and animals can adapt to the presence of a steady RF carrier more readily than to an intermittent, keyed or modulated energy source. There is some evidence that while EMR may not directly cause cancer, it may sometimes combine with chemical agents to promote its growth or inhibit the work of the body's immune system.

None of the research to date conclusively proves that low-level EMR causes adverse health effects. Although there has been much debate about the meaning and significance of this research, many medical authorities now urge "prudent avoidance" of unnecessary exposure to moderate or high-level electromagnetic energy until more is known about this subject.

### Safe Exposure Levels

How much EM energy is safe? Scientists have devoted a great deal of effort to deciding upon safe RF-exposure limits. This is a very complex problem, involving difficult public health and economic considerations. The recommended safe levels have been revised downward several times in recent years—and not all scientific bodies agree on this question even today. A new Institute of Electrical and Electronic Engineers (IEEE) guideline for recommended EM exposure limits went into

effect in 1991 (see Bibliography). It replaced a 1982 American National Standards Institute guideline that permitted somewhat higher exposure levels. ANSI-recommended exposure limits before 1982 were higher still.

This new IEEE guideline recommends frequency-dependent and time-dependent maximum permissible exposure levels. Unlike earlier versions of the standard, the 1991 standard recommends different RF exposure limits in *controlled environments* (that is, where energy levels can be accurately determined and everyone on the premises is aware of the presence of EM fields) and in *uncontrolled environments* (where energy levels are not known or where some persons present may not be aware of the EM fields).

The graph in Fig 9.8 depicts the new IEEE standard. It is necessarily a complex graph because the standards differ not only for controlled and uncontrolled environments but also for electric fields (E fields) and magnetic fields (H fields). Basically, the lowest E-field exposure limits occur at frequencies between 30 and 300 MHz. The lowest H-field exposure levels occur at 100-300 MHz. The ANSI standard sets the maximum E-field limits between 30 and 300 MHz at a power density of 1 mW/cm<sup>2</sup> (61.4 V/m) in controlled environments—but at one-fifth that level (0.2 mW/cm<sup>2</sup> or 27.5 V/m) in uncontrolled environments. The H-field limit drops to 1 mW/cm<sup>2</sup> (0.163 A/m) at 100-300 MHz in controlled environments and 0.2 mW/cm<sup>2</sup> (0.0728 A/m) in uncontrolled environments. Higher power den-

sities are permitted at frequencies below 30 MHz (below 100 MHz for H fields) and above 300 MHz, based on the concept that the body will not be resonant at those frequencies and will therefore absorb less energy.

In general, the IEEE guideline requires averaging the power level over time periods ranging from 6 to 30 minutes for power-density calculations, depending on the frequency and other variables. The ANSI exposure limits for uncontrolled environments are lower than those for controlled environments, but to compensate for that the guideline allows exposure levels in those environments to be averaged over much longer time periods (generally 30 minutes). This long averaging time means that an intermittently operating RF source (such as an Amateur Radio transmitter) will show a much lower power density than a continuous-duty station for a given power level and antenna configuration.

Time averaging is based on the concept that the human body can withstand a greater rate of body heating (and thus, a higher level of RF energy) for a short time than for a longer period. However, time averaging may not be appropriate in considerations of nonthermal effects of RF energy.

The IEEE guideline excludes any transmitter with an output below 7 W because such low-power transmitters would not be able to produce significant whole-body heating. (However, recent studies show that hand-held transceivers often produce power densities in excess of the

Fig 9.8—1991 RF protection guidelines for body exposure of humans. It is known officially as the "IEEE Standard for Safety Levels with Respect to Human Exposure to Radio Frequency Electromagnetic Fields, 3 kHz to 300 GHz."

IEEE standard within the head.)

There is disagreement within the scientific community about these RF exposure guidelines. The IEEE guideline is still intended primarily to deal with thermal effects, not exposure to energy at lower levels. A growing number of researchers now believe athermal effects should also be taken into consideration. Several European countries and localities in the United States have adopted stricter standards than the recently updated IEEE standard.

Another national body in the United States, the National Council for Radiation Protection and Measurement (NCRP), has also adopted recommended exposure guidelines. NCRP urges a limit of 0.2 mW/cm<sup>2</sup> for nonoccupational exposure in the 30-300 MHz range. The NCRP guideline differs from IEEE in two notable ways: It takes into account the effects of modulation on an RF carrier, and it does not exempt transmitters with outputs below 7 W.

### Low-Frequency Fields

Recently, much concern about EMR has focused on low-frequency energy rather than RF. Amateur Radio equipment can be a significant source of low-frequency magnetic fields, although there are many other sources of this kind of energy in the typical home. Magnetic fields can be measured relatively accurately with inexpensive 60-Hz dosimeters that are made by several manufacturers.

**Table 9.1** shows typical magnetic field intensities of Amateur Radio equipment and various household items. Because these fields dissipate rapidly with distance, "prudent avoidance" would mean staying perhaps 12 to 18 inches away from most Amateur Radio equipment (and 24 inches from power supplies with 1-kW RF amplifiers) whenever the ac power is turned on. The old custom of leaning over a linear amplifier on a cold winter night to keep warm may not be the best idea!

There are currently no national standards for exposure to low-frequency fields. However, epidemiological evidence suggests that when the general level of 60-Hz fields exceeds 2 milligauss, there is an increased cancer risk in both domestic environments and industrial environments. Typical home environments (not close to appliances or power lines) are in the range of 0.1-0.5 milligauss.

### Determining RF Power Density

Unfortunately, determining the power density of the RF fields generated by an amateur station is not as simple as measuring low-frequency magnetic fields. Al-

though sophisticated instruments can be used to measure RF power densities quite accurately, they are costly and require frequent recalibration. Most amateurs don't have access to such equipment, and the inexpensive field-strength meters that we do have are not suitable for measuring RF power density. The best we can usually do is to estimate our own RF power density based on measurements made by others or, given sufficient computer programming skills, use computer modeling techniques.

**Table 9.2** shows a sampling of measurements made at Amateur Radio stations by the Federal Communications Commission and the Environmental Protection Agency in 1990. As this table indicates, a good antenna well removed from inhabited

areas poses no hazard under any of the various exposure guidelines. However, the FCC/EPA survey also indicates that amateurs must be careful about using indoor or attic-mounted antennas, mobile antennas, low directional arrays or any other antenna that is close to inhabited areas, especially when moderate to high power is used.

Ideally, before using any antenna that is in close proximity to an inhabited area, you should measure the RF power density. If that is not feasible, the next best option is make the installation as safe as possible by observing the safety suggestions listed in **Table 9.3**.

It is also possible, of course, to calculate the probable power density near an antenna using simple equations. However,

**Table 9.1**

### Typical 60-Hz Magnetic Fields Near Amateur Radio Equipment and AC-Powered Household Appliances

Values are in milligauss.

Item	Field	Distance
Electric blanket	30-90	Surface
Microwave oven	10-100 1-10	Surface 12"
IBM personal computer	5-10 0-1	Atop monitor 15" from screen
Electric drill	500-2000	At handle
Hair dryer	200-2000	At handle
HF transceiver	10-100 1-5	Atop cabinet 15" from front
1-kW RF amplifier	80-1000 1-25	Atop cabinet 15" from front

(Source: measurements made by members of the ARRL Bio Effects Committee)

**Table 9.2**

### Typical RF Field Strengths Near Amateur Radio Antennas

A sampling of values as measured by the Federal Communications Commission and Environmental Protection Agency, 1990

Antenna Type	Freq (MHz)	Power (W)	E Field (V/m)	Location
Dipole in attic	14.15	100	7-100	In home
Discone in attic	146.5	250	10-27	In home
Half sloper	21.5	1000	50	1 m from base
Dipole at 7-13 ft	7.14	120	8-150	1-2 m from earth
Vertical	3.8	800	180	0.5 m from base
5-element Yagi at 60 ft	21.2	1000	10-20 14	In shack 12 m from base
3-element Yagi at 25 ft	28.5	425	8-12	12 m from base
Inverted V at 22-46 ft	7.23	1400	5-27	Below antenna
Vertical on roof	14.11	140	6-9 35-100	In house At antenna tuner
Whip on auto roof	146.5	100	22-75 15-30 90	2 m from antenna In vehicle Rear seat
5-element Yagi at 20 ft	50.1	500	37-50	10 m from antenna

such calculations have many pitfalls. For one, most of the situations in which the power density would be high enough to be of concern are in the near field—an area roughly bounded by several wavelengths of the antenna. In the near field, ground interactions and other variables produce power densities that cannot be determined by simple arithmetic.

Computer antenna-modeling programs such as MININEC or other codes derived from NEC (Numerical Electromagnetics Code) are suitable for estimating RF magnetic and electric fields around amateur

antenna systems. (See the **Propagation** chapter for more information about MININEC.) And yet, these too have limitations. Ground interactions must be considered in estimating near-field power densities. Also, computer modeling is not sophisticated enough to predict “hot spots” in the near field—places where the field intensity may be far higher than would be expected.

Intensely elevated but localized fields often can be detected by professional measuring instruments. These “hot spots” are often found near wiring in the shack and

metal objects such as antenna masts or equipment cabinets. But even with the best instrumentation, these measurements may also be misleading in the near field.

One need not make precise measurements or model the exact antenna system, however, to develop some idea of the relative fields around an antenna. Computer modeling using close approximations of the geometry and power input of the antenna will generally suffice. Those who are familiar with MININEC can estimate their power densities by computer modeling, and those who have access to professional power-density meters can make useful measurements.

While our primary concern is ordinarily the intensity of the signal radiated by an antenna, we should also remember that there are other potential energy sources to be considered. You can also be exposed to RF radiation directly from a power amplifier if it is operated without proper shielding. Transmission lines may also radiate a significant amount of energy under some conditions.

## FURTHER RF EXPOSURE SUGGESTIONS

Potential exposure situations should be taken seriously. Based on the FCC/EPA measurements and other data, the “RF awareness” guidelines of Table 9.3 were developed by the ARRL Bio Effects Committee. A longer version of these guidelines, along with a complete list of references, appeared in a *QST* article by Ivan Shulman, MD, WC2S (see Bibliography).

In addition, *QST* carries information regarding the latest developments for RF safety precautions and regulations at the local and federal levels.

**Table 9.3**

### RF Awareness Guidelines

These guidelines were developed by the ARRL Bio Effects Committee, based on the FCC/EPA measurements of Table 9.2 and other data.

- Although antennas on towers (well away from people) pose no exposure problem, make certain that the RF radiation is confined to the antennas' radiating elements themselves. Provide a single, good station ground (earth), and eliminate radiation from transmission lines. Use good coaxial cable, not open-wire lines or end-fed antennas that come directly into the transmitter area.
- No person should ever be near any transmitting antenna while it is in use. This is especially true for mobile or ground-mounted vertical antennas. Avoid transmitting with more than 25 W in a VHF mobile installation unless it is possible to first measure the RF fields inside the vehicle. At the 1-kW level, both HF and VHF directional antennas should be at least 35 ft above inhabited areas. Avoid using indoor and attic-mounted antennas if at all possible.
- Don't operate high-power amplifiers with the covers removed, especially at VHF/UHF.
- In the UHF/SHF region, never look into the open end of an activated length of waveguide or point it toward anyone. Never point a high-gain, narrow-bandwidth antenna (a paraboloid, for instance) toward people. Use caution in aiming an EME (moonbounce) array toward the horizon; EME arrays may deliver an effective radiated power of 250,000 W or more.
- With hand-held transceivers, keep the antenna away from your head and use the lowest power possible to maintain communications. Use a separate microphone and hold the rig as far away from you as possible.
- Don't work on antennas that have RF power applied.
- Don't stand or sit close to a power supply or linear amplifier when the ac power is turned on. Stay at least 24 inches away from power transformers, electrical fans and other sources of high-level 60-Hz magnetic fields.

## Other Hazards in the Ham Shack

### CHEMICALS

We can't seem to live without the use of chemicals, even in the electronics age. A number of substances are used everyday by amateurs without causing ill effects. A sensible approach is to become knowledgeable of the hazards associated with the chemicals we use in our shack and then treat them with respect.

A few key suggestions:

- Read the information that accompanies the chemical and follow the manufacturer's recommended safety practices. If you would like more information than is printed on the label, ask for a material safety data sheet.

- Store chemicals properly away from sunlight and sources of heat. Provide security so they won't fall off the shelf. Secure them so that children and untrained persons will not gain access.
- Always keep containers labeled so there is no confusion about the contents. Use the container in which the chemical was purchased.
- Handle chemicals carefully to avoid spills.
- Clean up any spills or leaks promptly but don't overexpose yourself in the process. Dispose of chemicals in accordance with local and/or state regulations—not in the sink or storm sewer! Your city waste

plant operator or fire department can explain disposal procedures in your community. The best solution is to use all of the chemical if at all possible. Buy only the amount you will need.

- Always use recommended personal protective equipment (such as gloves, face shield, splash goggles and aprons).
- If corrosives (acids or caustics) are splashed on you *immediately* rinse with cold water for a minimum of 15 minutes to flush the skin thoroughly. If splashed in the eyes, direct a gentle stream of cold water into the eyes for at least 15 minutes. Gently lift the eyelids so trapped liquids can be flushed completely. Start

flushing before removing contaminated clothing. Seek professional medical assistance. It is unwise to work alone since people splashed with chemicals need the calm influence of another person.

- Food and chemicals don't mix. Keep food, drinks and cigarettes *away* from areas where chemicals are used and don't bring your chemicals to places where you eat.

**Table 9.4** summarizes the uses and hazards of chemicals used in the ham shack. It includes preventive measures that can minimize risk.

## ERGONOMICS

Ergonomics is a term that loosely means "fitting the work to the person." If tools

and equipment are designed about what people can accommodate, the results will be much more satisfactory. For example, in the 1930s research was done in telephone equipment manufacturing plants because use of long-nosed pliers for wiring switchboards required considerable force at the end of the hand's range of motion. A simple tool redesign resolved this issue. Considerable attention has been focused on ergonomics in recent years because we have come to realize that long periods of time spent in unnatural positions can lead to repetitive-motion illness. Much of this attention has been focused on people whose job tasks have required them to operate video display terminals (VDTs). While most Amateur Radio operators do

not devote as much time to their hobby as they might in a full-time job, it does make sense to consider comfort and flexibility when choosing furniture and arranging it in the shack or workshop. Adjustable height chairs are available with air cylinders to serve as a shock absorber. Footrests might come in handy if the chair is so high that your feet cannot support your lower leg weight. The height of tables and keyboards often is not adjustable.

Placement of VDT screens should take into consideration the reflected light coming from windows. It is always wise to build into your sitting sessions time to walk around and stimulate blood circulation. Your muscles are less likely to stiffen, while the flexibility in your joints

**Table 9.4**

### Properties and Hazards of Chemicals often used in the Shack or Workshop

<i>Generic Chemical Name</i>	<i>Purpose or Use</i>	<i>Hazards</i>	<i>Ways to Minimize Risks</i>
Lead-tin solder	Bonding electrical components	<ul style="list-style-type: none"> <li>•Lead exposure (mostly from hand contact)</li> <li>•Flux exposure (inhalation)</li> </ul>	<ul style="list-style-type: none"> <li>•Always wash hands after soldering or touching solder.</li> <li>•Use good ventilation.</li> </ul>
Isopropyl alcohol	Flux remover	<ul style="list-style-type: none"> <li>•Dermatitis (skin rash)</li> <li>•Vapor inhalation</li> <li>•Fire hazard</li> </ul>	<ul style="list-style-type: none"> <li>•Wear molded gloves suitable for solvents.</li> <li>•Use good ventilation and avoid aerosol generation.</li> <li>•Use good ventilation, limit use to small amounts, keep ignition sources away, dispose of rags only in tightly sealed metal cans.</li> </ul>
Freons	Circuit cooling and general solvent	<ul style="list-style-type: none"> <li>•Vapor inhalation</li> <li>•Dermatitis</li> </ul>	<ul style="list-style-type: none"> <li>•Use adequate ventilation.</li> <li>•Wear molded gloves suitable for solvents.</li> </ul>
Phenols	Enameled wire stripper	Strong skin corrosive	Avoid skin contact; wear suitable molded gloves.
Beryllium oxide	Ceramic insulator which can conduct heat well	Toxic when in fine dust form and inhaled	Avoid grinding, sawing or reducing to dust form.
Beryllium metal	Lightweight metal, often alloyed with copper.	Same as beryllium oxide	Avoid grinding, sawing, welding, or reducing to dust. Contact supplier for special procedures.
Various paints	Finishing	<ul style="list-style-type: none"> <li>•Exposures to solvents</li> <li>•Exposures to sensitizers (especially urethane paint)</li> <li>•Exposure to toxic metals (lead, cadmium, chrome, and so on) in pigments</li> <li>•Fire hazard (especially when spray painting)</li> </ul>	<ul style="list-style-type: none"> <li>•Adequate ventilation; use respirator when spraying.</li> <li>•Adequate ventilation and use respirator. Contact supplier for more info.</li> <li>•Adequate ventilation and use respirator. Contact supplier for more info.</li> <li>•Adequate ventilation; control of residues; eliminate ignition sources.</li> </ul>
Ferric chloride	Printed circuit board etchant	Skin and eye contact	Use suitable containers; wear splash goggles and molded gloves suitable for acids.
Ammonium persulphate and mercuric chloride	Printed circuit board etchants	Skin and eye contact	Use suitable containers; wear splash goggles and molded gloves suitable for acids.
Epoxy resins	General purpose cement or paint	Dermatitis and possible sensitizer	Avoid skin contact. Mix only amount needed.
Sulfuric acid	Electrolyte in lead-acid batteries	<ul style="list-style-type: none"> <li>•Strong corrosive when on skin or eyes.</li> <li>•Will release hydrogen when charging (fire, explosion hazard).</li> </ul>	Always wear splash goggles and molded plastic gloves (PVC) when handling. Keep ignition sources away from battery when charging. Provide adequate ventilation.

can be enhanced by moving around.

Selection of hand tools is another area where there are choices to make that may affect how comfortable you will be while working in your shack. Look for screwdrivers with pliable grips. Take into account how heavy things are before picking them up—your back will thank you.

## ENERGIZED CIRCUITS

Working with energized circuits can be very hazardous since our senses cannot directly detect dangerous voltages. The first thing we should ask ourselves when faced with troubleshooting, aligning or other “live” procedures is, “Is there a way to reduce the hazard of electrical shock? Here are some ways of doing just that.

1. If at all possible, troubleshoot with an ohmmeter. With a reliable schematic diagram and careful consideration of how various circuit conditions may reflect resistance readings, it will often be unnecessary to do live testing.

2. Keep a fair distance from energized circuits. What is considered “good practice” in terms of distance? The *National Electrical Code* specifies minimum working space about electric equipment in Sections 110-16 and 110-34, depending on the voltage level. The principle here is that a person doing live work needs adequate space so they are not forced to be dangerously close to energized equipment.

3. If you need to measure the voltage of a circuit, install the voltmeter with the power safely off, back up, and only then energize the circuit. Remove the power before disconnecting the meter.

4. If you are building equipment that has hinged or easily removable covers that could expose someone to an energized circuit, install interlock switches that safely remove power in the event that the enclosure was opened with the power still on. Interlock switches are generally not used if tools are required to open the enclosure.

5. Never assume that a circuit is at zero potential even if the power is switched off and the power cable disconnected. Capacitors can retain a charge for a considerable period of time. Bleeder resistors should be installed, but don’t assume they have bled off the voltage. Instead, after power is removed and disconnected use a “shorting stick” to ground all exposed conductors and ensure that voltage is not present. Avoid using screwdrivers, as this brings the amateur too close to the circuit and could ruin the screwdriver’s blade.

6. If you must hold a probe to take a measurement, always keep one hand in your pocket. As mentioned in the sidebar on the effects of high voltages, the worst path current could take through your body

## High-Voltage Hazards

### *What happens when someone receives an electrical shock?*

Electrocutions (fatal electric shocks) usually are caused by the heart ceasing to beat in its normal rhythm. This condition, called ventricular fibrillation, causes the heart muscles to quiver and stop working in a coordinated pattern, in turn preventing the heart from pumping blood.

The current flow that results in ventricular fibrillation varies between individuals but may be in the range of 100 mA to 500 mA. At higher current levels the heart may have less tendency to fibrillate but serious damage would be expected. Studies have shown 60-Hz alternating current to be more hazardous than dc currents. Emphasis is placed on application of cardiopulmonary resuscitation (CPR), as this technique can provide mechanical flow of some blood until paramedics can “restart” the heart’s normal beating pattern. Defibrillators actually apply a carefully controlled dc voltage to “shock” the heart back into a normal heartbeat. It doesn’t always work but it’s the best procedure available.

### *What are the most important factors associated with severe shocks?*

You may have heard that the current that flows through the body is the most important factor, and this is generally true. The path that current takes through the body affects the outcome to a large degree. While simple application of Ohm’s Law tells us that the higher the voltage applied with a fixed resistance, the greater the current that will flow. Most electrical shocks involve skin contact. Skin, with its layer of dead cells and often fatty tissues, is a fair insulator. Nonetheless, as voltage increases the skin will reach a point where it breaks down. Then the lowered resistance of deeper tissues allows a greater current to flow. This is why electrical codes refer to the term “high voltage” as a voltage above 600 V.

### *How little a voltage can be lethal?*

This depends entirely on the resistance of the two contact points in the circuit, the internal resistance of the body, and the path the current travels through the body. Historically, reports of fatal shocks suggest that as little as 24 V *could* be fatal under extremely adverse conditions. To add some perspective, one standard used to prevent serious electrical shock in hospital operating rooms limits leakage flow from electronic instruments to only 50  $\mu$ A due to the use of electrical devices and related conductors inside the patient’s body.

is from hand to hand since the flow would pass through the chest cavity.

7. Make sure someone is in the room with you and that they know how to remove the power safely. If they grab you with the power still on they will be shocked as well.

8. Test equipment probes and their leads must be in very good condition and rated for the conditions they will encounter.

9. Be wary of the hazards of “floating” (ungrounded) test equipment. A number of options are available to avoid this hazard. Contact your test equipment manufacturer for suggested procedures.

10. Ground-fault circuit interrupters can offer additional protection for stray currents that flow through the ground on 120-V circuits. Know their limitations. They cannot offer protection for the plate supply voltages in linear amplifiers, for example.

11. Older radio equipment containing ac/dc power supplies have their own hazards. If working on these live, use an isolation transformer, as the chassis may be connected directly to the hot or neutral power conductor.

12. Be aware of electrolytic capacitors that might fail if used outside their intended applications.

13. Replace fuses only with those having proper ratings.

## SUMMARY

The ideas presented in this chapter are intended to reinforce the concept that ham radio, like many other activities in modern life, does have certain risks. But by understanding the hazards and how to deal effectively with them, the risk can be minimized. Common-sense measures can go a long way to help us prevent accidents. Traditionally, amateurs are inventors and experimenting is a major part of our nature. But reckless chance-taking is never wise, especially when our health and well-being is involved. A healthy attitude toward doing things the right way will help us meet our goals and expectations.

# Real-World Component Characteristics

## 10

**W**hen is an inductor not an inductor? When it's a capacitor! This statement may seem odd, but it suggests the main message of this chapter. In the earlier chapters about **DC and AC Theory**, the basic components of electronic circuits were introduced. You saw that each has its own unique function to perform. For example, a capacitor stores energy in an electric field, a diode rectifies current and a battery provides voltage. All of these unique and different functions are necessary in order to build large circuits that perform useful tasks. The first part of this chapter, up to Low-Frequency Transistor Models, was written by Leonard Kay, KB2R.

As you may know from experience, these component pictures are *ideal*. That is, they are perfect mathematical pictures. An ideal component (or *element*) by definition behaves exactly like the mathematical equations that describe it, and *only* in that fashion. For example, an ideal capacitor passes a current that is equal to the capacitance  $C$  times the rate of change of the voltage across it. Period, end of sentence.

We call any other exhibited behavior either *nonideal*, *nonlinear* or *parasitic*. Nonideal behavior is a general term that covers any deviation from the theoretical picture. Ideal circuit elements are often linear: The graphs of their current versus voltage characteristics are straight lines when plotted on a suitable (Cartesian, rectangular) set of axes. We therefore call deviation from this behavior nonlinear: For example, as current through a resistor exceeds its power rating, the resistor heats

up and its resistance changes. As a result, a graph of current versus voltage is no longer a straight line.

When a component begins to exhibit properties of a different component, as when a capacitor allows a dc current to pass through it, we call this behavior *parasitic*. Nonlinear and parasitic behavior are both examples of nonideal behavior.

Much to the bane of experimenters and design engineers, ideal components exist only in electronics textbooks and computer programs. Real components, the ones we use, only approximate ideal components (albeit very closely in most cases).

*Real* diodes store minuscule energy in electric fields (junction capacitance) and magnetic fields (lead inductance); *real* capacitors conduct some dc (modeled by a parallel resistance), and real battery voltage is not *perfectly* constant (it may even decrease nonlinearly during discharge).

Knowing to what extent and under what conditions real components cease to behave like their ideal counterparts, and what can be done to account for these behaviors, is the subject of component or circuit *modeling*. In this chapter, we will explore how and why the real components behave differently from ideal components, how we can account those differences when analyzing circuits, how to select components to minimize, or exploit, nonideal behaviors and give a brief introduction to computer-aided circuit modeling.

Much of this chapter may seem intuitive. For example, you probably know that #20 hookup wire works just fine for

wiring many experimental circuits. When testing a circuit after construction, you probably don't even think about the voltage drops across those pieces of wire (you inherently assume that they have zero resistance). But, connect that same #20 wire directly across a car battery—with no *other* series resistance—and suddenly, the resistance of the wire *does* matter, and it changes—as the wire heats, melts and breaks—from a very small value to infinity!

### LUMPED VS DISTRIBUTED ELEMENTS

Most electronic circuits that we use everyday are inherently and mathematically considered to be composed of *lumped elements*. That is, we assume each component acts at a single point in space, and the wires that connect these lumped elements are assumed to be *perfect conductors* (with zero resistance and insignificant length). This concept is illustrated in **Fig 10.1**. These assumptions are perfectly reasonable for many applications, but they have limits. Lumped element models break down when:

- Circuit impedance is so low that the small, but non-zero, resistance in the wires is important. (A significant portion of the circuit power may be lost to heat in the conductors.)
- Operating frequency ( $f_0$ ) is high enough that the length of the connecting wires is a significant fraction ( $>0.1$ ) of the wave-

**Fig 10.1—The lumped element concept.** Ideally, the circuit at A is assumed to be as shown at B, where the components are isolated points connected by perfect conductors. Many components exhibit nonideal behavior when these assumptions no longer hold.

length. (Radiation from the conductors may be significant.)

- When transmission lines are used as conductors. (Their characteristic impedance is usually significant, and impedances connected to them are transformed as a function of the line length. See the **Transmission Lines** chapter for more information.)

Effects such as these are called *distributed*, and we talk of *distributed* elements or effects to contrast them to lumped elements.

To illustrate the differences between lumped and distributed elements, consider the two resistors in **Fig 10.2**, which are both 12 inches long. The resistor at A is a uniform rod of carbon—a battery anode, for example. The second “resistor” B is made of two 6-inch pieces of silver rod (or other highly conductive material), with a small resistor soldered between them. Now imagine connecting the two probes of an ohmmeter to each of the two resistors, as in the figure. Starting with the probes at the far ends, as we slide the probes toward the center, the carbon rod will display a constantly decreasing resistance on the ohmmeter. This represents a *distributed* resistance. On the other hand, the ohmmeter connected to the other

**Fig 10.2—A, distributed and B, lumped resistances. See text for discussion.**

**Fig 10.3—The effects of distributed resistance on the phase of a sinusoidal current. There is no phase delay between ends of a lumped element.**

12-inch “resistor” will display a constant resistance as long as one probe remains on each side of the small resistance. (Oh yes, as long as we neglect the resistance of the silver rods!) This represents a *lumped* resistance connected by perfect conductors.

Lumped elements also have the very

desirable property that they introduce no phase shift resulting from propagation delay through the element. (Although combinations of lumped elements can produce phase shifts by virtue of their  $R$ ,  $L$  and  $C$  properties.) Consider a lumped element that is carrying a sinusoidal current, as in **Fig 10.3A**. Since the element has negligible length, there is no phase difference in the current between the two sides of the element—*no matter how high the frequency*—precisely *because* the element length is negligible. If the physical length of the element were long, say  $0.25 \lambda$  as shown in **Fig 10.3B**, the current phase would *not* be the same from end to end. In this instance, the current is delayed 90 electrical degrees. The amount of phase difference depends on the circuit’s electrical length.

Because the relationship between the physical size of a circuit and the wavelength of an ac current present in the circuit will vary as the frequency of the ac signal varies, the ideas of lumped and distributed effects actually occupy two ends of a spectrum. At HF (30 MHz and below), where  $\lambda \geq 10$  m, the lumped element concept is almost always valid. In the UHF region and above, where  $\lambda \leq 1$  m and physical component size can represent a significant fraction of a wavelength, everything shows distributed effects to one degree or another. From roughly 30 to 300 MHz, problems are usually examined on a case-by-case basis.

Of course, if we could make resistors, capacitors, inductors and so on, very small, we could treat them as lumped elements at much higher frequencies.

Thanks to the advances constantly being made in microelectronic circuit fabrication, this is in fact possible. Commercial monolithic microwave integrated circuits (MMICs) in the early 1990s often use lumped elements that are valid up to 50 GHz. Since this frequency represents a wavelength of roughly 5 mm, this implies a component size of less than 0.5 mm.

## LOW-FREQUENCY COMPONENT MODELS

Every circuit element behaves nonideally in some respect and under some conditions. It helps to know the most common types of nonideal behavior so we can design and build circuits that will perform as intended under expected ranges of operating conditions. In the sections below, we will discuss the basic components in order of increasing common nonideal behavior. Please note that much of this section applies only through HF; the pecu-

liarities of VHF frequencies and above are discussed later in the chapter.

First, remember that some of the common limitations associated with real components are manufacturing concerns: tolerance and standard values. Tolerance is the measure of how much the actual value of a component may differ from its labeled value; it is usually expressed in percent. By convention, a “higher” (actually *closer*) tolerance component indicates a *lower* (lesser) percentage deviation and will usually cost more. For example, a 1-k $\Omega$  resistor with a 5% tolerance has an actual resistance of anywhere from 950 to 1050  $\Omega$ . When designing circuits be careful to include the effects of tolerance. More specific examples will be discussed below.

Keep standard values in mind because not every conceivable component value is available. For instance, if circuit calculations yield a 4,932- $\Omega$  resistor for a demanding application, there may be trouble. The nearest commonly available values are 4700  $\Omega$  and 5600  $\Omega$ , and they’ll be rated at 5% tolerance!

These two constraints prevent us from building circuits that do precisely what we wish. In fact, the measured performance of any circuit is the summation of the tolerances and temperature characteristics of all the components in both the circuit under test and the test equipment itself. As a result, most circuits are designed to operate within tolerances such as “up to a certain power” or “within this frequency range.” Some circuits have one or more adjustable components that can compensate for variations in others. These limitations are then further complicated by other problems.

## RESISTORS

Resistors are made in several different ways: carbon composition, carbon film, metal film, and wire wound. Carbon composition resistors are simply small cylinders of carbon mixed with various binding agents. Carbon is technically a semiconductor and can be *doped* with various impurities to produce any desired resistance. Most common everyday 1/2- and 1/4-W resistors are of this sort. They are moderately stable from 0 to 60  $^{\circ}\text{C}$  (their resistance increases above and below this temperature range). They are not inductive, but they are relatively noisy, and have relatively wide tolerances.

The other resistors exploit the fact that resistance is proportional to the length of the resistor and inversely proportional to its cross-sectional area:

**Wire-wound** resistors are made from wire, which is cut to the proper length and wound on a coil form (usually ceramic).

They are capable of handling high power; their values are very stable, and they are manufactured to close tolerances.

**Metal-film** resistors are made by depositing a thin film of aluminum, tungsten or other metal on an insulating substrate. Their resistances are controlled by careful adjustments of the width, length and depth of the film. As a result, they have very close tolerances. They are used extensively in surface-mount technology. As might be expected, their power handling capability is somewhat limited. They also produce very little electrical noise.

**Carbon film** resistors use a film of doped carbon instead of metal. They are not quite as stable as other film resistors and have wider tolerances than metal-film resistors, but they are still as good as (or better than) composition resistors.

Resistors behave much like their ideal through AF; lead inductance becomes a problem only at higher frequencies. The major departure from ideal behavior is their temperature coefficient (TC). The resistivity of most materials changes with temperature, and typical TC values for resistor materials are given in **Table 10.1**. TC values are usually expressed in parts-per-million (PPM) for each degree (centigrade) change from some nominal temperature, usually room temperature (77  $^{\circ}\text{F}$ /27  $^{\circ}\text{C}$ ). A positive TC indicates an increase in resistance with increasing temperature while a negative TC indicates a decreasing resistance. For example, if a 1000- $\Omega$  resistor with a TC of +300 PPM/ $^{\circ}\text{C}$  is heated to 50  $^{\circ}\text{C}$ , the *change* in resistance is  $300(50 - 27) = 6900$  PPM, yielding a new resistance of

$$1000 \left( 1 + \frac{6900}{1000000} \right) = 1006.9 \Omega$$

Carbon-film resistors are unique among the major resistor families because they alone have a negative temperature coefficient. They are often used to “offset” the thermal effects of the other components (see Thermal Effects, below).

If the temperature increase is small (less than 30-40  $^{\circ}\text{C}$ ), the resistance change with temperature is nondestructive—the resistor will return to normal when the temperature returns to its nominal value. Resistors that get too hot to touch, however, may be permanently damaged even if they appear normal. For this reason, be conservative when specifying power ratings for resistors. It’s common to specify a resistor rated at 200% to 400% of the expected dissipation.

Wire-wound resistors are essentially inductors used as resistors. Their use is therefore limited to dc or low-frequency ac applications where their reactance is

**Table 10.1**

### Temperature Coefficients for Various Resistor Compositions

1 PPM = 1 part per million = 0.0001%

Type	TC (PPM/ $^{\circ}\text{C}$ )
Wire wound	$\pm(30 - 50)$
Metal Film	$\pm(100 - 200)$
Carbon Film	+350 to -800
Carbon composition	$\pm 800$

negligible. Remember that this inductance will also affect switching transient waveforms, even at dc, because the component will act as an RL circuit.

As a rough example, consider a 1- $\Omega$ , 5-W wire-wound resistor that is formed from #24 wire on a 0.5-inch diam form. What is the approximate associated inductance? First, we calculate the length of wire using the wire tables:

$$L = \frac{R}{\Omega/\text{ft for \#24 wire}}$$

$$= \frac{1}{25.7 \Omega/1000 \text{ ft}} \approx 39 \text{ ft}$$

This yields a total of  $(39 \times 12 \text{ inches}) / (0.5 \pi \text{ inch/turn}) \approx 298$  turns, which further yields a coil length (for #24 wire close-wound at 46.9 turns per inch) of 6.3 inches, assuming a single-layer winding. Then, from the inductance formula for air coils in the **AC Theory** chapter, calculate

$$L = \frac{(0.5)^2 \times 298^2}{18 \times 0.5 + 40 \times 6.3} = 85 \mu\text{H}$$

Real wire-wound resistors have multiple windings layered over each other to minimize both size and parasitic inductance (by winding each layer in opposite directions, much of the inductance is canceled). If we assume a five-layer winding, the length is reduced to 1.8 inches and the inductance to approximately 17  $\mu\text{H}$ . If we want the inductive reactance to stay below 10% of the resistor value, then this resistor cannot be used above  $f = 0.1 / (2 \pi 17 \mu\text{H}) = 937 \text{ Hz}$ , or roughly 1 kHz.

Another exception to the rule that resistors are, in general, fairly ideal has to do with skin effect at RF. This will be discussed later in the chapter. **Fig 10.4** shows some more accurate circuit models for resistors at low frequencies. For a treatment of pure resistance theory, look at the **DC Theory** chapter.

## VOLTAGE AND CURRENT SOURCES

An ideal voltage source maintains a constant voltage across its terminals no

**Fig 10.4—Circuit models for resistors.** A is the ideal element. At B is the simple temperature-varying model for noninductive resistors. The wire-wound model with associated inductance is shown at C. For UHF or microwave designs, the model at C could be used with L representing lead inductance.

matter how much current is drawn. Consequently, it is capable of providing infinite power, for an infinite period of time. Similarly, an ideal current source provides a constant current through its terminals no matter what voltage appears across it. It, too, can deliver an infinite amount of power for an infinite time.

### Internal Resistance

As you may have learned through experience, *real* voltage and current sources—batteries and power supplies—do not meet these expectations. All real power sources have a finite *internal resistance* associated with them that limits the maximum power they can deliver.

We can model a real dc voltage source as a Thevenin-equivalent circuit of an *ideal* source in series with a resistance  $R_{\text{th}}$  that is equal to the source's internal resistance. Similarly, we can model a real dc current source as a Norton-equivalent circuit: an ideal current source in *parallel* with  $R_{\text{th}}$ . These two circuits shown in **Fig 10.5** are interchangeable through the relation

$$V_{\text{oc}} = I_{\text{sc}} \times R_{\text{th}} \quad (1)$$

Using these more realistic models, the maximum current that a real voltage source can deliver is seen to be  $I_{\text{sc}}$  and the maximum voltage is  $V_{\text{oc}}$ .

We can model sinusoidal voltage or current sources in much the same way, keeping in mind that the internal *impedance*,  $Z_{\text{th}}$ , for such a source may not be purely resistive, but may have a reactive component that varies with frequency.

### Battery Capacity and Discharge Curves

Batteries have a finite energy capacity as well as an internal resistance. Because of the physical size of most batteries, a convenient unit for measuring capacity is the *milliampere hour* (mAh) or, for larger

**Fig 10.5—Thevenin and Norton equivalent circuits for real voltage and current sources.**

units, the *ampere hour* (Ah). Note that these are units of charge (coulombs per second  $\times$  seconds) and thus they measure the total net charge that the battery holds on its plates when full.

A capacity of 1 mAh indicates that a battery, when fully charged, holds sufficient electrochemical energy to supply a steady current of 1 mA for 1 hour. If a battery discharges at a constant rate, you could estimate the useful time of a battery charge by the simple formula

$$\text{Time (hr)} = \frac{\text{capacity (mAh)}}{\text{current (mA)}} \quad (2)$$

In practice, however, the usable capacity of a rechargeable battery depends on the discharge *rate*, decreasing slightly as the current increases. For example, a 500 mAh nickel-cadmium (NiCd) battery may supply a current of 50 mA for almost 10 hours while maintaining a current of 500 mA for only 45 minutes.

The finite capacity of a battery does not *in itself* change the circuit model for a real source as shown in **Fig 10.5**. However, the chemistry of electrolytic cells, from which batteries are made, does introduce a minor, but significant, change. The voltage of a discharging battery does not stay constant, but slowly drops as time goes on. **Fig 10.6** illustrates the *discharge curve* for a typical NiCd rechargeable battery. For a given battery design, such curves are

**Fig 10.6—Discharge curve (terminal voltage vs percent capacity remaining) for a typical NiCd rechargeable battery.** Note the dramatic voltage drop near the end.

**Fig 10.7—The ideal parallel-plate capacitor.**

fairly reproducible and often used by battery-charging circuits to sense when a battery is fully charged or discharged.

### CAPACITORS

The ideal capacitor is a pair of infinitely large parallel metal plates separated by an insulating or *dielectric* layer, ideally a vacuum (see **Fig 10.7**). (For a discussion of pure capacitance see the **AC Theory** chapter.) For this case, the capacitance is given by

$$C = \frac{A \epsilon_r \epsilon_0}{d} \quad (3)$$

where

$C$  = capacitance, in farads

$A$  = area of plates, cm

$d$  = spacing of the plates, cm

$\epsilon_r$  = dielectric constant of the insulating material

$\epsilon_0$  = permittivity of free space,  
 $8.85 \times 10^{14}$  F/cm.

If the plates are not infinite, the actual capacitance is somewhat higher due to *end effect*. This is the same phenomenon that causes a dipole to resonate at a lower frequency if you place large insulators (which add capacitance) on the ends.

If we built such a capacitor, we would find that (neglecting the effects of quantum mechanics) it would be a perfect open circuit at dc, and it could be operated at whatever voltage we desire without breakdown.

## Leakage Conductance and Breakdown

If we use anything other than a vacuum for the insulating layer, even air, we introduce two problems. Because there are atoms between the plates, the capacitor will now be able to conduct a dc current. The magnitude of this *leakage current* will depend on the insulator quality, and the current is usually very small. Leakage current can be modeled by a resistance  $R_L$  in parallel with the capacitance (in the ideal case, this resistance is infinite).

In addition, when a high enough voltage is applied to the capacitor, the atoms of the dielectric will ionize due to the extremely high electric field and cause a large dc current to flow. This is *dielectric breakdown*, and it is destructive to the capacitor if the dielectric is ruined. To avoid dielectric breakdown, a capacitor has a *working voltage* rating, which represents the maximum voltage that can be permitted to develop across it.

## Dielectrics

The leakage conductance and breakdown voltage characteristics of a capacitor are strongly dependent on the composition and quality of the dielectric. Various materials are used for different reasons such as availability, cost, and desired capacitance range. In rough order of “best” to “worst” they are:

**Vacuum** Both fixed and variable vacuum capacitors are available. They are rated by their maximum working voltages (3 to 60 kV) and currents. Losses are specified as negligible for most applications.

**Air** An *air-spaced* capacitor provides the best commonly available approximation to the ideal picture. Since  $\epsilon_r = 1$  for air, air-dielectric capacitors are large when compared to those of the same value using other dielectrics. Their capacitance is very stable over a wide temperature range, leakage losses are low, and therefore a high  $Q$  can be obtained. They also can withstand high voltages. For these reasons (and ease of construction) most variable capacitors in tuning circuits are air-spaced.

**Plastic film** Capacitors with plastic film (polystyrene, polyethylene or Mylar) dielectrics are more expensive than paper capacitors, but have much lower leakage rates (even at high temperatures) and low TCs. Capacitance values are more stable than those of paper capacitors. In other respects, they have much the same characteristics as paper capacitors. Plastic-film variable capacitors are available.

**Mica** The capacitance of mica capacitors is very stable with respect to time, temperature and electrical stress. Leakage

and losses are very low. Values range from 1 pF to 0.1  $\mu$ F, with tolerances from 1 to 20%. High working voltages are possible, but they must be derated severely as operating frequency increases.

Silver mica capacitors are made by depositing a thin layer of silver on the mica dielectric. This makes the value even more stable, but it presents the possibility of silver migration through the dielectric. The migration problem worsens with increased dc voltage, temperature and humidity. Avoid using silver-mica capacitors under such conditions.

**Ceramic** There are two kinds of ceramic capacitors. Those with a low dielectric constant are relatively large, but very stable and nearly as good as mica capacitors at HF. High dielectric constant ceramic capacitors are physically small for their capacitance, but their value is not as stable. Their dielectric properties vary with temperature, applied voltage and operating frequency. They also exhibit piezoelectric behavior. Use them only in coupling and bypass roles. Tolerances are usually +100% and -20%. Ceramic capacitors are available in a wide range of values: 10 pF to 1  $\mu$ F. Some variable units are available.

**Electrolytic** These capacitors have the space between their foil plates filled with a chemical paste. When voltage is applied, a chemical reaction forms a layer of insulating material on the foil.

Electrolytic capacitors are popular because they provide high capacitance values in small packages at a reasonable cost. Leakage is high, as is inductance, and they are polarized—there is a definite positive and negative plate, due to the chemical reaction that provides the dielectric. Internal inductance restricts aluminum-foil electrolytics to low-frequency applications. They are available with values from 1 to 500,000  $\mu$ F.

Tantalum electrolytic capacitors perform better than aluminum units but their cost is higher. They are smaller, lighter and more stable, with less leakage and inductance than their aluminum counterparts. Reformation problems are less frequent, but working voltages are not as high as with aluminum units.

Electrolytics should not be used if the dc potential is well below the capacitor working voltage.

**Paper** Paper capacitors are inexpensive; capacitances from 500 pF to 50  $\mu$ F are available. High working voltages are possible, but paper-dielectric capacitors have high leakage rates and tolerances are no better than 10 to 20%. Paper-dielectric capacitors are not polarized; however, the body of the capacitor is usually marked

with a color band at one end. The band indicates the terminal that is connected to the outermost plate of the capacitor. This terminal should be connected to the side of the circuit at the lower potential as a safety precaution.

## Loss Angle

For ac signals (even at low frequencies), capacitors exhibit an additional parasitic resistance that is due to the electromagnetic properties of dielectric materials. This resistance is often quantified in catalogs as *loss angle*,  $\theta$ , because it represents the angle, in the complex impedance plane, between  $Z_C = R + jX_C$  and  $X_C$ . This angle is usually quite small, and would be zero for an ideal capacitor.

Loss angle is normally specified as  $\tan \theta$  at a certain frequency, which is simply the ratio  $R/X_C$ . The loss angle of a given capacitor is relatively constant over frequency, which means the *effective series resistance* or  $ESR = (\tan \theta) / (2\pi f C)$  goes down as frequency goes up. This resistance is placed in *series* with the capacitor because it came (mathematically) from the equation for  $Z_C$  above. It can always be converted into a parallel resistance if desired. To summarize, **Figs 10.8 and 10.9** show a reasonable models for the capacitor that are good up to VHF.

## Temperature Coefficients and Tolerances

As with resistors, capacitor values vary in production, and most capacitors have a tolerance rating either printed on them or listed on a data sheet. Capacitance varies with temperature, and this is important to consider when constructing a circuit that will carry high power levels or operated in a hot environment. Also, as just described, not all capacitors are available in all ranges of values due to inherent differences in material properties. Typical values, temperature coefficients and leakage conduc-

**Fig 10.8—A simple capacitor model for frequencies well below self-resonance.**

**Fig 10.9—A capacitor model for VHF and above including series resistance and distributed inductance.**

tances for several capacitor types are given in **Table 10.2**.

## DIODES

An ideal diode acts as a rectifying switch—it is a short circuit when forward biased and an open circuit when reverse biased. Many circuit components can be completely described in terms of current-voltage (or  $I$ - $V$ ) characteristics, and to discuss the diode, this approach is especially helpful. **Fig 10.10A** shows the  $I$ - $V$  curve for an ideal rectifier.

In contrast, the  $I$ - $V$  curve for a semiconductor diode junction is given by the following equation (slightly simplified).

$$I = I_s \left( e^{\frac{V}{V_t}} \right) \quad (4)$$

where

$I$  = diode current

$V$  = diode voltage

$I_s$  = reverse-bias saturation current

$V_t = kT/q$ , the thermal equivalent of voltage (about 25 mV at room temperature).

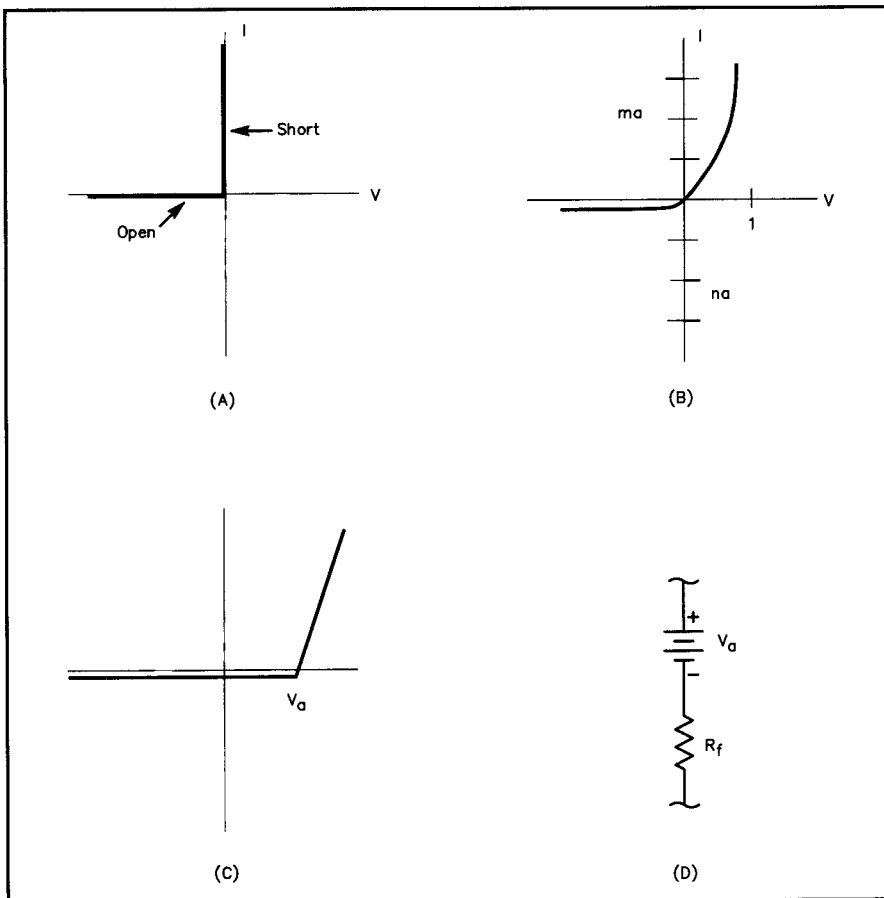

This curve is shown in **Fig 10.10B**.

The obvious differences between **Fig 10.10A** and **B** are that the semiconductor diode has a finite *turn-on* voltage—it requires a small but nonzero forward bias voltage before it begins conducting. Furthermore, once conducting, the diode voltage continues to increase very slowly with increasing current, unlike a true short circuit. Finally, when the applied voltage is negative, the current is not exactly zero

**Table 10.2**

**Typical Temperature Coefficients and Leakage Conductances for Various Capacitor Constructions**

Type	TC @ 20°C (PPM/°C)	DC Leakage Conductance ( $\Omega$ )
Ceramic Disc	$\pm 300$ (NP0) $+150/-1500$ (GP)	$> 10$ M $> 10$ M
Mica	$-20$ to $+100$	$> 100,000$ M
Polyester	$\pm 500$	$> 10$ M
Tantalum Electrolytic	$\pm 1500$	$> 10$ M $\Omega$
Small Al Electrolytic( $\approx 100$ $\mu$ F)	$-20,000$	500 k - 1 M
Large Al Electrolytic( $\approx 10$ mF)	$-100,000$	10 k
Vacuum (glass)	$+100$	$\approx \infty$
Vacuum (ceramic)	$+50$	$\approx \infty$

but very small (picoamperes).

For bias (dc) circuit calculations, a useful model for the diode that takes these two effects into account is shown by the artificial  $I$ - $V$  curve in **Fig 10.10C**. The small reverse bias current  $I_s$  is assumed to be completely negligible.

When converted into an equivalent circuit, the model in **Fig 10.10C** yields the picture in **Fig 10.10D**. The ideal voltage source  $V_d$  represents the turn-on voltage

and  $R_f$  represents the effective resistance caused by the small increase in diode voltage as the diode current increases. The turn-on voltage is material-dependent: approximately 0.3 V for germanium diodes and 0.7 for silicon.  $R_f$  is typically on the order of 10  $\Omega$ , but it can vary according to the specific component.  $R_f$  can often be completely neglected in comparison to the other resistances in the circuit. This very common simplification leaves only a pure

voltage drop for the diode model.

## Temperature Bias Dependence

The reverse saturation current  $I_s$  is not constant but is itself a complicated function of temperature. For silicon diodes (and transistors) near room temperature,  $I_s$  increases by a factor of 2 every 4.8 °C. This means that for every 4.8 °C rise in temperature, either the diode current doubles (if the voltage across it is constant), or if the current is held constant by other resistances in the circuit, the diode voltage will decrease by  $V_t \times \ln 2 = 18 \text{ mV}$ . For germanium, the current doubles every 8 °C and for gallium arsenide (GaAs), 3.7 °C. This dependence is highly reproducible and may actually be exploited to produce temperature-measuring circuits.

While the change resulting from a rise of several degrees may be tolerable in a circuit design, that from 20 or 30 degrees may not. Therefore it's a good idea with diodes, just as with other components, to specify power ratings conservatively (2 to 4 times over) to prevent self-heating.

While component derating does reduce self-heating effects, circuits must be designed for the expected operating environment. For example, mobile radios may face temperatures from -20° to +140°F (-29° to 60°C).

## Junction Capacitance

Immediately surrounding a PN junction is a *depletion layer*. This is an electrically charged region consisting primarily of ionized atoms with relatively few electrons and holes (see Fig 10.11). Outside the depletion layer are the remainder of the P and N regions, which do not contribute to diode operation but behave primarily as parasitic series resistances.

We can treat the depletion layer as a tiny capacitor consisting of two parallel plates. As the reverse bias applied to a diode changes, the width of the depletion layer, and therefore the capacitance, also changes. There is an additional *diffusion capacitance* that appears under forward bias due to electron and hole storage in the bulk regions, but we will not discuss this here because diodes are usually reverse biased when their capacitance is exploited. The diode junction capacitance under a reverse bias of  $V$  volts is given by

$$C_j = C_{j0} \sqrt{V_{on} - V} \quad (5)$$

where  $C_{j0}$  = measured capacitance with zero applied voltage.

Note that the quantity under the radical is a large *positive* quantity for reverse bias. As seen from the equation, for large reverse biases  $C_j$  is inversely proportional to the square root of the voltage.

Junction capacitances are small, on the order of pF. They become important, however, for diode circuits at RF, as they can affect the resonant frequency. In fact, *varactors* are diodes used for just this purpose.

## Reverse Breakdown and Zener Diodes

If a sufficiently large reverse bias is applied to a real diode, the internal electric field becomes so strong that electrons and holes are ripped from their atoms, and a large reverse current begins to flow. This

is called *breakdown* or *avalanche*. Unless the current is so large that the diode fails from overheating, breakdown is not destructive and the diode will again behave normally when the bias is removed.

Once a diode breaks down, the voltage across it remains relatively constant regardless of the level of breakdown current. *Zener diodes* are diodes that are specially made to operate in this region with a very constant voltage, called the *Zener voltage*. They are used primarily as voltage regulators. When operating in this region, they can be modeled as a simple voltage source. Zener diodes are rated by their Zener voltage and power dissipation.

## A Diode AC Model

Fig 10.12A shows a simple resistor-diode circuit to which is applied a dc bias voltage plus an ac signal. Assuming that the voltage drop across the diode is 0.6 V and  $R_f$  is negligible, we can calculate the bias current to be  $I \approx (5 - 0.6) / 1 \text{ k}\Omega = 4.4 \text{ mA}$ . This point is marked on the diodes I-V curve in Fig 10.12B. If we draw a line tangent to this point, as shown, the slope of this line represents the *dynamic resistance*  $R_d$  of the diode seen by a small ac signal, which at room temperature can be approximated by

$$R_d = \frac{25}{I} \Omega \quad (6)$$

where  $I$  is the diode current in mA. Note that this resistance changes with bias current and should not be confused with the dc forward resistance in the previous section, which has a similar value but represents a different concept. Fig 10.13 shows a low-frequency ac model for the diode, including the dynamic resistance and junction capacitance.

## Switching Time

If you change the polarity of a signal applied to the ideal switch whose I-V

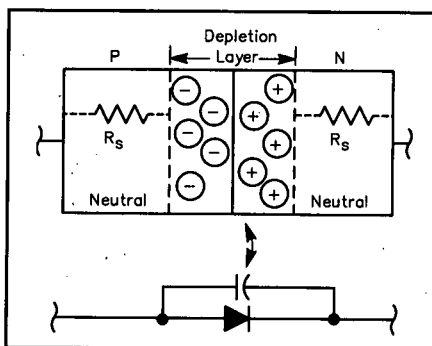

Fig 10.11—A more detailed picture of the PN junction, showing depletion layer, bulk regions and junction capacitance.

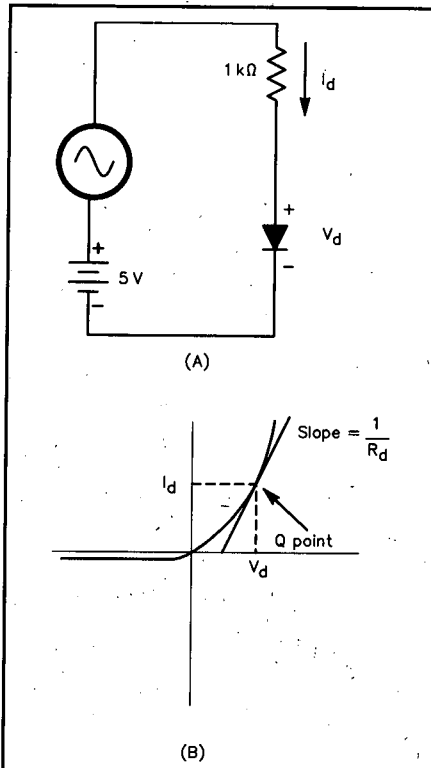

Fig 10.12—A simple resistor-diode circuit used to illustrate dynamic resistance. The ac input voltage "sees" a diode resistance whose value is the slope of the line at the Q-point, shown in B.

Fig 10.13—An ac model for diodes.  $R_d$  is the dynamic resistance and  $C_j$  is the junction capacitance.

curve appears in Fig 10.10A, the switch turns on or off instantaneously. A real diode cannot do this, as a finite amount of time is required to move electrons and holes in or out of the diode as it changes states (effectively, the diode capacitances must be charged or discharged). As a result, diodes have a maximum useful frequency when used in switching applications. The operation of diode switching circuits can often be modeled by the picture in Fig 10.14. The approximate switching time (in seconds) for this circuit is given by

$$t_s = \tau_p \left( \frac{V_1}{R_1} \right) = \tau_p \left( \frac{I_1}{I_2} \right) \quad (7)$$

where  $\tau_p$  is the minority carrier lifetime of the diode (a material constant determined during manufacture, on the order of 1 ms).  $I_1$  and  $I_2$  are currents that flow during the switching process. The minimum time in which a diode can switch from one state to the other and back again is therefore  $2 t_s$ , and thus the maximum usable switching frequency is  $f_{sw} \text{ (Hz)} = 1/2 t_s$ . It is usually a good idea to stay below this by a factor of two. Diode data sheets usually give typical switching times and show the circuit used to measure them.

Note that  $f_{sw}$  depends on the forward and reverse currents, determined by  $I_1$  and  $I_2$  (or equivalently  $V_1$ ,  $V_2$ ,  $R_1$ , and  $R_2$ ). Within a reasonable range, the switching time can be reduced by manipulating these currents. Of course, the maximum power that other circuit elements can handle places an upper limit on switching currents.

### Schottky Diodes

Schottky diodes are made from metal-semiconductor junctions rather than PN

Fig 10.14—Circuit used for computation of diode switching time.

junctions. They store less charge internally and as a result, have shorter switching times and junction capacitances than standard PN junction diodes.

Their turn-on voltage is also less, typically 0.3 to 0.4 V. In most other respects they behave similarly to PN diodes.

### INDUCTORS

Inductors are the problem children of the component world. (Fundamental inductance is discussed in the AC Theory chapter.) Besides being difficult to fabricate on integrated circuits, they are perhaps the most nonideal of real-world components. While the leakage conductance of a capacitor is usually negligible, the series resistance of an inductor often is not. This is basically because an inductor is made of a long piece of relatively thin wire wound into a small coil. As an example, consider a typical air-core tuning coil from a component catalog, with  $L = 33 \mu\text{H}$  and a minimum  $Q$  of 30 measured at 2.5 MHz. This would indicate a series resistance of  $R_s = 2 \pi f L / Q = 17 \Omega$ . This  $R_s$  could significantly alter the resonant frequency of a circuit. For frequencies up to HF this is the only significant nonlinearity, and a low-frequency circuit model for the inductor is shown in Fig 10.15. Many of the problems associated with inductors are actually due to core materials, and not the coil itself.

### Magnetic Materials

Many discrete inductors and transformers are wound on a core of iron or other magnetic material. As discussed in the AC Theory chapter, the inductance value of a coil is proportional to the density of magnetic field lines that pass through it. A piece of magnetic material placed inside a coil will concentrate the field lines inside itself. This permits a higher number of field lines to exist inside a coil of a given cross-sectional area, thus allowing a much higher inductance than what would be possible with an air core. This is especially important for transformers that operate at

Fig 10.15—Low- to mid-frequency inductor equivalent circuit showing series resistance  $R_s$ .

low frequencies (such as 60 Hz) to ensure the reactance of the windings is high.

### Core Saturation

Magnetic (more precisely, ferromagnetic) materials exhibit two kinds of non-linear behavior that are important to circuit design. The first is the phenomenon of *saturation*. A magnetic core increases the magnetic flux density of a coil because the current passing through the coil forces the atoms of the iron (or other material) to line up, just like many small compass needles, and the magnetic field that results from the atomic alignment is *much* larger than that produced by the current with no core. As coil current increases, more and more atoms line up. At some high current, all of the atoms will be aligned and the core is *saturated*. Any further increase in current can't increase the core alignment any further. Of course, added current generates its own magnetic flux, but it is very small compared to the magnetic field contributed by the aligned atoms in the magnetic core.

The important concept in terms of circuit design is that as long as the coil current remains below saturation, the inductance of the coil is essentially constant. Fig 10.17 shows graphs of magnetic flux linkage ( $N\phi$ ) and inductance ( $L$ ) vs current ( $i$ ) for a typical iron-core inductor. These quantities are related by the equation

$$N \phi = L i \quad (8)$$

where

- $N$  = number of turns,
- $\phi$  = flux density
- $L$  = inductance
- $i$  = current.

In the lower graph, a line drawn from any point on the curve to the (0,0) point

Fig 10.16—Typical construction of a magnetic-core inductor. The air gap greatly reduces core saturation at the expense of some inductance. The insulating laminations between the core layers help to minimize eddy currents.

will show the effective inductance,  $L = N \phi / i$ , at that current. These results are plotted on the upper graph.

Note that below saturation, the inductance is constant because both  $N \phi$  and  $i$  are increasing at a steady rate. Once the saturation current is reached, the inductance decreases because  $N \phi$  does not increase anymore (except for the tiny additional magnetic field the current itself provides). This may render some coils useless at VHF and higher frequencies. Air-coil inductors do not suffer from saturation.

One common method of increasing the saturation current level is to cut a small air gap in the core (see Fig 10.16). This gap forces the flux lines to travel through air for a short distance. Since the saturation flux linkage of the core is unchanged, this method works by requiring a higher current to achieve saturation. The price that is paid is a reduced inductance below saturation. Curves B in Fig 10.17 show the result of an air gap added to that inductor.

Manufacturer's data sheets for magnetic cores usually specify the saturation flux density. Saturation flux density,  $\phi$ , in gauss can be calculated for ac and dc currents from the following equations:

$$\phi_{ac} = \frac{3.49 V}{fNA} \quad (9)$$

$$\phi_{dc} = \frac{NIA_L}{10 A} \quad (10)$$

where

$V$  = RMS ac voltage

$f$  = frequency, in MHz

$N$  = number of turns

$A$  = equivalent area of the magnetic path in square inches (from the data sheet)

$I$  = dc current, in A

$A_L$  = inductance index (also from the data sheet).

### Hysteresis

Consider Fig 10.18. If the current passed through a magnetic-core inductor is increased from zero (point a) to near the point of saturation (point b) and then decreased back to zero, we find that a magnetic field remains, because some of the core atoms retain their alignment. If we then increase the current in the opposite direction and again return to zero (through points c, d and e), the curve does not retrace itself. This is the property of *hysteresis*.

If a circuit carries a large ac current (that is, equal to or larger than saturation), the path shown in Fig 10.18 (from b to e and back again) will be retraced many times each second. Since the curve is nonlinear, this will introduce distortion in the result-

ing waveform. Where linear circuit operation is crucial, it is important to restrict the operation of magnetic-core inductors well below saturation.

### Eddy Currents

The changing magnetic field produced by an ac current generates a "back voltage" in the core as well as the coil itself. Since magnetic core material is usually conductive, this voltage causes a current to flow in the core. This eddy current serves no useful purpose and represents power lost to heat. Eddy currents can be substantially reduced by laminating the core—slicing the core into thin sheets and placing a suitable insulating material

(such as varnish) between them (see Fig 10.16).

### Transformers

In an ideal transformer (described in the AC Theory chapter), *all* the power supplied to its primary terminals is available at the secondary terminals. An air-core transformer provides a very good approximation to the ideal case, the major loss being the series resistances of the windings. As you might guess, there are several ways that a magnetic-core transformer can lose power. For example, useless heat can be generated through hysteresis and eddy currents; power may be lost to harmonic generation through nonlinear saturation effects.

Another source of loss in transformers (or actually, any pair of mutual inductances) is *leakage reactance*. While the main purpose of a magnetic core is to concentrate the magnetic flux entirely within itself, in a real-life device there is always some small amount of flux that does not pass through both windings. This leakage reactance can be pictured as a small amount of self-inductance appearing on each winding. Fig 10.19 shows a fairly complete circuit model for a transformer at low to medium frequencies.

**Fig 10.17—Magnetic flux linkage and inductance plotted versus coil current for (A) a typical iron-core inductor. As the flux linkage  $N \phi$  in the coil saturates, the inductance begins to decrease since inductance = flux linkage / current. The curves marked B show the effect of adding an air gap to the core. The current handling capability has increased but at the expense of reduced inductance.**

**Fig 10.18—Hysteresis loop. A large current (larger than saturation current) passed through a magnetic-core coil will cause some permanent magnetization of the core. This results in a different path of flux linkage vs current to be traced as the current decreases.**

**Fig 10.19—An equivalent circuit for a transformer at low to medium frequencies.  $R_p$  and  $R_s$  represent the series resistances of the windings,  $X_p$  and  $X_s$  are the leakage inductances, and  $R_c$  represents the dissipative losses in the core due to eddy currents and so on.**

## COMPONENTS AT RF

The models described in the previous section are good for dc, and ac up through AF and low RF. At HF and above (where we do much of our circuit design) several other considerations become very important, in some cases dominant, in our component models. To understand what happens to circuits at RF (a good cutoff is 30 MHz and above) we turn to a brief discussion of some electromagnetic and microwave theory concepts.

### Parasitic Inductance

Maxwell's equations—the basic laws of electromagnetics that govern the propagation of electromagnetic waves and the operation of all electronic components—tell us that any wire carrying a current that changes with time (one example is a sine wave) develops a changing magnetic field around it. This changing magnetic field in turn induces an opposing voltage, or back EMF, on the wire. The back EMF is proportional to how fast the current changes (see Fig 10.20).

We exploit this phenomenon when we make an inductor. The reason we typically form inductors in the shape of a coil is to concentrate the magnetic field lines and

thereby maximize the inductance for a given physical size. However, *all* wires carrying varying currents have these inductive properties. This includes the wires we use to connect our circuits, and even the *leads* of capacitors, resistors and so on.

The inductance of a straight, round, nonmagnetic wire in free space is given by:

$$L = 0.00508b \left[ \ln \left( \frac{2b}{a} \right) - 0.75 \right] \quad (11)$$

where

$L$  = inductance, in  $\mu\text{H}$

$a$  = wire radius, in inches

$b$  = wire length, in inches

$\ln$  = natural logarithm ( $2.303 \times \log_{10}$ ).

Skin effect (see below) changes this formula slightly at VHF and above. As the frequency approaches infinity, the constant 0.75 in the above equation approaches 1. This effect usually presents no more than a few percent change.

As an example, let's find the inductance of a #18 wire (diam = 0.0403 inch) that is 4 inches long (a typical wire in a circuit).

Then  $a = 0.0201$  and  $b = 4$ :

$$L = 0.00508(4) \left[ \ln \left( \frac{8}{0.0201} \right) - 0.75 \right] \\ = 0.0203[5.98 - 0.75] = 0.106 \mu\text{H}$$

It is obvious that this *parasitic* inductance is usually very small. It becomes important *only at very high frequencies*; at AF or LF, the parasitic inductive reactance is practically zero. To use this example, the reactance of a  $0.106 \mu\text{H}$  inductor even at 10 MHz is only  $6.6 \Omega$ . Fig 10.21 shows a graph of the inductance for wires of various gauges (radii) as a function of length.

Any circuit component that has wires attached to it, or is fabricated from wire, will have a parasitic inductance associated with it. We can treat this parasitic inductance in component models by adding an inductor of appropriate value in *series* with the component (since the wire lengths are in series with the element). This (among other reasons) is why minimizing lead lengths and interconnecting wires becomes very important when designing circuits for VHF and above.

Fig 10.20—Inductive consequences of Maxwell's equations. At A, any wire carrying a changing current develops a voltage difference along it. This can be mathematically described as an effective inductance. B adds parasitic inductance to a generic component model.

Fig 10.21—A plot of inductance vs length for straight conductors in several wire sizes.

## Parasitic Capacitance

Maxwell's equations also tell us that if the voltage between any two points changes with time, a *displacement* current is generated between these points. See Fig 10.22. This displacement current results from the propagation, at the speed of light, of the electromagnetic field between the two points and is not to be confused with conduction current, which is caused by the movement of electrons. This displacement current is directly proportional to how fast the voltage is changing.

A capacitor takes advantage of this consequence of the laws of electromagnetics. When a capacitor is connected to an ac voltage source, a steady ac current can flow because taken together, conduction current and displacement current "complete the loop" from the positive source terminal, across the plates of the capacitor, and back to the negative terminal.

In general, parasitic capacitance shows up *wherever* the voltage between two points is changing with time, because the laws of electromagnetics require a displacement current to flow. Since this phenomenon represents an *additional* current path from one point in space to another, we can add this parasitic capacitance to our component models by adding a capacitor of appropriate value in *parallel* with the component. These parasitic capacitances are typically on the order of nF to

**Fig 10.22—Capacitive consequences of Maxwell's equations. A:** Any changing voltage between two points, for example along a bent wire, generates a *displacement* current running between them. This can be mathematically described as an effective capacitance. **B** adds parasitic capacitance to a generic component model.

**Fig 10.23—Coils exhibit distributed capacitance as explained in the text. The graph at B shows how distributed capacitance resonates with the inductance. Below resonance, the reactance is inductive, but it decreases as frequency increases. Above resonance, the reactance is capacitive and increases with frequency.**

pF, so that below VHF they can be treated as open circuits (infinite resistances) and thus neglected.

Consider the inductor in Fig 10.23. If this coil has  $n$  turns, then the ac voltage between identical points of two neighboring turns is  $1/n$  times the ac voltage across the entire coil. When this voltage changes due to an ac current passing through the coil, the effect is that of many small capacitors acting in parallel with the inductance of the coil. Thus, in addition to the capacitance resulting from the leads, inductors have higher parasitic capacitance due to their physical shape.

## Package Capacitance

Another source of capacitance, also in the nF to pF range and therefore important only at VHF and above, is the packaging of the component itself. For example, a power transistor packaged in a TO-220 case (see Fig 10.24), often has either the emitter or collector connected to the metal tab itself. This introduces an extra *interelectrode* capacitance across the junctions.

The copper traces on a PC board also present capacitance to the circuit it holds. Double-sided PC boards have a certain capacitance per square inch. It is possible to create capacitors by leaving unetched areas of copper on both sides of the board. The capacitance is not well controlled on inexpensive low-frequency boards, however. For this reason, the copper on one side of a double-sided board should be completely removed under frequency-determining circuits such as VFOs. Board capacitance is *exploited* to make micro-

**Fig 10.24—Unexpected stray capacitance.** The mounting tab of TO-220 transistors is often connected to one of the device leads. Because one lead is connected to the chassis, small capacitances from the other leads to the chassis appear as additional package capacitance at the device. Similar capacitance can appear at any device with a conductive package.

wave transmission lines (microstrip lines). The capacitance of boards for microwave use is better controlled than that of less expensive board material.

*Stray* capacitance (a general term used for any "extra" capacitance that exists due to physical construction) appears in any circuit where two metal surfaces exist at different voltages. Such effects can be modeled as an extra capacitor in parallel with the given points in the circuit. A rough value can be obtained with the parallel-plate formula given above.

Thus, similar to inductance, any circuit

component that has wires attached to it, or is fabricated from wire, or is near or attached to metal, will have a parasitic capacitance associated with it, which again, becomes important only at RF.

## A GENERAL MODEL

The parasitic problems due to component leads, packaging, leakage and so on are relatively common to all components. When working at frequencies where many or all of the parasitics become important, a complex but completely general model such as that in Fig 10.25 can be used for just about any component, with the actual component placed in the box marked "\*". Parasitic capacitance  $C_p$  and leakage conductance  $G_L$  appear in parallel across the device, while series resistance  $R_s$  and parasitic inductance  $L_p$  appear in series with it. Package capacitance  $C_{pkg}$  appears as an additional capacitance in parallel across the whole device. This maze of effects may seem overwhelming, but remember that it is very seldom necessary to consider all parasitics. In the Computer-Aided-Design section of this chapter, we will use the power of the computer to examine the combined effects of these multiple parasitics on circuit performance.

## Self-Resonance

Because of the effects just discussed, a capacitor or inductor—all by itself—exhibits the properties of a resonant RLC circuit as we increase the applied frequency.

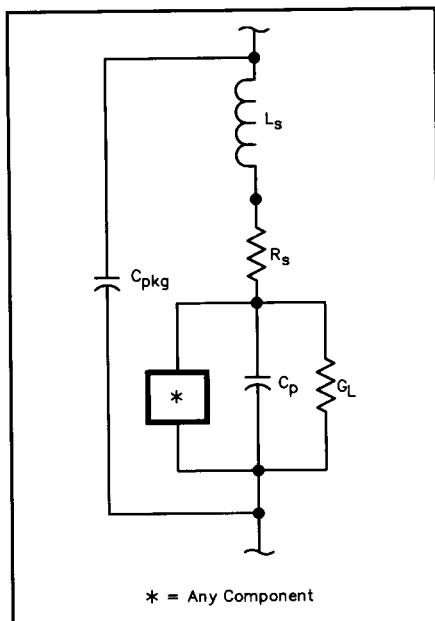

Fig 10.25—A general model for electrical components at VHF frequencies and above. The box marked "\*" represents the component itself. See text for discussion.

quency. Fig 10.26 illustrates RF models for the capacitor and inductor, which are based on the general model in Fig 10.25, leaving out the packaging capacitance. Note the slight difference in configuration; the pairs  $C_p$ ,  $R_p$  and  $L_s$ ,  $R_s$  are in series in the capacitor but in parallel in the inductor. This is because in the inductor,  $C_p$  and  $R_p$  are the parasitics, while in the capacitor,  $L_s$  and  $R_s$  are the added effects.

At some sufficiently high frequency, both inductors and capacitors become *self-resonant*. Just like a tuned circuit, above that frequency the capacitor will appear inductive, and the inductor will appear capacitive.

For an example, let's calculate the approximate self-resonant frequency of a 470-pF capacitor whose leads are made from #20 wire (diam 0.032 inch), with a total length of 1 inch. From the formula above, we calculate the approximate parasitic inductance

$$L(\mu\text{H}) = 0.00508(1) \left[ \ln \left( \frac{2(1)}{(0.032/2)} \right) - 0.75 \right] \\ = 0.021 \mu\text{H}$$

and then the self-resonant frequency is roughly

$$f = \frac{1}{2\pi\sqrt{LC}} = 50.6 \text{ MHz}$$

The purpose of making these calculations is to give you a rough feel for actual component values. They could be used as a rough design guideline, but should not be used quantitatively. Other factors such as lead orientation, shielding and so on, can alter the parasitic effects to a large extent. Large-value capacitors tend to have higher parasitic inductances (and therefore a lower self-resonant frequency) than small-value ones.

Self-resonance becomes critically im-

Fig 10.26—Capacitor (A) and inductor (B) models for RF frequencies.

portant at VHF and UHF because the self-resonant frequency of many common components is at or below the frequency where the component will be used. In this case, either special techniques can be used to construct components to operate at these frequencies, by reducing the parasitic effects, or else the idea of lumped elements must be abandoned altogether in favor of microwave techniques such as striplines and waveguides.

## Skin Effect

The resistance of a conductor to ac is different than its value for dc. A consequence of Maxwell's equations is that thick, near-perfect conductors (such as metals) conduct ac only to a certain depth that is proportional to the wavelength of the signal. This decreases the effective cross-section of the conductor at high frequencies and thus increases its resistance.

This resistance increase, called *skin effect*, is insignificant at low (audio) frequencies, but beginning around 1 MHz (depending on the size of the conductor) it is so pronounced that practically all the current flows in a very thin layer near the conductor's surface. For this reason, at RF a hollow tube and a solid tube of the same diameter and made of the same metal will have the same resistance. The depth of this skin layer decreases by a factor of 10 for every 100x increase in frequency. Consequently, the RF resistance is often much higher than the dc resistance. Also, a thin highly conductive layer, such as silver plating, can greatly lower resistance for UHF or microwaves, but does little to improve HF conductivity.

A rough estimate of the cutoff frequency where a nonferrous wire will begin to show skin effect can be calculated from

$$f = \frac{124}{d^2} \quad (12)$$

where

$f$  = frequency, in MHz

$d$  = diam, in mils (a mil is 0.001 inch).

Above this frequency, increase the resistance of the wire by 10x for every 2 decades of frequency (roughly 3.2x for every decade). For example, say we wish to find the RF resistance of a 2-inch length of #18 copper wire at 100 MHz. From the wire tables, we see that this wire has a dc resistance of (2 in.) (6.386  $\Omega$ /1000 ft) = 1.06 milliohms. From the above formula, the cutoff frequency is found to be  $124 / 40.32 = 76 \text{ kHz}$ . Since 100 MHz is roughly three decades above this (100 kHz to 100 MHz), the RF resistance will be approximately (1.06 m $\Omega$ ) (10  $\times$  3.2) = 34 m $\Omega$ . Again, values calculated in this

manner are approximate and should be used qualitatively—that is, when you want an answer to a question such as, “Can I neglect the RF resistance of this length of connecting wire at 100 MHz?”

### Effects on Q

Recall from the **AC Theory** chapter that circuit Q, a useful figure of merit for tuned RLC circuits, can be defined in several ways:

$$Q = \frac{X_L \text{ or } X_C \text{ (at resonance)}}{R} \quad (13)$$

$$= \frac{\text{energy stored per cycle}}{\text{energy dissipated per cycle}}$$

Q is also related to the bandwidth of a tuned circuit’s response by

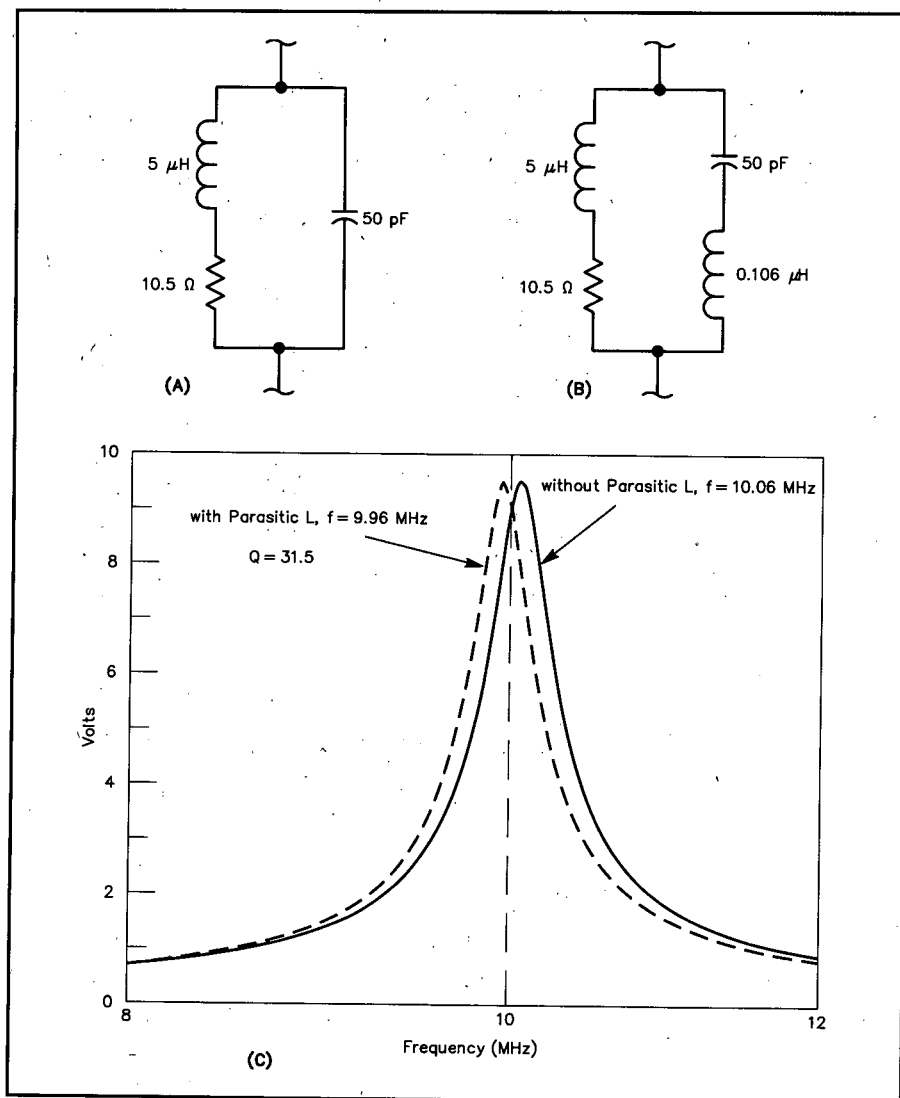

$$Q = \frac{f_0}{\text{BW}_{3\text{dB}}} \quad (14)$$

Parasitic inductance, capacitance and resistance can significantly alter the performance and characteristics of a tuned circuit if the design frequency is anywhere near the self-resonant frequencies of the components.

As an example, consider the resonant circuit of **Fig 10.27A**, which could represent the input tank circuit of an oscillator. Neglecting any parasitics,  $f_0 = 1 / (2 \pi (LC)^{0.5}) = 10.06 \text{ MHz}$ . As in many real cases, assume the resistance arises entirely from the inductor series resistance. The data sheet for the inductor specified a minimum Q of 30, so assuming  $Q = 30$  yields an R value of  $X_L / Q = 2 \pi (10.06 \text{ MHz}) (5 \mu\text{H}) / 30 = 10.5 \Omega$ .

Next, let’s include the parasitic inductance of the capacitor (**Fig 10.27B**). A reasonable assumption is that this capacitor has the same physical size as the example from the Parasitic Inductance discussion above, for which we calculated  $L_s = 0.106 \mu\text{H}$ . This would give the capacitor a self-resonant frequency of 434 MHz—well above our area of interest. However, the added parasitic inductance does account for an extra  $0.106/5.00 = 2\%$  inductance. Since this circuit is no longer strictly series or parallel, we must convert it to an equivalent form before calculating the new  $f_0$ .

An easier and faster way is to *simulate* the altered circuit by computer. This analysis was performed on a desktop computer using *SPICE*, a standard circuit simulation program; for more details, see the Computer-Aided Design section below. The voltage response of the circuit (given an input current of 1 mA) was calculated as a function of frequency for both cases, with and without parasitics. The results are shown in the plot in **Fig 10.27C**,

**Fig 10.27—A** is a tank circuit, neglecting parasitics. **B** same circuit including  $L_p$  on capacitor. **C** frequency response curves for **A** and **B**. The solid line represents the unaltered circuit (also see **Fig 10.29**) while the dashed line shows the effects of adding parasitic inductance.

where we can see that the parasitic circuit has an  $f_0$  of 9.96 MHz (a shift of 1%) and a Q (measured from the  $-3 \text{ dB}$  points) of 31.5. For comparison, the simulation of the unaltered circuit does in fact show  $f_0 = 10.06 \text{ MHz}$  and  $Q = 30$ .

### Inductor Coupling

Mutual inductance will also have an effect on the resonant frequency and Q of the involved circuits. For this reason, inductors in frequency-critical circuits should always be shielded, either by constructing compartments for each circuit block or through the use of “can”-mounted coils. Another helpful technique is to mount nearby coils with their axes perpendicular as in **Fig 10.28**. This will minimize coupling.

As an example, assume we build an oscillator circuit that has both input and out-

**Fig 10.28—Unshielded coils in close proximity should be mounted perpendicular to each other to minimize coupling.**

put filters similar to the resonant circuit in **Fig 10.27A**. If we are careful to keep the two coils in these circuits uncoupled, the frequency response of either of the two circuits is that of the solid line in **Fig 10.29**, reproduced from **Fig 10.27C**.

If the two coils are coupled either

**Fig 10.29—Result of light coupling ( $k=0.05$ ) between two identical circuits of Fig 10.27A on their frequency responses.**

through careless placement or improper shielding, the resonant frequency and  $Q$  will be affected. The dashed line in Fig 10.29 shows the frequency response that results from a coupling coefficient of  $k = 0.05$ , a reasonable value for air-wound inductors mounted perpendicularly in close proximity on a circuit chassis. Note the resonant frequency shifted from 10.06 to 9.82 MHz, or 2.4%. The  $Q$  has gone up slightly from 30.0 to 30.8 as a result of the slightly higher inductive reactance at the resonant frequency.

To summarize, even small parasitics can significantly affect frequency responses of RF circuits. Either take steps to minimize or eliminate them, or use simple circuit theory to predict and anticipate changes.

### Dielectric Breakdown and Arcing

Anyone who has ever watched a capacitor burn out, or heard the hiss of an arc across the inductor of an antenna tuner, while loading the 2-m vertical on 160-m, or touched a doorknob on a cold winter day has seen the effects of dielectric breakdown. When the dielectric is gaseous, especially air, we often call this *arcing*.

In the ideal world, we could take any two conductors and put as large a voltage as we want across them, no matter how close together they are. In the real world, there is a voltage limit (*dielectric strength*, measured in kV/cm and determined by the insulator between the two conductors) above which the insulator will break down.

Because they are charged particles, the electrons in the atoms of a dielectric material feel an attractive force when placed in an electric field. If the field is sufficiently strong, the force will strip the electron from the atom. This electron is available to conduct current, and furthermore, it is traveling at an extremely high velocity. It is very likely that this electron will hit another atom, and free another electron. Before long, there are many stripped electrons producing a large current. When this happens, we say the dielectric has suffered *breakdown*.

If the dielectric is liquid or gas, it can heal when the applied voltage is removed. A solid dielectric, however, cannot repair itself. A good example of this is a CMOS integrated circuit. When exposed to the very high voltages associated with static electricity, the electric field across the very thin gate oxide layer exceeds the dielectric strength of silicon dioxide, and the device is permanently damaged.

Capacitors are, by nature, perhaps the component most often associated with dielectric failure. To prevent damage, the working voltage of a capacitor—and there are separate dc and ac ratings—should ideally be 2 or 3 times the expected maximum voltage in the circuit.

Arcing is most often seen in RF circuits where the voltages are normally high, but it is possible anywhere two components at significantly different voltage levels are closely spaced.

The breakdown voltage of a dielectric

**Table 10.3**

### Dielectric Constants and Breakdown Voltages

Material	Dielectric Constant*	Puncture Voltage**
Aisimag 196	5.7	240
Bakelite	4.4-5.4	240
Bakelite, mica filled	4.7	325-375
Cellulose acetate	3.3-3.9	250-600
Fiber	5-7.5	150-180
Formica	4.6-4.9	450
Glass, window	7.6-8	200-250
Glass, Pyrex	4.8	335
Mica, ruby	5.4	3800-5600
Mycalox	7.4	250
Paper, Royalgrey	3.0	200
Plexiglas	2.8	990
Polyethylene	2.3	1200
Polystyrene	2.6	500-700
Porcelain	5.1-5.9	40-100
Quartz, fused	3.8	1000

Teflon	2.1	1000-2000

\* At 1 MHz

\*\* In volts per mil (0.001 inch)

layer depends on its composition and thickness (see Table 10.3). The variation with thickness is not linear; doubling the thickness does not quite double the breakdown voltage. Breakdown voltage is also a function of geometry: Because of electromagnetic considerations, the breakdown voltage between two conductors separated by a fixed distance is less if the surfaces are pointed or sharp-edged than if they are smooth or rounded. Therefore, a simple way to help prevent breakdown in many projects is to file and smooth the edges of conductors.

### Radiative Losses and Coupling

Another consequence of Maxwell's equations states that any conductor placed in an electromagnetic field will have a current induced in it. We put this principle to good use when we make an antenna. The unwelcome side of this law of nature is the phrase "any conductor"; even conductors we don't intend as antennas will act this way.

Fortunately, the *efficiency* of such "antennas" varies with conductor length. They will be of importance only if their length is a significant fraction of a wavelength. When we make an antenna, we usually choose a length on the order of  $\lambda/2$ . Therefore, when we *don't* want an antenna, we should be sure that the conductor length is *much less* than  $\lambda/2$ , no more than  $0.1 \lambda$ . This will ensure a very low-efficiency antenna. This is why 60-Hz power lines do not lose a significant frac-

tion of the power they carry over long distances—at 60 Hz,  $0.1 \lambda$  is about 300 miles!

In addition, we can use shielded cables. Such cables do allow some penetration of EM fields if the shield is not solid, but even 95% coverage is usually sufficient, especially if some sort of RF choke is used to reduce shield current.

Radiative losses and coupling can also be reduced by using twisted pairs of conductors—the fields tend to cancel. In some applications, such as audio cables, this may work better than shielding.

This argument also applies to large components, and remember that a component or long wire can *radiate* RF, as well as receive them. Critical stages such as tuned circuits should be placed in shielded compartments where possible. See the **EMI and Transmission Lines** chapters for more information.

## REMEDIES FOR PARASITICS

The most common effect (always the most annoying) of parasitics is to influence the resonant frequency of a tuned circuit. This shift could cause an oscillator to fail, or more commonly, to cause a stable circuit to oscillate. It can also degrade filter performance (more on this later) and basically causing any number of frequency-related problems.

We can often reduce parasitic effects in discrete-component circuits by simply exploiting the models in Fig 10.26. Since parasitic inductance and loss resistance appear in series with a capacitor, we can reduce both by using several smaller capacitances in parallel, rather than of one large one.

An example is shown in the circuit block in Fig 10.30, which is representative of the input tank circuit used in many HF VFOs.  $C_{main}$ ,  $C_{trim}$ ,  $C1$  and  $C3$  act with  $L$  to set the oscillator frequency. Therefore, temperature effects are critical in these components. By using several capacitors in parallel, the RF current (and resultant heat) is reduced in each component. Parallel combinations are used at the feedback capacitors for the same reason.

Another example of this technique is the common capacitor bypass arrangement shown in Fig 10.31.  $C1$  provides a bypass path at audio frequencies, but it has a low self-resonant frequency due to its large capacitance. How low? Even if we assume the  $0.02\text{-}\mu\text{H}$  value above,  $f_{sc} = 355\text{ kHz}$ . Adding  $C2$  (with a smaller capacitance but much higher self-resonant frequency) in parallel provides bypass at high frequencies where  $C1$  appears inductive.

## Construction Techniques

These concepts also help explain why

so many different components exist with similar values. As an example, assume you're working on a project that requires you to wind a  $5\text{ }\mu\text{H}$  inductor. Looking at the coil inductance formula in the **AC Theory** chapter, it comes to mind that many combinations of length and diameter could yield the desired inductance. If you happen to have both 0.5 and 1-inch coil forms, why should you select one over the other? To eliminate some other variables, let's make both coils 1 inch long, close-wound, and give them 1-inch leads on each end.

Let's calculate the number of turns required for each. On a 0.5-inch-diameter form:

$$n = \frac{\sqrt{5[(18 \times 0.5) + (40 \times 1)]}}{0.5}$$

$$= 31.3 \text{ turns}$$

This means coil 1 will be made from #20 wire (29.9 turns per inch). Coil 2, on the 1-inch form, yields

$$n = \frac{\sqrt{5[(18 \times 1) + (40 \times 1)]}}{1}$$

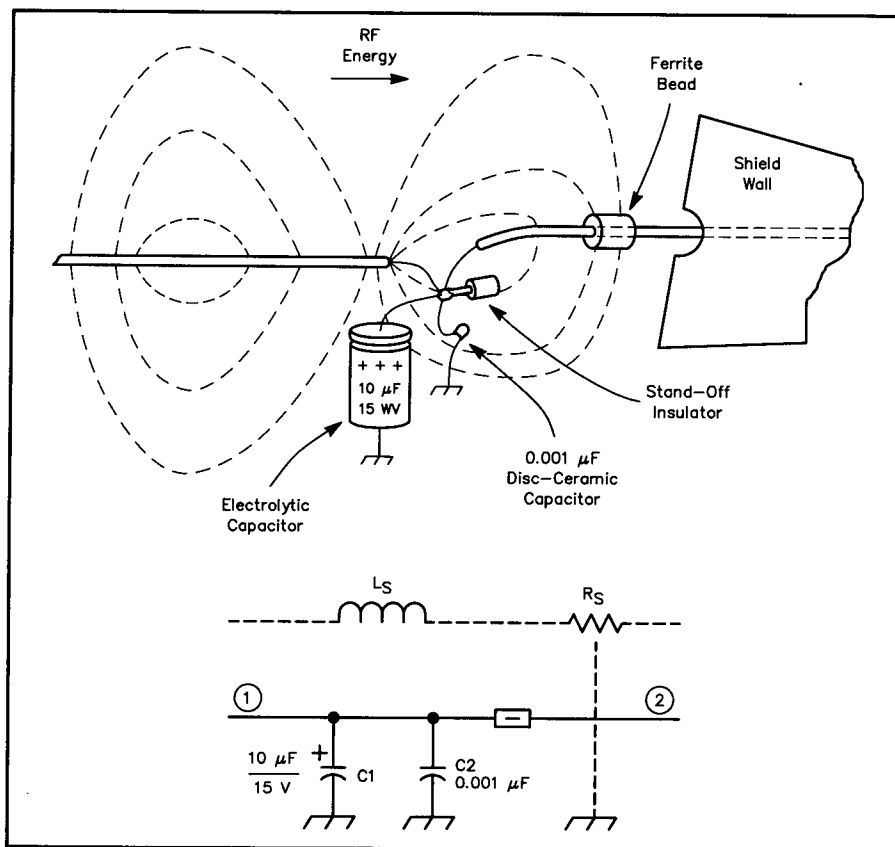

$$= 17.0 \text{ turns}$$

which requires #15 wire in order to be close-wound.

What are the series resistances associated with each? For coil 1, the total wire length is 2 inches +  $(31.3 \times \pi \times 0.5) = 51$  inches, which at  $10.1\text{ }\Omega/1000\text{ ft}$  gives  $R_s = 0.043\text{ }\Omega$  at dc. Coil 2 has a total wire

**Fig 10.30—A tank circuit of the type commonly used in VFOs. Several capacitors are used in parallel to distribute the RF current, which reduces temperature effects.**

**Fig 10.31—A typical method to provide bypassing at high frequencies when a large capacitor with a low-self-resonant frequency is required.**

length of 2 inches +  $(17.0 \times \pi \times 1) = 55$  inches, which at  $3.18 \Omega/1000 \text{ ft}$  gives a dc resistance of  $R_s = 0.015 \Omega$ , or about  $\frac{1}{3}$  that of coil 1. Furthermore, at RF, coil 1 will begin to suffer from skin effect at a frequency about 3 times lower than coil 2 because of its smaller conductor diameter. Therefore, if Q were the sole consideration, it would be better to use the larger diameter coil.

Q is not the only concern, however. Such coils are often placed in shielded enclosures. Rule of thumb says the enclosure should be at least one coil diameter from the coil on all sides. That is,  $3 \times 3 \times 2$  inches for the large coil and  $1.5 \times 1.5 \times 1.5$  for the small coil, a volume difference of over 500%.

## THERMAL CONSIDERATIONS

Any real energized circuit consumes electric power because any real circuit contains components that convert electricity into other forms of energy.<sup>1</sup> This *dissipated power* appears in many forms. For example, a loudspeaker converts electrical energy into the motion of air molecules we call sound. An antenna (or a light bulb) converts electricity into electromagnetic radiation. Charging a battery converts electrical energy into chemical energy (which is then converted back to electrical energy upon discharge). But the most common transformation by far is the conversion, through some form of *resistance*, of electricity into heat.

Sometimes the power lost to heat serves a useful purpose—toasters and hair dryers come to mind. But most of the time, this heat represents a power loss that is to be minimized wherever possible or at least taken into account. Since all real circuits contain resistance, even those circuits (such as a loudspeaker) whose primary purpose is to convert electricity to some *other* form of energy also convert some part of their input power to heat. Often, such losses are negligible, but sometimes they are not.

If unintended heat generation becomes significant, the involved components will get warm. Problems arise when the temperature increase affects circuit operation by either

- causing the component to fail, by explosion, melting, or other catastrophic event, or, more subtly,

- causing a slight change in the properties of the component, such as through a temperature coefficient (TC).

In the first case, we can design conservatively, ensuring that components are rated to safely handle two, three or more times the maximum power we expect them to dissipate. In the second case, we can specify components with low TCs, or we can design the circuit to minimize the effect of any one component. Occasionally we even exploit temperature effects (for example, using a resistor, capacitor or diode as a temperature sensor). Let's look more closely at the two main categories of thermal effects.

### HEAT DISSIPATION

Not surprisingly, heat dissipation (more correctly, the efficient removal of generated heat) becomes important in medium- to high-power circuits: power supplies, transmitting circuits and so on. While these are not the only examples where elevated temperatures and related failures are of concern, the techniques we will discuss here are applicable to all circuits.

#### Thermal Resistance

The transfer of heat energy, and thus the change in temperature, between two ends of a block of material is governed by the following heat flow equation (see Fig 10.32):

$$P = \frac{\kappa A}{L} \Delta T = \frac{\delta T}{\theta} \tag{15}$$

where

P = power (in the form of heat) conducted between the two points

$\kappa$  = *thermal conductivity*, measured in  $W/(\text{°C m})$ , of the material between the two points, which may be steel, silicon, copper, PC board material and so on

Fig 10.32—Physical and “circuit” models for the heat-flow equation.

L = length of the block

A = area of the block

$\delta T$  = *change* in temperature between the two points;

$\theta = \frac{L}{\kappa A}$  is often called the *thermal resistance* and has units of  $\text{°C/W}$ .

Thermal conductivities of various common materials at room temperature are given in Table 10.4.

A very useful property of the above equation is that it is *exactly* analogous to Ohm's Law, and therefore the same principles and methods apply to heat flow problems as circuit problems. The following correspondences hold:

- Thermal conductivity ( $W/\text{°C m}$ )  $\longleftrightarrow$  Electrical conductivity ( $S/m$ ).
- Thermal resistance ( $\text{°C/W}$ )  $\longleftrightarrow$  Electrical resistance ( $\Omega$ ).
- Thermal current (heat flow) ( $W$ )  $\longleftrightarrow$  Electrical current ( $A$ ).
- Thermal potential ( $T$ )  $\longleftrightarrow$  Electrical potential ( $V$ ).
- Heat source  $\longleftrightarrow$  Current source.

For example, calculate the temperature of a 2-inch (0.05 m) long piece of #12 copper wire at the end that is being heated by a 25 W (input power) soldering iron, and whose other end is clamped to a large metal vise (assumed to be an infinite heat sink), if the ambient temperature is  $25 \text{ °C}$  ( $77 \text{ °F}$ ).

First, calculate the thermal resistance of the copper wire (diameter of #12 wire is 2.052 mm, cross-sectional area is  $3.31 \times 10^{-6} \text{ m}^2$ )

$$\theta = \frac{L}{\kappa A} = \frac{(0.05 \text{ m})}{(390 \text{ W/°Cm})(3.31 \times 10^{-6} \text{ m}^2)} = 38.7 \text{ °C/W}$$

Then, rearranging the heat flow equation above yields (after assuming the heat

Table 10.4

#### Thermal Conductivities of Various Materials

Gases at  $0 \text{ °C}$ , Others at  $25 \text{ °C}$ ; from *Physics*, by Halliday and Resnick, 3rd Ed.

Material	$\left( k \frac{W}{\text{°Cm}} \right)$
Aluminum	200
Brass	110
Copper	390
Lead	35
Silver	410
Steel	46
Silicon	150
Air	0.024
Glass	0.8
Wood	0.08

<sup>1</sup>Superconducting circuits are the one exception; but they are outside the scope of this book.

energy actually transferred to the wire is around 10 W)

$$\delta T = P\theta = (10 \text{ W}) (38^\circ\text{C} / \text{W}) = 387^\circ\text{C}$$

So the wire temperature at the hot end is  $25^\circ\text{C} + \delta T = 412^\circ\text{C}$  (or  $774^\circ\text{F}$ ). If this sounds a little high, remember that this is for the steady state condition, where you've been holding the iron to the wire for a long time.

From this example, you can see that things can get very hot even with application of moderate power levels. In the case of a soldering iron, that's good, but in the case of a 25-W power transistor in a transmitter output stage, it's bad. For this reason, circuits that generate sufficient heat to alter, not necessarily damage, the components must employ some method of cooling, either active or passive. Passive methods include heat sinks or careful component layout for good ventilation. Active methods include forced air (fans) or some sort of liquid cooling (in some high-power transmitters).

### Heat Sink Design and Use

The purpose of a heat sink is to provide a high-power component with a large surface area through which to dissipate heat. To use the models above, it provides a low thermal-resistance path to a cooler temperature, thus allowing the hot component to conduct a large "thermal current" away from itself.

Power supplies probably represent one of the most common high-power circuits amateurs are likely to encounter. Everyone has certainly noticed that power supplies get warm or even hot if not ventilated properly. Performing the thermal design for a properly cooled power supply is a very well-defined process and is a good illustration of heat-flow concepts.

A 28-V, 10-A power supply will be used for this design example. This material was originally prepared by ARRL Technical Advisor Dick Jansson, WD4FAB, and the steps described below were actually followed during the design of that supply.

An outline of the design procedure shows the logic applied:

1. Determine the expected power dissipation ( $P_{in}$ )
2. Identify the requirements for the dissipating elements (minimum thermal conductivity).
3. Estimate heat-sink requirements.
4. Rework the electronic device (if necessary) to meet the thermal requirements.
5. Select the heat exchanger (from heat sink data sheets).

The first step is to estimate the filtered, unregulated supply voltage under full

**Fig 10.33—Resistive model of thermal conduction in a power transistor and associated heat sink. See text for calculations.**

**Fig 10.34—Thermal resistance vs heat-sink volume for natural convection cooling and 50°C temperature rise. The graph is based on engineering data from EG&G Wakefield.**

load. Since the transformer secondary output is 32 V ac (RMS) and feeds a full-wave bridge rectifier, let's estimate 40 V as the filtered dc output at a 10-A load.

The next step is to determine our critical components and estimate their power dissipations. In a regulated power supply, the pass transistors are responsible for nearly all the power lost to heat. Under full load, and allowing for some small voltage drops in the power-transistor emitter circuitry, the output of the series pass transistors is about 29 V for a delivered 28 V under a 10-A load. With an unregulated input voltage of 40 V, the total energy heat dissipated in the pass transistors is  $(40 \text{ V} - 29 \text{ V}) \times 10 \text{ A} = 110 \text{ W}$ . The heat sink for this power supply must be able to handle that amount of dissipation and still keep the transistor junctions below the specified safe operating temperature limits. It is a good rule of thumb to select a transistor that has a maximum power dissipation of twice the desired output power.

Now, consider the ratings of the pass transistors to be used. This supply calls for 2N3055s as pass transistors. The data sheet shows that a 2N3055 is rated for

15-A service and 115-W dissipation. But the design uses *four* in parallel. Why? Here we must look past the big, bold type at the top of the data sheet to such subtle characteristics as the junction-to-case thermal resistance,  $\theta_{jc}$ , and the maximum allowable junction temperature,  $T_j$ .

The 2N3055 data sheet shows  $\theta_{jc} = 1.52^\circ\text{C/W}$ , and a maximum allowable case (and junction) temperature of  $220^\circ\text{C}$ . While it seems that one 2N3055 could barely, on paper at least, handle the electrical requirements, at what temperature would it operate?

To answer that, we must model the entire "thermal circuit" of operation, starting with the transistor junction on one end and ending at some point with the ambient air. A reasonable model is shown in **Fig 10.33**. The ambient air is considered here as an infinite heat sink; that is, its temperature is assumed to be a constant  $25^\circ\text{C}$  ( $77^\circ\text{F}$ ).  $\theta_{jc}$  is the thermal resistance from the transistor junction to its case.  $\theta_{cs}$  is the resistance of the mounting interface between the transistor case and the heat sink.  $\theta_{sa}$  is the thermal resistance between the heat sink and the ambient air. In this

“circuit,” the generation of heat (the “thermal current source”) occurs in the transistor at  $P_{in}$ .

Proper mounting of most TO-3 package power transistors such as the 2N3055 requires that they have an electrical insulator between the transistor case and the heat sink. However, this electrical insulator must at the same time exhibit a low thermal resistance. To achieve a quality mounting, use thin polyimide or mica formed washers and a suitable thermal compound to exclude air from the interstitial space. “Thermal greases” are commonly available for this function. Any silicone grease may be used, but filled silicone oils made specifically for this purpose are better.

Using such techniques, a conservatively high value for  $\theta_{cs}$  is  $0.50^\circ\text{C/W}$ . Lower values are possible, but the techniques needed to achieve them are expensive and not generally available to the average amateur. Furthermore, this value of  $\theta_{cs}$  is already much lower than  $\theta_{jc}$ , which cannot be lowered without going to a somewhat more exotic pass transistor.

Finally, we need an estimate of  $\theta_{sa}$ . **Fig 10.34** shows the relationship of heat-sink volume to thermal resistance for natural-convection cooling. This relationship presumes the use of suitably spaced fins (0.35 inch or greater) and provides a “rough order-of-magnitude” value for sizing a heat sink. For a first calculation, let’s assume a heat sink of roughly  $6 \times 4 \times 2$  inch (48 cubic inches). From **Fig 10.34**, this yields a  $\theta_{sa}$  of about  $1^\circ\text{C/W}$ .

Returning to **Fig 10.33**, we can now calculate the approximate temperature increase of a single 2N3055:

$$\delta T = P \theta_{total} = (110 \text{ W}) (1.52^\circ\text{C/W} + 0.5^\circ\text{C/W} + 1.0^\circ\text{C/W}) = 332^\circ\text{C}$$

Given the ambient temperature of  $25^\circ\text{C}$ , this puts the junction temperature  $T_j$  of the 2N3055 at  $25 + 332 = 357^\circ\text{C}$ ! This is

clearly too high, so let’s work backward from the air end and calculate just how many transistors we need to handle the heat.

First, putting more 2N3055s in parallel means that we will have the thermal model illustrated in **Fig 10.35**, with several identical  $\theta_{jc}$  and  $\theta_{cs}$  in parallel, all funneled through the same  $\theta_{sa}$  (we have one heat sink).

Keeping in mind the physical size of the project, we could comfortably fit a heat sink of approximately 120 cubic inches ( $6 \times 5 \times 4$  inches), well within the range of commercially available heat sinks. Furthermore, this application can use a heat sink where only “wire access” to the transistor connections is required. This allows the selection of a more efficient design. In contrast, RF designs require the transistor mounting surface to be completely exposed so that the PC board can be mounted close to the transistors to minimize parasitics. Looking at **Fig 10.34**, we see that a 120-cubic-inch heat sink yields a  $\theta_{sa}$  of  $0.55^\circ\text{C/W}$ . This means that the temperature of the heat sink when dissipating 110 W will be  $25^\circ\text{C} + (110 \text{ W}) (0.55^\circ\text{C/W}) = 85.5^\circ\text{C}$ .

Industrial experience has shown that silicon transistors suffer substantial failure when junctions are operated at highly elevated temperatures. Most commercial and military specifications will usually not permit design junction temperatures to exceed  $125^\circ\text{C}$ . To arrive at a safe figure for our maximum allowed  $T_j$ , we must consider the intended use of the power supply. If we are using it in a 100% duty-cycle transmitting application such as RTTY or FM, the circuit will be dissipating 110 W continuously. For a lighter duty-cycle load such as CW or SSB, the “key-down” temperature can be slightly higher as long as the average is less than  $125^\circ\text{C}$ . In this intermittent type of service, a good conservative figure to use is  $T_j = 150^\circ\text{C}$ .

Given this scenario, the temperature rise across each transistor can be  $150 - 85.5 = 64.5^\circ\text{C}$ . Now, referencing **Fig 10.35**, remembering the total  $\theta$  for each 2N3055 is  $1.52 + 0.5 = 2.02^\circ\text{C/W}$ , we can calculate the maximum power each 2N3055 can safely dissipate:

$$P = \frac{\delta T}{\theta} = \frac{64.5^\circ\text{C}}{2.02^\circ\text{C/W}} = 31.9 \text{ W}$$

Thus, for 110 W full load, we need four 2N3055s to meet the thermal requirements of the design. Now comes the big question: What is the “right” heat sink to use? We have already established its requirements: it must be capable of dissipating 110 W, and have a  $\theta_{sa}$  of  $0.55^\circ\text{C/W}$  (see above).

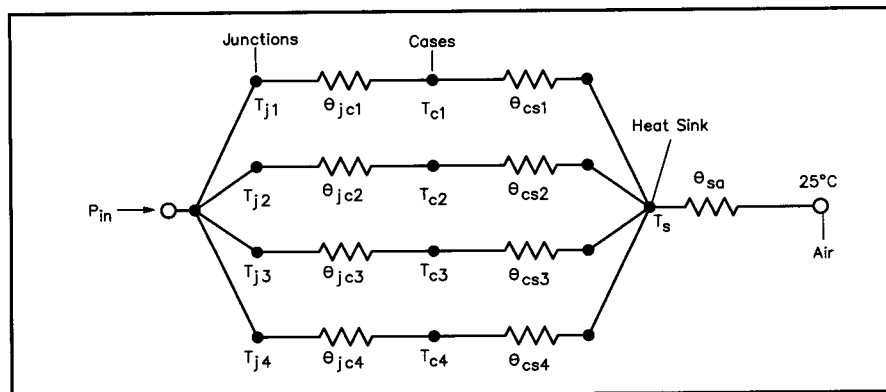

A quick consultation with several manufacturer’s catalogs reveals that Wakefield Engineering Co model nos. 441 and 435 heat sinks meet the needs of this application.<sup>2</sup> A Thermalloy model no. 6441 is suitable as well. Data published in the catalogs of these manufacturers show that in natural-convection service, the expected temperature rise for 100 W dissipation would be just under  $60^\circ\text{C}$ , an almost perfect fit for this application. Moreover, the no. 441 heat sink can easily mount four TO-3-style 2N3055 transistors. See **Fig 10.36**. Remember: heat sinks should be mounted with the fins and transistor mounting area vertical to promote convection cooling.

The design procedure just described is applicable to any circuit where heat buildup is a potential problem. By using the thermal-resistance model, we can easily calculate whether or not an external means of cooling is necessary, and if so, how to choose it. Aside from heat sinks, forced air cooling (fans) is another common method. In commercial transceivers, heat sinks with forced-air cooling are common.

## Transistor Derating

Maximum ratings for power transistors are usually based on a case temperature of  $25^\circ\text{C}$ . These ratings will decrease with increasing operating temperature. Manufacturer’s data sheets usually specify a derating figure or curve that indicates how the maximum ratings change per degree rise in temperature. If such information is not available (or even if it is!), it is a good

<sup>2</sup>There are numerous manufacturers of excellent heat sinks. References to any one manufacturer are not intended to exclude the products of any others, nor to indicate any particular predisposition to one manufacturer. The catalogs and products referred to here are from: EG&G Wakefield Engineering (see the Address List in the References chapter).

**Fig 10.35—Thermal model for multiple power transistors mounted on a common heat sink.**

rule of thumb to select a power transistor with a maximum power dissipation of at least twice the desired output power.

## Rectifiers

Diodes are physically quite small, and they operate at high current densities. As a result their heat-handling capabilities are somewhat limited. Normally, this is not a problem in high-voltage, low-current supplies. The use of high-current (2 A or greater) rectifiers at or near their maximum ratings, however, requires some form of heat sinking. Frequently, mounting the rectifier on the main chassis (di-

rectly, or with thin mica insulating washers) will suffice. If the diode is insulated from the chassis, thin layers of silicone grease should be used to ensure good heat conduction. Large, high-current rectifiers often require special heat sinks to maintain a safe operating temperature. Forced-air cooling is sometimes used as a further aid.

## Forced-Air Cooling

In Amateur Radio today, forced-air cooling is most commonly found in vacuum-tube circuits or in power supplies built in small enclosures, such as those in solid-state transceivers or computers. Fans or blowers are commonly specified in cubic feet per minute (CFM). While the nomenclature and specifications differ from those used for heat sinks, the idea remains the same: to offer a low thermal resistance between the inside of the enclosure and the (ambient) exterior.

For forced air cooling, we basically use the "one resistor" thermal model of Fig 10.32. The important quantity to be determined is heat generation,  $P_{in}$ . For a power supply, this can be easily estimated as the difference between the input power, measured at the transformer primary, and the output power at full load. For variable-voltage supplies, the worst-case output condition is minimum voltage with maximum current.

A discussion of forced-air tube cooling appears in the **Amplifiers** chapter.

## TEMPERATURE STABILITY

Aside from catastrophic failure, temperature changes may also adversely affect circuits if the TCs of one or more components is too large. If the resultant change is not too critical, adequate temperature stability can often be achieved simply by using higher-precision components with low TCs (such as NP0/C0G capacitors or metal-film resistors). For applications where this is impractical or impossible (such as many solid-state circuits), we can minimize temperature sensitivity by *compensation* or *matching*—using temperature coefficients to our advantage.

Compensation is accomplished in one of two ways. If we wish to keep a certain circuit quantity constant, we can interconnect pairs of components that have equal but opposite TCs. For example, a resistor with a negative TC can be placed in series with a positive TC resistor to keep the total resistance constant. Conversely, if the important point is to keep the *difference* between two quantities constant, we can use components with the *same* TC so that the pair "tracks." That is, they both change by the same amount with temperature.

An example of this is a Zener reference circuit. Since the I-V equation for a diode is strongly affected by operating temperature, circuits that use diodes or transistors to generate stable reference voltages must use some form of temperature compensation. Since, for a constant current, a reverse-biased PN junction has a negative voltage TC while a forward-biased junction has a positive voltage TC, a good way to temperature-compensate a Zener reference diode is to place one or more forward-biased diodes in series with it.

## RF Heating

RF current often causes component heating problems where the same level of dc current may not. An example is the tank circuit of an RF oscillator. If several small capacitors are connected in parallel to achieve a desired capacitance, skin effect will be reduced and the total surface area available for heat dissipation will be increased, thus significantly reducing the RF heating effects as compared to a single large capacitor. This technique can be applied to any similar situation; the general idea is to divide the heating among as many components as possible.

## CAD TOOLS FOR CIRCUIT DESIGN

Hams today enjoy the easy availability of tremendous computing power to aid them in their hobby. A commercial application that computers perform very well is circuit simulation. Today anyone with access to a computer software bulletin board is likely to find shareware or other inexpensive software to perform such analysis. Indeed, ARRL now offers *ARRL Radio Designer*, which provides excellent RF design capabilities at a reasonable price. *Radio Designer* is discussed in October 1994 *QST* and an ongoing *QST* column, "Exploring RF."

The advantages of computer circuit simulation over pencil-and-paper calculation are many. For example, while the analysis of a small circuit, say 5 to 10 components, may be recomputed without too much effort if the design changes, the same is not true for a 50 to 100-component circuit. Indeed, the larger circuit may require too many simplifying assumptions to calculate by hand at all. It is much faster to watch and adjust the response of a circuit on a computer screen than to breadboard the circuit in search of the same information.

All circuit simulators, including *SPICE*, work from a *netlist* that is simply a component-by-component list of the circuit that tells the program how components are in-

(A)

(B)

**Fig 10.36—An EG&G Wakefield 441 heat sink with four 2N3055 transistors mounted.**

terconnected. The program then uses standard techniques of numerical analysis and matrix mathematics to calculate the analysis you wish to perform. Common analyses include dc and ac bias and operating point calculations, frequency response curves, transient analysis (looking at waveforms in the circuit over a specified period of time), Fourier transforms, transfer functions, two-port parameter calculations, and pole-zero analysis. Many packages also perform sensitivity analyses: calculating what happens to the voltages and currents as you sweep the value(s) of an individual component (or group of components), and statistical analyses: determining the variational "window" of the system response that would result if all component values randomly varied by a given tolerance (also known as *Monte Carlo* analysis).

### Beware!

Before we turn to a brief introduction to circuit simulation for the amateur, a *caution* to the reader is definitely in order: However fast and powerful the computer may seem, keep in mind that it is only another tool in your workshop, just like your 'scope or soldering iron. Circuit simulations are only meaningful if you can interpret the results correctly, and a good initial circuit design based on real experience and common sense is mandatory. *SPICE* and other programs have no problem with a bench-top power supply delivering 10,000 V to a 5- $\Omega$  resistor because you made a mistake when specifying the circuit. Software also won't remind you that the resistor better be rated for 20 megawatts! Remember, the real power behind any simulation software is *your mind*.

### SPICE

The electronics industry has been the main consumer of circuit simulation packages ever since the development of *SPICE* (or *Simulation Program with Integrated Circuit Emphasis*) on main-frame systems in the mid 1970s. While many companies today produce other simulation software, *SPICE* remains the *de facto* industry standard. *SPICE* itself now exists in many "flavors" and specially tailored versions for desktop computers are sold by several companies, including *PSPICE* by Microsim Corp and *HSPICE* by Intusoft. In fact, an "evaluation" copy of *PSPICE* has been placed in the public domain by Microsim and is probably the easiest and most inexpensive way for amateurs to begin circuit simulation. It may be obtained (with a companion reference book) from technical bookstores, and

also from many ftp sites on the Internet. Two popular sites are:

```
oak.oakland.edu
/pub/msdos/electric
ftp.wustl.edu
/systems/tmp/msdos/electric
```

### A Basic Circuit

Consider the simple RC low-pass filter in Fig 10.37A. To simulate this circuit, we must first precisely describe it. Conventional sets ground as *node* 0, and we label all other nodes (a node is a place where two or more components meet) with numbers, as shown in the figure. We give each element a unique name, and then prepare a *netlist*, listing each element with the numbers of its "+" and "-" nodes (*SPICE* assumes the ground node to be labeled 0), and its value, as shown at B in the figure.

The question we wish to answer by simulation is the following: what is the frequency response of this filter? Of course, for this simple problem we can calculate the answer by hand. The cutoff frequency of a simple RC filter is given by:

$$f_{co} = \frac{1}{2\pi RC} \quad (17)$$

where

$f_{co}$  = cutoff frequency (-3 dB)  
 $R$  = resistance, in ohms  
 $C$  = capacitance, in farads.

In this case  $f_{co}$  is 1.59 kHz. Beyond this, with one storage element (the capacitor) we expect the output to decrease by 20 dB for each decade of frequency.

Fig 10.38 shows the graph of the ratio of output to input voltages  $V_{out}/V_{in}$ , in dB for that frequency range as calculated by *SPICE*. Note the 3-dB point is indeed 1.59 kHz, and above that frequency the response drops by 20-dB/decade.

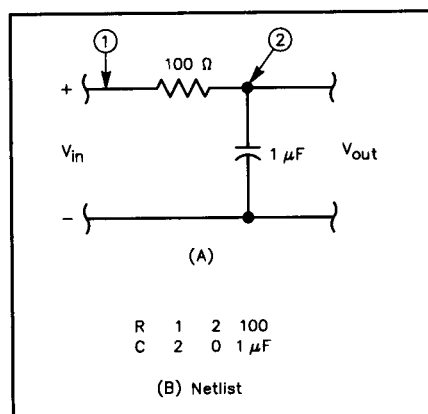

Fig 10.37—A, a simple RC low-pass filter.

At this point we could use this circuit to ask some "What if?" questions, but for a circuit this simple we could answer those questions with pencil and paper. Below is a more extensive design to show the power of simulation, where "What if?" questions and the interaction of numerous components are much more easily and clearly examined with a computer.

### Case Study No. 1: Transmitter Low-Pass Filter Design

Our first design illustration will be a low-pass transmitter filter for 10 m and down that provides good attenuation at TV channel 2 and above. Such a filter is a real example of the effects discussed in this chapter and their magnitude. The chosen design specifications are as follows:

Insertion Loss:  $\leq 0.5$  dB for  $f < 29.7$  MHz  
 Attenuation:  $\geq 40$  dB for  $f > 54$  MHz (TV channel 2)

We will design the filter using the design tables found in the **References** chapter, and then use circuit simulation to correct, tweak, and verify our design. Our objective is to include all the parasitic effects we have been discussing, and examine their effect and possible degradation of the filter transfer function. We will examine:

1. Attenuation due to series resistance in inductors.
2. Effects due to component tolerance.
3. Self-resonance effects of the capacitors.

From common sense, more components in the filter mean greater total possible parasitic effects, and greater total possible variation from the desired response curve. Therefore, we will choose the filter with the least number of components that can meet the specified rolloff (40 dB from 29.7 to 54 MHz). The filter tables give parameters for the three common filter classes—

Fig 10.38—Low-pass filter output simulation.

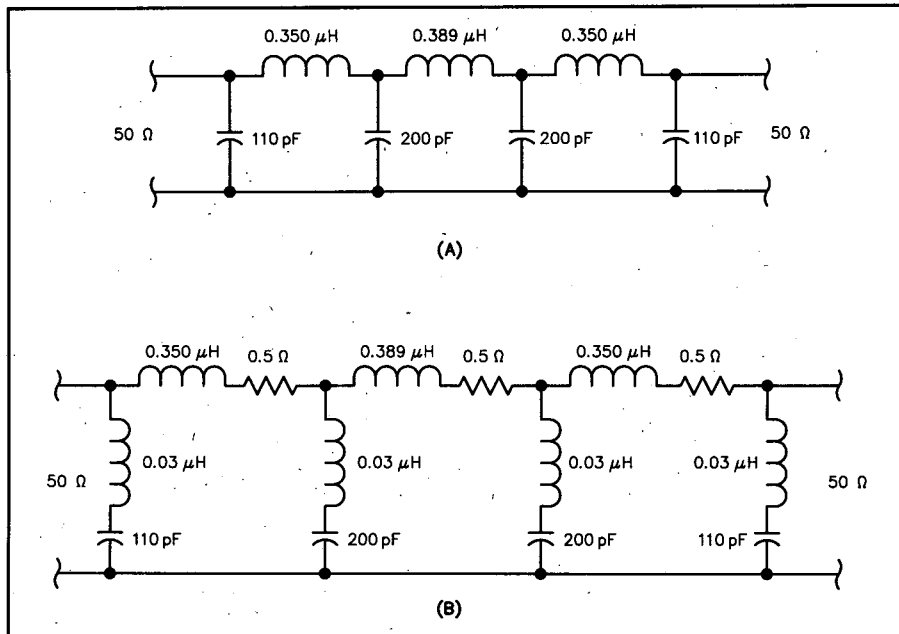

Butterworth, Chebyshev, and Elliptic. Normalizing the filter specifications gives a ratio of  $f_{40\text{dB}} / f_{\text{co}} = 54 / 29.7 = 1.82$ , or equivalently, a rolloff of  $40 / \log_{10}(1.82) = 154$  dB/decade. Scanning the filter tables, we see that the minimum filter configurations that meet our needs are a 10-element Butterworth, a 7-element Chebyshev (at various ripple factors), and a 5-branch (7-element) Elliptic. The Butterworth will require 10 elements even though at first glance it seems an 8-element, at 160 dB/decade, should fit the bill. The reason for this is that the Butterworth filter has a 3-dB loss at cut-off. Obtaining  $< 0.5$  dB in the passband requires pushing the cutoff frequency to around 33 MHz, which then requires 187 dB/decade, 10 elements.

We therefore eliminate the Butterworth. The Chebyshev and Elliptic designs tie for the fewest elements (seven). The capacitive input/output Chebyshev contains 3 Ls and 4 Cs, the inductive version contains 4 Ls and 3 Cs, and the Elliptic has 2 Ls and 5 Cs. Given these three choices, we chose the 7-element capacitive input/output Chebyshev, even though the Elliptic may perform better, because its ideal rolloff curve is simpler than the Elliptic and the effects we are trying to show will be more easily discernible.

Scanning the appropriate filter design table, it seems filter 52 will fit the bill if we scale it up by a factor of 10, using the procedure outlined in the **Filters** chapter. This yields a cutoff frequency  $f_{\text{co}} = 32.6$  MHz and a 40-dB frequency of 51.9 MHz—plenty of room, or so it would seem. This design, which we'll call Filter A, is shown in **Fig 10.39A**.

The calculated frequency response from *SPICE* for Filter A is shown by the line labeled "Ideal" in **Fig 10.40**. (NOTE: The *SPICE* input files that were used for generating the figures are grouped at the end of the discussion). The large figure shows the complete response while the inset shows a magnified picture around the cut-off frequency. At this stage the design seems to be performing nicely. Let's build it, okay? Not so fast. At this point, the inductors and capacitors are still perfectly ideal.

We should now approximate real effects as best we can. We know the inductors have series resistance—but how much? An approximate value (within a factor of 2) should be good enough. Since this filter should be able to handle 100 W of power, we should wind our coils ourselves using fairly large wire with an air core; this will also reduce the series resistance. Using the inductance formula from the **AC Theory** chapter, a 1-inch 0.5  $\mu\text{H}$  coil with a di-

**Fig 10.39—Filter A, the initial design for the low-pass TVI filter. Values are in  $\mu\text{H}$  and pF. A, ideal case. B, nominal case including parasitics.**

**Fig 10.40—Response curves for Filter A for Ideal and Nominal cases.**

ameter of 0.5 inch, wound from #14 wire with 0.5-inch leads on each end, takes about 7 inches of wire, which for #14 translates to a resistance of about 0.01  $\Omega$ . This is a *dc* value! Counting skin effect increases this to about 0.3  $\Omega$ . We'll round this up to 0.5  $\Omega$  to be conservative.

The capacitors also will have some parasitic inductance. Again using the value computed above for the 470-pF ca-

pacitor, we'll round this up as well to 0.03  $\mu\text{H}$ . We'll ignore the parasitic capacitance of the inductors just to keep it from getting too complicated; it's probably the smallest of all these effects anyway.

With these additions, the electrical circuit for Filter A now looks like **Fig 10.39B**. This is now approaching the limits of hand calculations. *SPICE* has no problem, however, and the response is shown by the

“Nominal” curve in Fig 10.40, again with the cutoff region magnified in the inset. Note that the notches produced by the capacitor self-resonances actually *help* the stopband attenuation. *However*, the series resistances have now increased the insertion loss at 29.7 MHz to slightly more than 1 dB! Our filter already shows signs of failure, but we have one more step to perform before reevaluating our design.

The curves in Fig 10.40 assume that the values of our components are *exactly*

what we say they are, but the real capacitors we buy will have a tolerance rating, probably in the range of  $\pm 10\%$ . Granted, if we have the means to measure capacitors, we could hand-pick components with exactly the required values from a bag of capacitors, but our goal is to not to have to do that. We are hand-winding our inductors, and we will assume a tolerance of  $\pm 20\%$ .

We can ask *SPICE* to perform a “Monte Carlo” or statistical analysis to answer the

question, “How much can the filter response change from the nominal response if each component value actually falls randomly within a certain tolerance range?” Such an analysis is conducted by recalculating the filter response *n* times, each time selecting a random value for each component from the specified range. To illustrate, say we performed this analysis on the simple low-pass filter mentioned earlier, where  $R = 100\ \Omega$ ,  $\pm 5\%$ , and  $C = 1\ \mu\text{F}$ ,  $\pm 10\%$ . On each run of the analysis, *SPICE* would randomly choose a resistor value between 95 and 105  $\Omega$  and a capacitor value between 0.9 and 1.1  $\mu\text{F}$ , and compute the new filter response.

Obviously, the more “trials” we perform in our statistical analysis, the more confidently we can say we will see the total possible variation. For our filter design, we performed 80 trials. The results are shown in Fig 10.41. We now see a response “band” instead of a single response. While we can easily guarantee a cutoff of 40 dB at 54 MHz, the best we can do at 29.7 MHz is about 8 dB! In fact, from the magnified graph we see that we can guarantee 0.5 dB only up to about 17 MHz or so. Accounting for tolerances has produced the worst effect!

Let’s tweak the design to compensate. The outer tolerance of our response band for 40 dB is about 43 MHz. Let’s scale the filter *up* to place this point at 54 MHz. Hopefully by so doing, we will move the response band near the cutoff region inside our specs. This is a scaling of  $54/43 \approx 1.25\times$ , placing the new cutoff at  $32.6 \times 1.25 = 40.7\ \text{MHz}$ . Scaling the components appropriately, we arrive at the new circuit of Fig 10.42, which we’ll call Filter B.

The new “Ideal” and “Nominal” graphs are shown in Fig 10.43. The same parasitic values for Filter A were used for Filter B. Statistical analysis results for Filter B, where we assumed the same tolerances as for Filter A, are shown in Fig 10.44. As anticipated, the response window at 40 dB falls snugly inside 54 MHz. Now, the  $f_{co}$  specification is still inside the response band, but the majority of curves do fall above it.

Given these results, at this point we could proceed in two directions. If we insist on the more robust design that has the tolerances factored in, we would decide that we do in fact need a steeper rolloff and would repeat this analysis for a 9-element Chebyshev filter, pushing the cutoff frequency out a little bit further. If we have the luxury of hand-picking precise component values, we could

Fig 10.41—Statistical analysis results for Filter A.

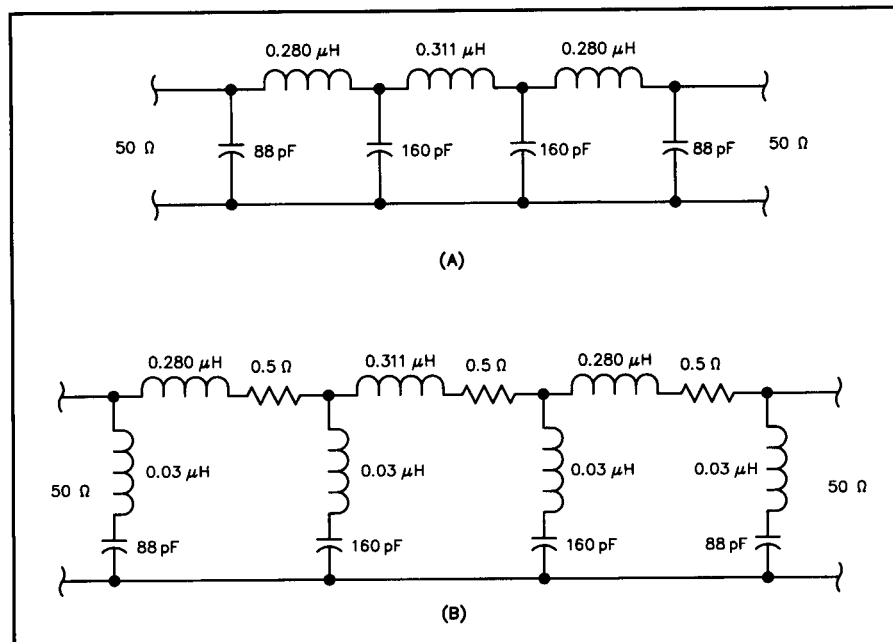

Fig 10.42—Filter B circuit and component values.

stop here, since the nominal response curve is more than adequate. The main purpose of this example was to illustrate the power of simulation when the circuit gets complicated, and we wish to ask "What if?" questions.

### Case Study No. 2: Amplifier Distortion

Another application where computer circuit simulation does a much faster, easier, and more accurate job than pencil and paper is Fourier analysis. Recall that any periodic signal can be broken down into a sum of sine waves of different am-

plitudes whose frequencies are multiples of the fundamental frequency of the signal. Performing such an analysis allows us to identify how much signal power is contained in the fundamental frequency and its harmonics. A Fourier transform is the representation of a signal by its frequency components, and resembles what you would see if you fed the signal into a spectrum analyzer.

Consider the amplifier circuit in Fig 10.45, which is a simple common-emit-

ter audio amplifier. The frequency response of its voltage gain, calculated from *SPICE*, is shown in Fig 10.46. Pay particular attention to the voltage gain at 1 kHz, which is 148, or 43.4 dB. If we place a small ac signal on the input as shown in Fig 10.45, the output will be a faithfully amplified sine wave. However, the amplifier is powered from a 9-V supply, so when the output reaches this level, the waveform will begin to show signs of clipping. For a

### Ready-Made Models

Many manufacturers provide computer models or data helpful when modeling their devices. William Sabin, WØIYH, author of the **Transceivers** chapter, does quite a bit of computer modeling, so he provided this list of resources (for IBM PCs and compatible computers). Do not write to Mr. Sabin for this software, but rather contact the manufacturer listed.

1. Avantek, "S Parameter Performance and Data Library." Collection of transistor S Parameters. To be used in *SPICE* programs. Two disks.

2. Linear Technology Co, "*SPICE* Models for LTC Linear IC Products." A second disk contains "Noise Models" for *SPICE* that are used to predict noise performance using *SPICE*.

3. Burr-Brown, "*PSPICE* Macromodels" for Burr-Brown op amps.

4. Analog Devices Co, "*SPICE* Model Library" for Analog Devices Op amps and other linear ICs.

5. Texas Instruments, "Operational Amplifier, Comparator and Building Block Macromodels."

6. Motorola, "Discrete Data Disk."

7. Motorola, "Scattering Parameter Library," for EESOF *Touchstone*.

8. Motorola, "Scattering Parameter Plotting Utility," for EESOF *Touchstone*.

9. Motorola, "Impedance Matching Program," for EESOF *Touchstone*.

10. ARRL, "UHF/Microwave Experimenter's Manual," Software Disk.

11. Precision Monolithics, "*SPICE* Macro-Models," op amps.

12. Tektronix, "BJT *SPICE* Subcircuits."

13. Harris, "*SPICE* Macro-Models," op amps.

Fig 10.44—Statistical analysis results for Filter B.

Except as indicated, decimal values of capacitance are in microfarads ( $\mu\text{F}$ ); others are in picofarads (pF); resistances are in ohms; k=1,000, M=1,000,000.

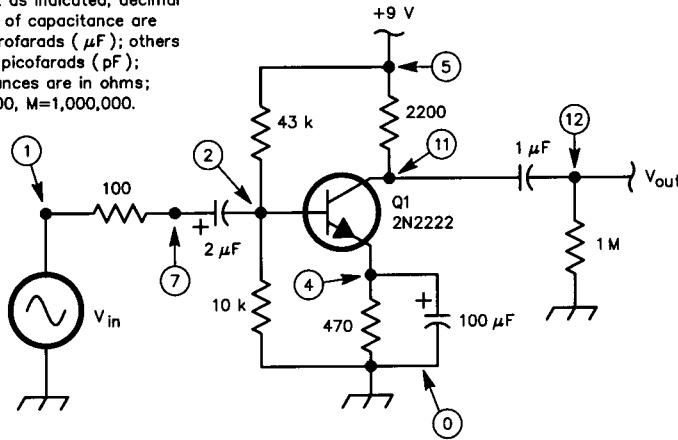

Fig 10.45—Common-emitter audio amplifier used in the text.

Fig 10.46—Frequency response of the voltage gain of the amplifier in Fig 10.45. The gain at 1 kHz is approximately 148 or 43 dB.

Fig 10.47—Output waveforms for 1-kHz inputs of different magnitudes. Note the clipping that begins to appear at approximately  $V_{in} = 0.03$  V.

1-kHz signal, this will occur at roughly  $V_{in} = 4.5/148 = 0.03$  V amplitude.

Total Harmonic Distortion is a common figure of merit for audio amplifiers, and is defined as

$$\text{THD} = \frac{P_H}{P_F} \times 100 \quad (18)$$

where

THD = total harmonic distortion, in percent

$P_H$  = total power in all harmonics above the fundamental

$P_F$  = power in fundamental.

*SPICE* readily calculates the Fourier content of a signal and also THD. Assume that we will tolerate 5% THD for our design. What is the maximum swing we can allow the input signal?

Fig 10.47 shows the output waveforms that *SPICE* calculates for our circuit with input signals of 0.001, 0.003, 0.01, 0.03 and 0.1-V amplitude. Note that, as expected, the last two input voltages show definite signs of clipping. What is not so evident is that the smaller inputs have some distortion as well, due to the small but finite nonlinearity of the amplifier even at those voltages.

Fig 10.48 shows the relative amplitudes of the harmonic content (Fourier transform) of the Fig 10.47 waveforms, all normalized to fundamental = 100%. You can see how the higher harmonics grow in strength as the signal increases, especially when the clipping starts. The THD for each case is also shown, and from this simulation we see we must limit our input to somewhere between 0.003 and 0.01 V. We would pin this down more closely by running another simulation around this "window."

A caution is in order here. Circuit models have limits just as do circuits. The models apply only over a limited dynamic range. that's why we have both small- and large-signal models. One challenge of CAD is determining the limits of your models. There is more information about this in the sections on modeling transistors.

## Conclusion

Start using your computer for more challenging tasks than QSL bookkeeping! Just like any other piece of software, you'll find yourself using *SPICE* to do things you never thought of trying before. It can even do digital circuits and transmission lines (no antennas, though). Remember that a computer is only as smart as the person using it! Have fun!

# LOW-FREQUENCY TRANSISTOR MODELS

## THE FUNDAMENTAL EQUATIONS

Design models are based on the physics of the components we use. The complexity of models can vary widely though, and many times we can use very simple models to achieve our goals. Increasingly complex models are developed and used only when demanded by the circuit application.

In this discussion, we will focus on simple models for bipolar transistors (BJTs) and FETs. These models are reasonably accurate at low frequencies, and they are of some use at RF. For more sophisticated RF models, look to profes-

sional RF-design literature. This discussion is adapted from Wes Hayward's *Introduction to RF Design*. Derivations of the material shown here appear in that book, an excellent text for the beginning RF designer.

This discussion is centered on NPN BJTs and N-channel JFETs. The material here applies to PNPs and P-channel FETs when you simply change the bias polarities.

First, consider the bipolar transistor as a current controlled device. When the base current controls the collector current, this equation defines the transistor operation

$$I_c = \beta I_b \quad (19)$$

where  $\beta$  = common-emitter current gain.

When we consider a transistor as a voltage-controlled device, this equation describes it (emitter current,  $I_e$ , in terms of base-emitter voltage,  $V_{be}$ ):

$$I_e = I_{es} [\exp(qV/kT) - 1] \\ \approx I_{es} \exp(qV/kT) \quad (20)$$

where

$V = V_{be}$

$q$  = electronic charge

$k$  = Boltzmann's constant

$T$  = temperature in kelvins (K)

$I_b$  = emitter saturation current, typically  $1 \times 10^{-13}$  A.

Both equations approximate models of more complex behavior. Equation 20 is a simplification of the first Ebers-Moll model (Ref 1). More sophisticated models for BJTs are described by Getreu in Ref 2. Equations 19 and 20 apply to both transistor dc biasing and signal design.

The operation of an N-channel JFET can be characterized by

$$I_D = I_{DSS} (1 - V_{sg}/V_p)^2 \quad (21)$$

where

$I_{DSS}$  = drain saturation current

$V_{sg}$  = the source-gate voltage

$V_p$  = the pinch-off voltage.

This equation applies on so long as  $V_{sg}$  is between 0 and  $V_p$ . JFETs are seldom

used with the gate-to-channel diode forward biased. Drain current,  $I_D$ , is 0 when  $V_{sg}$  exceeds  $V_p$ . This equation applies to both biasing and signal design.

Now that we have some basic equations, let's go on to some other areas:

- Small-signal amplifier design (and application limits).

- Large-signal amplifier design (distortion from nonlinearity).

## BIPOLAR TRANSISTORS (SMALL SIGNALS)

Transistors are usually driven by both biasing and signal voltages. Small-signal models treat only the signal components. We will consider bias and nonlinear signal effects later.

### A Basic Common-Emitter Model

Fig 10.49 shows a BJT amplifier. The circuit is adequately described by equation 19. A mathematical analysis of the control and output currents and voltages yields the small-signal common-emitter amplifier model shown in Fig 10.50. This is the most common of all transistor small-signal models, a controlled current source with emitter resistance.

In order to use this model, however, we must have a value for  $r_e$ . That's no trouble, however,  $r_e = kT/qI_0$ , or  $r_e = 26/I_e$ , where  $I_e$  is the dc bias current in milliamperes. This value applies at a typical ambient temperature of 300 K.

The device output resistance is infinite because it is a pure current source, which is a good approximation for most silicon transistors at low frequencies. In use, the collector lead would feed a load resistor,  $R_L$ . For this model, that resistance must be small enough so that the collector bias voltage is positive for the chosen bias current.

### Gain vs Frequency

Fig 10.50 is a low frequency approximation. As signal frequency increases, however, current gain appears to decrease. The low-frequency current gain is  $\beta_0$ .  $\beta_0$  is constant through the audio spectrum, but it eventually decreases, and at some high frequency it will drop by a factor of 2 for each doubling of signal frequency. A transistor's frequency vs current gain relationship is specified by its *gain-bandwidth product*, or  $F_T$ .  $F_T$  is the frequency at which the current gain is 1. Common transistors for lower RF applications might have  $\beta_0 = 100$  and  $F_T = 500$  MHz. The frequency where current gain is  $\beta_0/\sqrt{2}$  is called  $F_\beta$  and related to  $F_T$  by  $F_\beta = F_T/\beta_0$ .

The frequency dependence of current gain is modeled by adding a capacitor across the base resistor of Fig 10.50A; Fig 10.51, the *hybrid-pi* model results. The

Fig 10.49—Bipolar transistor with voltage bias and input signal.

Fig 10.50—Simplified low-frequency model for the bipolar transistor, a "beta generator with emitter resistance."  $r_e = 26/I_e$  (mA dc).

Fig 10.51—The hybrid-pi model for the bipolar transistor.

capacitor reactance should equal the low-frequency input resistance,  $(\beta + 1)r_e$ , at  $F_\beta$ . This simulates a frequency-dependent current gain.

### Three Simple Models

Even though transistor gain varies with frequency, the simple model is still useful under certain conditions. Calculations show that the simple model is valid, with  $\beta = F_T / F$ , for frequencies well above  $F_\beta$ . The approximation worsens, however, as

the operating frequency ( $f_0$ ) approaches  $F_T$ . Fig 10.52 shows small-signal models for the three common amplifier configurations: common emitter (ce), common base (cb) and common collector (cc).

The common-collector amplifier, unlike the common-emitter or common-base configurations, has a finite output resistance. This resistance is calculated by short circuiting the input voltage source,  $V_s$ , and "driving" the output port with either a voltage or current source. The re-

sult is the equation for  $R_{out}$  that appears in the figure.

The common-collector example shows characteristics that are more typical of practical RF amplifiers than the idealized ce and cb amplifiers. Specifically, the input resistance is a function of both the device and the termination at the output. The output resistance is critically dependent upon the input driving source resistance.

These examples have used the simplest of models, the controlled current genera-

tor with an emitter resistance,  $r_e$ . Better models are necessary to design at high frequencies. The simplified hybrid-pi of Fig 10.51 is often suitable.

### Small-Signal Design at RF

Fig 10.53 shows a better small-signal model for RF design that expands on the hybrid-pi. Consider the physical aspects of a real transistor: There is some capacitance across each of the PN junctions ( $C_{cb}$  and  $C_{\pi}$ ) a capacitance from collector to emitter ( $C_c$ ). There are also capacitances between the device leads ( $C_e$ ,  $C_b$  and  $C_c$ ). There is a resistance in each current path, emitter to base and collector. From emitter to base, there is  $r_{\pi}$  from the hybrid-pi model and  $r'_b$ , the “base spreading” resistance. From emitter to collector is  $R_0$ , the output resistance. The leads from the die to the circuit present three inductances.

Manual circuit analysis with this model doesn’t look like much fun. It’s best tackled with the aid of a computer and specialized software. Other methods are presented in Hayward’s *Introduction to RF Design*.

Don’t be intimidated by the complexity of the model, however. Surprisingly accurate results may be obtained, even at RF, from the simple models. Simple models also give a better “feel” for device characteristics that might be obscured by the mathematics of a more rigorous treatment. Use the simplest model that describes the important features of the device and circuit at hand.

### Biasing Bipolar Transistors

Proper biasing of the bipolar transistor is more complicated than it might appear. The Ebers-Moll equation would suggest that a common-emitter amplifier could be built as shown in Fig 10.49, grounding the emitter and biasing the base with a constant voltage source. Further examination shows that this presents many problems. The worst is that constant-voltage bias ultimately leads to thermal runaway. Constant-voltage biasing applied to the base is almost never used.

Constant base-current biasing is shown in Fig 10.54A. This works reasonably well if the current gain is known, which is rarely true. A transistor with a typical  $\beta$  of 100 might actually have values ranging from 50 to 250. A slightly improved method is shown in Fig 10.54B, where the bias is derived from the collector. As current increases collector voltage decreases, as does the bias current flowing through  $R_1$ . This ensures operation in the transistor active region.

The most common biasing method is shown in Fig 10.55A. The device model

used, shown in Fig 10.55B, is based on the Ebers-Moll equation, which shows that virtually no transistor current flows until the base-emitter voltage reaches about 0.6. Then, current increases dramatically with small additional voltage change. The transistor is thus modeled as a current controlled generator with a battery in series with the base. The battery voltage is  $\Delta V$ .

The circuit is analyzed with nodal equations. The collector resistance,  $R_5$ , is initially assumed to be zero. The analysis results in three equations for  $V_b$ ,  $V_c'$  and  $I_b$ :

$$V_b = \frac{V_{cc} R_2 R_3 + \Delta V R_2 \left( \frac{R_4 + R_1}{\beta + 1} \right)}{R_3 R_4 + R_2 R_4 + R_2 R_3 + R_1 R_3 + \frac{R_1 R_2}{\beta + 1}} \quad (22)$$

$$V_c' = \frac{R_1 V_{cc} R_4 V_b + \beta R_1 R_4 \left( \frac{\Delta V - V_b}{R_3 (\beta + 1)} \right)}{R_1 + R_4} \quad (23)$$

$$I_b = \frac{V_b - \Delta V}{R_3 (\beta + 1)} \quad (24)$$

The emitter current is then  $I_b(\beta + 1)$ . Once the circuit has been analyzed,  $R_5$  may be taken into account. The final collector voltage is

$$V_c = V_c' - \beta I_b R_5 \quad (25)$$

The solution is valid so long as  $V_c$  exceeds  $V_b$ .

Analysis of these equations with a computer or hand-held programmable calculator shows that  $I_c$  is not a strong function of the transistor parameters,  $\Delta V$  and  $\beta$ . In practice, the base biasing resistors,  $R_1$  and  $R_2$ , should be chosen to draw a current that is much larger than  $I_b$  (to eliminate effects of  $\beta$  variation).  $V_b$  should be much larger than  $\Delta V$  to reduce the effects of variations in  $\Delta V$ .

Three additional biasing schemes are presented in Fig 10.56. All provide bias that is stable regardless of device parameter variations. A and B require a negative power supply. The circuit of Fig 10.56C uses a second, PNP, transistor for bias control. The PNP transistor may be replaced with an op amp if desired. All three circuits have the transistor emitter grounded directly. This is often of great importance in microwave amplifiers. These circuits may be analyzed using the simple model of Fig 10.55.

The biasing equations presented may be solved for the resistors in terms of desired

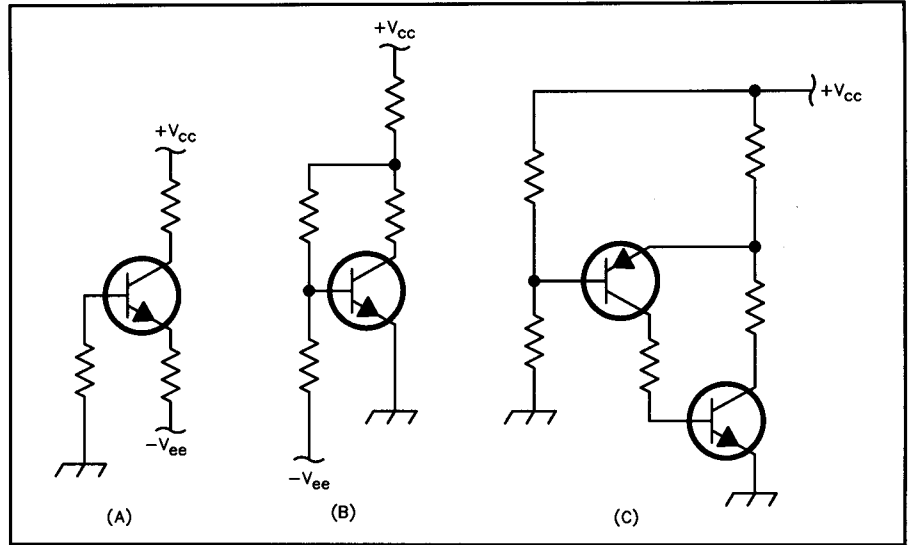

Fig 10.56—Alternative biasing methods. (A) and (B) use dual power supplies, (B) and (C) allow the emitter to be at ground while still providing temperature-stable operation.

Fig 10.57—Normalized relative current of bipolar transistor under sinusoidal drive at the base.

operating conditions and device parameters. It is generally sufficient, however, to repetitively analyze the circuit, using standard resistor values.

The small-signal transconductance of a common-emitter amplifier was found in the previous section. If biased for constant current, the small-signal voltage gain will vary inversely with temperature. Gain may be stabilized against temperature variations with a biasing scheme that causes the bias current to vary in *proportion to absolute temperature*. Such methods, termed PTAT methods, are often used in modern integrated circuits and are finding increased application in circuits built

from discrete components.

### Large-Signal Operation

The models presented in previous sections have dealt with small signals applied to a bipolar transistor. While small-signal design is exceedingly powerful, it is not sufficient for many designs. Large signals must also be processed with transistors. Two significant questions must be considered with regard to transistor modeling. First, what is a reasonable limit to accurate application of small-signal methods? Second, what are the consequences of exceeding these limits?

The same analysis of the Ebers-Moll

model yields an equation for collector current. The mathematics show that current will vary in a complicated way, for the sinusoidal signal voltage is embedded within an exponential function. Nonetheless, the output is a sinusoidal current if the signal voltage is sufficiently low.

The current of the equation may be studied by normalizing the current to its peak value. The result is relative current,  $I_r$ , which is plotted in Fig 10.57 for  $V_p$  values of 1, 10, 30, 100, and 300 mV. The 1-mV case is very sinusoidal. Similarly, the 10-mV curve is generally sinusoidal with only minor distortions. The higher amplitude cases show increasing distortion.

Constant base-voltage biasing is unusual. More often, a transistor is biased to produce nearly constant emitter current. When such an amplifier is driven by a large input signal, the average bias voltage will adjust itself until the time average of the nonlinear current equals the previous constant bias current. Hence, it is vital to consider the average relative current of the waveforms of Fig 10.57. This is evaluated through calculus.

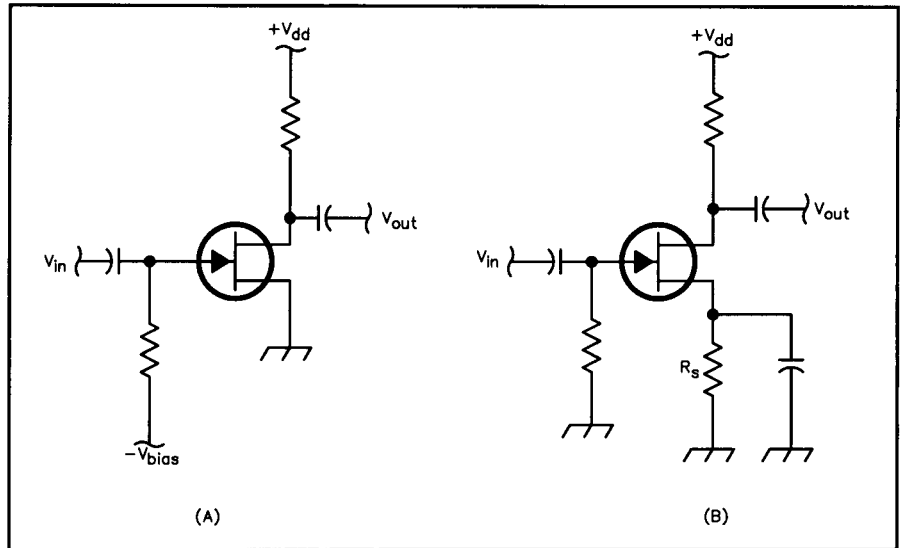

The average relative currents for the cases analyzed occur at the intersection of the curves with the dotted lines of Fig 10.57. For example, the dotted curve intersects the  $V_p = 300$ -mV waveform at an average relative current of 0.12. If an amplifier was biased to a constant current of 1 mA, but was driven with a 300-mV signal, the positive peak current would reach a value greater than the average by a factor of  $1/(0.12)$ . The average current would remain at 1 mA, but the positive peak would be 8 mA. The transistor would not conduct for most of the cycle.

The curves have presented data based upon the simplest of large-signal models, the Ebers-Moll equation. Still, the simple model has yielded considerable information. The analysis suggests that a reasonable upper limit for accurate small-signal analysis is a peak base signal of about 10 mV. The effect of emitter degeneration is also evident. Assume a transistor is biased for  $r_e = 5 \Omega$  and an external emitter resistor of  $10 \Omega$  is used. Only the  $r_e$  portion of the  $15 \Omega$  total is nonlinear. Hence, this amplifier would tolerate a 30-mV signal while still being well described with a small-signal analysis.

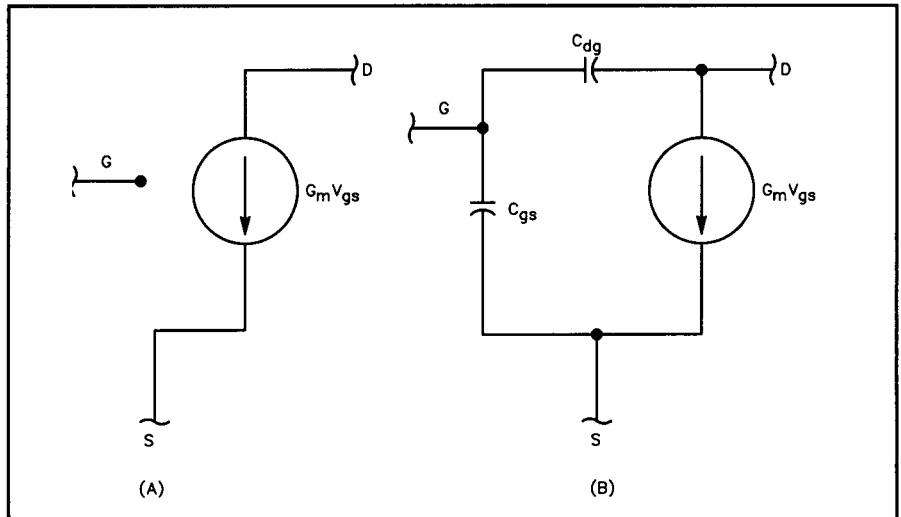

## FETS

An often used device in RF applications is the field-effect transistor (FET). There are many kinds: JFETs, MOSFETs and so on. Here we will discuss JFETs, with the understanding that other FETs are similar.

We viewed the bipolar transistor as controlled by either voltage or current. The

**Fig 10.58—Biasing schemes for a common-source JFET amplifier.  $-V_{bias}$  is normally adjusted to suit each device; there is a significant spread over a product run. Also note that some FETs can exhibit thermal runaway in some current/temperature ranges.**

**Fig 10.59—Small-signal models for the JFET. (A) is useful at low frequency, (B) is a modification to approximate high-frequency behavior.**

JFET, however, is purely a voltage controlled element, at least at low frequencies. The input gate is usually a reverse biased diode junction with virtually no current flow. The drain current is related to the source-gate voltage by:

$$I_D = I_{DSS} \left( 1 - \frac{V_{sg}}{V_p} \right)^2 \quad 0 \leq V_{sg} \leq V_p$$

$$I_D = 0 \quad V_{sg} > V_p \quad (26)$$

where  $I_{DSS}$  is the drain saturation current and  $V_p$  is the pinch-off voltage. Operation is not defined when  $V_{sg}$  is less than zero

because the gate diode is then forward biased. Equation 26 is a reasonable approximation as long as the drain bias voltage exceeds the magnitude of the pinch-off voltage.

## Biasing FETs

Two virtually identical amplifiers using N-channel JFETs are shown in Fig 10.58. The two circuits illustrate the two popular methods for biasing the JFET. Fixed gate-voltage bias, Fig 10.58A, is feasible for JFETs because of their favorable temperature characteristics. As the temperature of the usual FET increases, current decreases, avoiding the thermal-

runaway problem of bipolar transistors.

A known source resistor,  $R_s$  in Fig 10.58B, will lead to a known source voltage. This is obtained from a solution of equation 26:

$$V_{sg} = \frac{\left[ \frac{1}{R_s I_{DSS}} + \frac{2}{V_p} \right] - \left[ \left( \frac{1}{R_s I_{DSS}} + \frac{2}{V_p} \right)^2 - \left( \frac{2}{V_p} \right)^2 \right]^{0.5}}{\frac{2}{V_p^2}} \quad (27)$$

The drain current is then obtained by direct substitution.

Alternatively, a desired drain current less than  $I_{DSS}$  may be achieved with a proper choice of source resistor

$$R_s = \frac{V_p \left( 1 - \frac{I_D}{I_{DSS}} \right)^{0.5}}{I_D} \quad (28)$$

The small-signal transconductance of the JFET is obtained by differentiating equation 26

$$g_m = \frac{dI_D}{dV_{sg}} = \frac{-2I_{DSS}}{V_p} \left( 1 - \frac{V_{sg}}{V_p} \right) \quad (29)$$

The minus sign indicates that the equation describes a common-gate configuration. The amplifiers of Fig 10.58 are both common-source types and are described by equation 29 except that  $g_m$  is now positive. Small-signal models for the JFET are shown in Fig 10.59. The simple model is that inferred from the equations while the model of Fig 10.59B contains capacitive elements that are effective in describing high-frequency behavior. Like the bipolar transistor, the JFET model will grow in complexity as more sophisticated applications are encountered.

### Large-Signal Operation

Large-signal JFET operation is examined by normalizing the previous equation to  $V_p = 1$  and  $I_{DSS} = 1$  and injecting a sinusoidal signal. The circuit is shown in Fig 10.60. Also shown in the figure are examples for a variety of bias and sinusoid amplitude conditions. The main feature is the asymmetry of the curves. The positive portions of the oscillations are farther from the mean than are the negative excursions. This is especially dramatic when the bias,  $v_0$ , is large, which places the quiescent point close to pinch-off. With such bias and high-amplitude drive, conduction occurs only over a small fraction of the total input waveform period.

Fig 10.60—Relative normalized drain current for a JFET with constant voltage bias and sinusoidal signals. Relatively “clean” waveforms exist for low signals while large input amplitudes cause severe distortion.

The average current for these operating conditions can be determined by calculus. The average current values obtained may be further normalized by dividing by the corresponding dc bias current,  $I_0 = (1 - v_0)^2$ . The results are shown in Fig 10.61. The curves show that the average current increases as the amplitude of the drive increases. This, again, is most pronounced when the FET is biased close to pinch-off.

Although practical for the JFET, constant-voltage operation in the previous curves is not common. Instead, a resistive bias is usually employed, Fig 10.58B. With this form of bias, the increased current from high signal drive will cause the voltage drop across the bias resistor to increase. This will then move the quiescent operating level closer to pinch-off, accompanied by a reduced small-signal transconductance. This behavior is vital in describing the limiting found in FET oscillators.

The limits on small-signal operation are not as well defined for a FET as they were for the bipolar transistor. Generally, a maximum voltage of 50 to 100 mV is allowed at the input (normalized to a 1-V pinch-off) without severe distortion. The voltages are much higher than they were for the bipolar transistor. However, the input resistance of the usual common source amplifier is so high and the corresponding transconductance low enough that the available gain is no greater than could be obtained with a bipolar transis-

Fig 10.61—Change in average current of a JFET with increasing input signals. The average current with no input signals is  $i_0$ , while  $v_1$  is the normalized drive amplitude, and  $v_0$  is the bias voltage.

tor. The distortion is generally less with FETs, owing to the lack of high-order curvature in the defining equations.

Many of the standard circuits used with bipolar transistors are also practical with FETs. Noting that the transconductance of a bipolar transistor is  $g_m = I_e (\text{dc mA}) / 26$ , the previous equations may be applied directly. The “emitter current” is chosen to correspond with the FET transconductance. A very large value is used for current gain. The same calculator or computer program is then used directly. In practice, much higher terminating impedances are needed to obtain transducer gain values similar to those of bipolar transistors.

# Power Supplies and Projects

## 11

### Glossary

**Bipolar Transistor** — A term used to denote the common two junction transistor types (NPN, PNP) as opposed to the field effect families of devices (JFET, MOSFET and so on.).

**Bleeder** — A resistive load across the output or filter of a power supply, intended to quickly discharge stored energy once the supply is turned off.

**C-Rate** — The charging rate for a battery, expressed as a ratio of the battery's ampere-hour rating.

**Circular Mills** — A convenient way of expressing the cross-sectional area of a round conductor. The area of the conductor in circular mills is found by squaring its diameter in mills (thousandths of an inch), rather than squaring its radius and multiplying by pi. For example, the diameter of 10-gauge wire is 101.9 mills (0.1019 inch). Its cross-sectional area is 10380 CM, or 0.008155 square inches.

**Core Saturation (Magnetic)** — That condition whereby the magnetic flux in a transformer or inductor core is more than the core can handle. If the flux is forced beyond this point, the permeability of the core will decrease, and it will approach the permeability of air.

**Crowbar** — A last-ditch protection circuit included in many power supplies to protect the load equipment against failure of the regulator in the supply. The crowbar senses an overvoltage condition on the supply's output and fires a shorting device (usually an SCR) to directly short-circuit the supply's output and protect the load. This causes very high currents in the power supply, which blow the supply's input-line fuse.

**Darlington Transistor** — A package of two transistors in one case, with the collectors tied together, and the emitter of one transistor connected to the base of the other. The effective current gain of the pair is approximately the product of the individual gains of the two devices.

**DC-DC Converter** — A circuit for changing the voltage of a dc source to ac, transforming it to another level, and then rectifying the output to produce direct current.

**Fast Recovery Rectifier** — A specially doped rectifier diode designed to minimize the time necessary to halt conduction when the diode is switched from a forward-biased state to a reverse-biased state.

**Foldback Current Limiting** — A special type of current limiting used in linear power supplies, which reduces the current through the supply's regulator to a low value under short circuited load conditions in order to protect the series pass transistor from excessive power dissipation and possible destruction.

**Ground Fault (Circuit) Interrupter (GFI or GFCI)** — A safety device installed between the household power mains and equipment where there is a danger of personnel touching an earth ground while operating the equipment. The GFI senses any current flowing directly to ground and immediately switches off all power to the equipment to minimize electrical shock. GFIs are now standard equipment in bathroom and outdoor receptacles.

**Input-Output Differential** — The voltage drop appearing across the series pass transistor in a linear voltage regulator. This term is usually stated as a minimum value, which is that voltage necessary to allow the regulator to function and conduct current. A typical figure for this drop in most three-terminal regulator ICs is about 2.5 V. In other words, a regulator that is to provide 12.5 V dc will need a source voltage of at least 15.0 V at all times to maintain regulation.

**Inverter** — A circuit for producing ac power from a dc source.

**Peak Inverse Voltage** — The maximum reverse-biased voltage which a semiconductor is rated to handle safely. Exceeding the peak inverse rating can result in junction breakdown and device destruction.

**Power Conditioner** — Another term for a power supply.

**Regulator** — A device (such as a Zener diode) or circuitry in a power supply for maintaining a constant output voltage over a range of load currents and input voltages.

**Resonant Converter** — A form of dc-dc converter characterized by the series pass switch turning on into an effective series-resonant load. This allows a zero current condition at turn-on and turn-off. The resonant converter normally operates at frequencies between 100 kHz and 500 kHz and is very compact in size for its power handling ability.

**Ripple** — The residual ac left after rectification, filtration and regulation of the input power.

**RMS** — Root of the Mean of the Squares. Refers to the effective value of an alternating voltage or current, corresponding to the dc voltage or current that would cause the same heating effect.

**Second Breakdown** — A runaway failure condition in a transistor, occurring at higher collector-emitter voltages, where hot spots occur due to (and promoting) localization of the collector current at that region of the chip.

**Series Pass Transistor, or Pass Transistor** — The transistor(s) that controls the passage of power between the unregulated dc source and the load in a regulator. In a linear regulator, the series pass transistor acts as a controlled resistor to drop the voltage to that needed by the load. In a switch-mode regulator, the series pass transistor switches between its ON and OFF states.

**SOAR (Safe Operating Area)** — The range of permissible collector current and collector-emitter voltage combinations where a transistor may be safely operated without danger of device failure.

**Spike** — An extremely short perturbation on a power line, usually lasting less than a few micro-seconds.

**Surge** — A moderate-duration perturbation on a power line, usually lasting for hundreds of milliseconds to several seconds.

**Transient** — A short perturbation on a power line, usually lasting for microseconds to tens of milliseconds.

**Varistor** — A surge suppression device used to absorb transients and spikes occurring on the power lines, thereby protect electronic equipment plugged into that line. Frequently, the term MOV (Metal Oxide Varistor) is used instead.

**Volt-Amperes** — The product obtained by multiplying the current times the voltage in an ac circuit without regard for the phase angle between the two. This is also known as the *apparent power* delivered to the load as opposed to the actual or *real power* absorbed by the load, expressed in watts.

**Voltage Multiplier** — A type of rectifier circuit that is arranged so as to charge a capacitor or capacitors on one half-cycle of the ac input voltage waveform, and then to connect these capacitors in series with the rectified line or other charged capacitors on the alternate half-cycle. The voltage doubler and tripler are commonly used forms of the voltage multiplier.

# Alternating-Current Power

The text for the theory portion of this chapter was written by Ken Stuart, W3VVN.

In most residences, three wires are brought in from the outside electrical-service mains to the house distribution panel. In this three-wire system, one wire is neutral and is at earth ground. The voltage between the other two wires is 60 Hz alternating current with a potential difference of approximately 240 V RMS. Half of this voltage appears between each of these wires and the neutral, as indicated in **Fig 11.1A**. In systems of this type, the 120 V household loads are divided at the breaker panel as evenly as possible between the two sides of the power mains. Heavy appliances such as electric stoves, water heaters, central air conditioners and so forth, are designed for 240 V operation and are connected across the two ungrounded wires.

Both ungrounded wires should be fused. A fuse or switch should never be used in the neutral wire, however. The reason for this is that opening the neutral wire does not disconnect the equipment from an active or "hot" line, creating a potential shock hazard between that line and earth ground.

Another word of caution should be given at this point. Since one side of the ac line is grounded to earth, all communications equipment should be reliably connected to the ac-line ground through a heavy ground braid or bus wire of #14 or heavier-gauge wire. This not only places the chassis of the equipment at earth ground for minimal RF energy on the chassis, but also provides a measure of safety for the operator in the event of accidental short or leakage of one side of the ac line

to the chassis. Remember, the antenna system is almost always bypassed to the chassis via an RF choke or tuning circuit, which could make the antenna electrically "live" with respect to the earth ground and create a potentially lethal shock hazard. A Ground Fault Circuit Interrupter (GFCI or GFI) is also desirable for safety reasons, and should be a part of the shack's electrical power wiring.

## FUSES AND CIRCUIT BREAKERS

All transformer primary circuits should be fused properly, and multiple secondary outputs should also be individually fused. To determine the approximate current rating of the fuse or circuit breaker to be used, multiply each current being drawn by the load or appliance, in amperes, by the voltage at which the current is being drawn. In the case of linear regulated power supplies, this voltage has to be the voltage appearing at the output of the rectifiers before being applied to the regulator stage. Include the current taken by bleeder resistors and voltage dividers. Also include filament power if the transformer is supplying filaments.

After multiplying the various voltages and currents, add the individual products. This will be the total power drawn from the line by the supply. Then divide this power by the line voltage and add 10 or 20%. Use a fuse or circuit breaker with the nearest larger current rating. Remember that the charging of filter capacitors can take large surges of current when the supply is turned on, and the fuse rating might have to be increased to accommodate this

surge. If turn on is a problem, use slow-blow fuses, which allow for high initial surge currents.

For low-power semiconductor circuits, use fast-blow fuses. As the name implies, such fuses open very quickly once the current exceeds the fuse rating by more than 10%.

## ELECTRICAL POWER CONDITIONING

We often use the term "power supply" to denote a piece of equipment that will process the electrical power from a source, such as the ac power mains, by manipulating it so the device output will be acceptable to other equipment that we want to power. The common form of the power supply is the familiar direct-current power supply, which will power a transmitter, receiver or other of a wide variety of electronic devices.

In the strictest terms, however, the power supply is not actually a source, or "supply" of power, but is actually a processor of already existing energy. Therefore, the old term of "power supply" is becoming obsolete, and a new term has arisen to refer to the technology of the processing of electrical power: "power conditioning." By contrast, the term "power supply" is now used to refer to devices for chemical to electrical energy conversion (batteries) or mechanical to electrical conversion (generators). Other varieties include thermoelectric generators (TEGs) and radioactive thermoelectric generators (RTGs).

In this chapter, we shall examine the traditional forms of power conditioning, which consists of the following component parts in various combinations: transformer, rectifier, filter and regulator. We will also look briefly at true power supplies as we examine battery technology and emergency power generation.

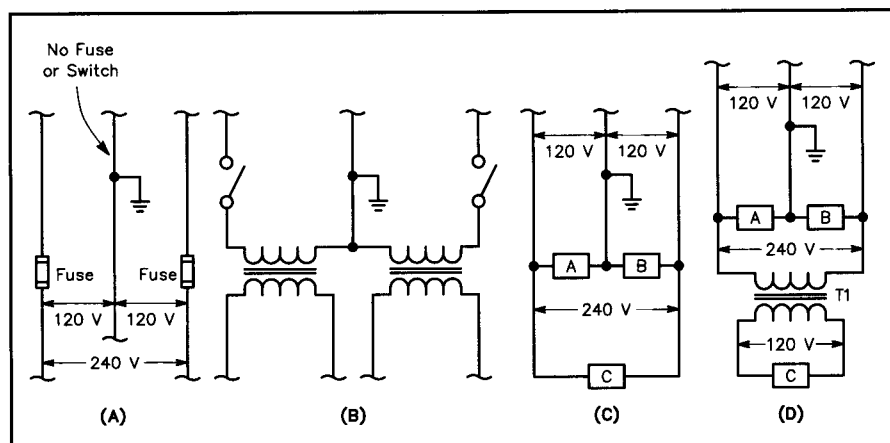

## POWER TRANSFORMERS

Numerous factors are considered in order to match a transformer to its intended use. Some of these parameters are listed below:

1. Output voltage and current (volt-ampere rating)
2. Power source voltage and frequency
3. Ambient temperature
4. Duty cycle and temperature rise of the transformer at rated load
5. Mechanical shape and mounting

## Volt-Ampere Rating

In alternating-current equipment, the term "volt-ampere" is often used rather

**Fig 11.1 — Three-wire power-line circuits.** At A, normal three-wire-line termination. No fuse should be used in the grounded (neutral) line. At B, the "hot" lines each have a switch, but a switch in the neutral line would not remove voltage from either side of the line, and so should never be used. At C, connections for both 120 and 240-V transformers. At D, operating a 120-V plate transformer from the 240-V line to avoid light blinking. T1 is a 2:1 step-down transformer.

than the term “watt.” This is because ac components must handle reactive power as well as real power. If this is confusing, consider a capacitor connected directly across the secondary of a transformer. The capacitor appears as a reactance that permits current to flow, just as if the load were a resistor. The current is at a 90° phase angle, however. If we assume a perfect capacitor, there will be no heating of the capacitor, so no real power (watts) will be delivered by the transformer. The transformer must still be capable of supplying the voltage, and be able to handle the current required by the reactive load. The current in the transformer windings will heat the windings as a result of the  $I^2R$  losses in the winding resistances. The product of the voltage and current is referred to as “volt-amperes”, since “watts” is reserved for the real, or dissipated, power in the load. The volt-ampere rating will always be equal to, or greater than, the power actually being drawn by the load.

The number of volt-amperes (VA) delivered by a transformer depends not only upon the dc load requirements, but also upon the type of dc output filter used (capacitor or choke input), and the type of rectifier used (full-wave center tap or full-wave bridge). With a capacitive-input filter, the heating effect in the secondary is higher because of the high peak-to-average current ratio. The volt-amperes handled by the transformer may be several times the power delivered to the load. The primary winding volt-amperes will be somewhat higher because of transformer losses.

### Source Voltage and Frequency

A transformer operates by producing a magnetic field in its core and windings. The intensity of this field varies directly with the instantaneous voltage applied to the transformer primary winding. These variations, coupled to the secondary windings, produce the desired output voltage. Since the transformer appears to the source as an inductance in parallel with the (equivalent) load, the primary will appear as a short circuit if dc is applied to it. The unloaded inductance of the primary must be high enough so as not to draw an excess amount of input current at the design line frequency (normally 60 Hz). This is achieved by providing sufficient turns on the primary and enough magnetic core material so that the core does not saturate during each half-cycle.

The magnetic field strength produced in the core is usually referred to as the *flux density*. It is set to some percentage of the maximum flux density that the core can stand without saturating, since at saturation the core becomes ineffective and

**Fig 11.2 — Use a test fixture like this to test unknown transformers. Don't omit the isolation transformer, and be sure to insulate all connections before you plug into the ac mains.**

causes the inductance of the primary to plummet to a very low level and input current to rise rapidly. This causes high primary currents and extreme heating in the primary windings. For this reason, transformers and other electromagnetic equipment designed for 60-Hz systems must not be used on 50-Hz power systems unless specifically designed to handle the lower frequency.

### How to Evaluate an Unmarked Power Transformer

Many hams who regularly visit hamfests eventually end up with a junk box filled with used and unmarked transformers. After years of use, transformer labels or markings on the coil wrappings may come off or be obscured. There is a good possibility that the transformer is still useable. The problem is to determine what voltages and currents the transformer can supply.

If the transformer has color-coded leads, you are in luck. There is a standard for transformer lead color-coding, as is given in the **Component Data** chapter. Where two colors are listed, the first one is the main color of the insulation; the second is the color of the stripe.

Check the transformer windings with an ohmmeter to determine that there are no shorted (or open) windings. The primary winding usually has a resistance higher than a filament winding and lower than a high-voltage winding.

A convenient way to test the transformer is to rig a pair of test leads to an electrical plug with a 25-W household

light bulb in series to limit current to safe (for the transformer) levels. See **Fig 11.2**. Use an isolation transformer, and be sure to insulate all connections before you plug into the ac mains. Switch off the power while making or changing any connections. Connect the test leads to each winding separately. **BE CAREFUL! YOU ARE DEALING WITH HAZARDOUS VOLTAGES!** The filament/heater windings will cause the bulb to light to full brilliance. The high-voltage winding will cause the bulb to be extremely dim or to show no light at all, and the primary winding will probably cause a small glow.

When you are connected to what you think is the primary winding, measure the voltages at the low-voltage windings with an ac voltmeter. If you find voltages close to 6 V ac and 5 V ac, you know that you have found the primary. Label the primary and low voltage windings.

Even with the light bulb, a transformer can be damaged by connecting mains power to a low-voltage or filament winding. In such a case the insulation could break down in a high-voltage winding.

Connect the voltmeter to the high-voltage windings. Remember that the old TV transformers will typically put out as much as 800 V or so across the winding, so make sure that your meter can withstand these potentials without damage. Divide the voltage you measured across the 6.3-V winding in this test setup into 6.3. This gives a multiplier that you can use to determine the actual no-load voltage rating of the high-voltage secondary. Simply multiply the ac voltage measured across

**Fig 11.3 — Cross-sectional drawing of a typical power transformer.** Multiplying the height (or thickness of the laminations) by the width of the central core area in inches gives the value to be applied to Fig 11.4.

the winding by the multiplier.

The current rating of the windings can be determined by loading each winding with the primary connected directly (no bulb) to the ac line. Using power resistors, increase loading on each winding until its voltage drops by about 10% from the no-load figure. The current drawn by the resistors is the approximate winding load-current rating.

### How to Wind a Transformer Properly

Few amateurs undertake the task of winding power transformers. It isn't difficult to rewind a transformer secondary to give some desired low voltage, however. It involves a matter of only a small number of turns, and the wire is usually large enough to be handled easily. Often a receiver power transformer with a burned-out high-voltage winding, or the power transformer from a discarded TV set, can be converted into an entirely satisfactory transformer without great effort and with little expense.

Winding a new high-voltage secondary may be more difficult. Such a winding will require many turns, and proper insulation between the turns and the other windings is essential.

The average TV power transformer for a 17-inch or larger vacuum tube set can deliver about 350 to 450 W, continuous duty. To operate an amateur transmitter, the service is not continuous, so the ratings can be increased by 40 or 50% without danger of overloading the transformer.

You can use the primary volt-ampere rating of the transformer to be rewound, if you know it, to determine its power-handling capability. The secondary volt-ampere rating will be 10 to 20% less than

**Fig 11.4 — Transformer power-handling capability versus core cross-sectional area.**

the primary rating. The power rating may also be determined approximately from the cross-sectional area of the core that is inside the windings. Fig 11.3 shows the method of determining the area, and Fig 11.4 may be used to convert this information into a power rating.

Before disconnecting the winding leads from their terminals, mark each one for identification. When removing the core laminations, take care to note how the core is assembled, so you can reassemble it in the same manner. Most transformers have secondaries wound over the primary. If the secondaries are on the inside, the turns can be pulled out from the center after slitting and removing the fiber core.

Carefully count the turns removed from one of the original filament windings of known voltage as you remove them. This will give the number of turns per volt; the same figure should be used in determining the number of turns for the new secondary. For instance, if the old filament winding was rated at 5 V and had 15 turns, this is  $15 / 5 = 3$  turns per volt. If the new secondary is to deliver 18 V, the required number of turns on the new winding will be  $18 \times 3 = 54$  turns.

In winding a transformer, the wire size is an important factor in the heat developed in operation. A cross-sectional area of 1000 circular mils per ampere (cmil/A) is a conservative estimate of sufficient wire size. A value commonly used in amateur service transformers is 700 cmil/A. The larger the cmil/A figure, the cooler the transformer will

run. The current rating in amperes of various wire sizes is shown in the copper-wire table in the **Component Data** chapter. If the transformer being rewound is a filament transformer, it may be necessary to choose the wire size carefully to fit the small available space. On the other hand, if the transformer is a power unit with the high-voltage winding removed, there should be plenty of room for a size of wire that will conservatively handle the required current.

After the first layer of turns is put on during rewinding, secure the ends with masking tape. Each layer should be insulated from the next. Strips cut from brown paper grocery bags to the size of the winding area are excellent for this purpose. A single layer is adequate between layers of each winding, with two layers between windings. Strips may be secured over each layer with tape. Be sure to bring all leads out the same side of the core so the covers will go in place when the unit is completed. When the last layer of the winding is put on, use two sheets of paper and then cover those with vinyl electrical tape, keeping the tape as taut as possible. This will add mechanical strength to the assembly.

The laminations and housing are assembled in just the opposite sequence to that followed in disassembly. Use a light coating of shellac between each lamination. During reassembly, the lamination stack may be compressed by clamping in a vise. If the last few lamination strips cannot be replaced, it is better to omit them than to force the unit together.

# Rectifier Types

## VACUUM TUBE

Once the mainstay of the rectifier field, the vacuum-tube rectifier has largely been supplanted by the silicon diode, but it may be found in vintage receivers still in use. Vacuum-tube rectifiers were characterized by high forward voltage drops and inherently poor regulation, but they were immune to ac line transients that can destroy other rectifier types.

## MERCURY VAPOR

The mercury-vapor rectifier was an improvement over the vacuum tube rectifier in that the electron stream from cathode to plate would ionize the vaporized mercury in the tube and greatly reduce the forward voltage drop. Since ionized mercury is a much better conductor of current than a vacuum, these tubes can carry relatively high currents. As a result, they were popular in transmitters and RF power amplifiers.

Mercury rectifiers had to be treated with special care, however. When power was initially applied, the tube filament had to be turned on first to vaporize condensed mercury before the high-voltage ac could be applied to the plate. This could take from one to two minutes. Also, if the tube was handled or the equipment transported, filament power would have to be applied for about a half hour to vaporize any mercury droplets that might have been shaken onto tube insulating surfaces. Mercury vapor rectifiers have mostly been replaced by silicon diodes.

## SELENIUM

The selenium rectifier was the first of the solid-state rectifiers to find its way into commercial electronic equipment. Offering a relatively low forward voltage drop, selenium rectifiers found their way into the plate supplies of test equipment and

accessories, which needed only a few tens of milliamperes of current at about a hundred volts, such as grid-dip meters, VTVMs and so forth.

Selenium rectifiers had a relatively low reverse resistance and were therefore inefficient. Voltage breakdown per rectifying junction was only about 20 V.

## GERMANIUM

Germanium diodes were the first of the solid-state semiconductor rectifiers. They have an extremely low forward voltage drop. Germanium diodes are relatively temperature sensitive, however. They can be easily destroyed by overheating during soldering, for instance. Also, they have some degree of back resistance, which varies with temperature.

Germanium diodes are used for special applications where the very low forward drop is needed, such as signal diodes used for detectors and ring modulators.

## SILICON

Silicon diodes are the main choice today for virtually all rectifier applications. They are characterized by extremely high reverse resistance, forward drops of usually a volt or less and operation at high temperatures.

## FAST RECOVERY

DC-DC converters regularly operate at 25 kHz and higher frequencies. Switch-mode regulators also operate in these same frequency ranges. When the switching transistors in these devices switch, voltage transitions take place within time periods usually much less than one microsecond, and the new FET switching transistors cause transitions that are often less than 100 ns.

The transitions in these circuits cause

current changes in output rectifiers and reverse recovery diodes to occur at the same time with the desired effect being for the diodes to cease conduction immediately in order to allow opposite-phase rectifiers to conduct. Unfortunately, solid-state rectifiers cannot be made to cease conduction instantaneously. As a result, when the opposing diodes in a bridge rectifier or full-wave rectifier become conductive when the converter switches states, the diodes being turned off will actually conduct in the reverse direction for a brief time, and effectively short circuit the converter for several microseconds. This puts excessive strain on the switching transistors and creates high current spikes, leading to electromagnetic interference. As the switching frequency of the converter or regulator increases, more of these transitions happen each second, and more power is lost due to this diode cross-conduction.

Semiconductor manufacturers have recognized this as a problem for some time. Many companies have product lines of specially doped diodes designed to minimize this storage time. These diodes are called fast-recovery rectifiers and are commonly used in high-frequency dc-dc converters and regulators. Diodes are available that can recover in about 50 ns and less, as compared to standard-recovery diodes that can take several microseconds to cease conduction in the reverse direction.

Amateurs building their own switching power supplies and dc-dc converters will find greatly improved performance with the use of these diodes in their output rectifiers. Fast-recovery rectifiers are not needed for 60 Hz rectification because the source voltage is a sine wave (no fast transitions) and the input frequency is too slow for transitions to be of significance.

# Rectifier Circuits

## HALF-WAVE RECTIFIER

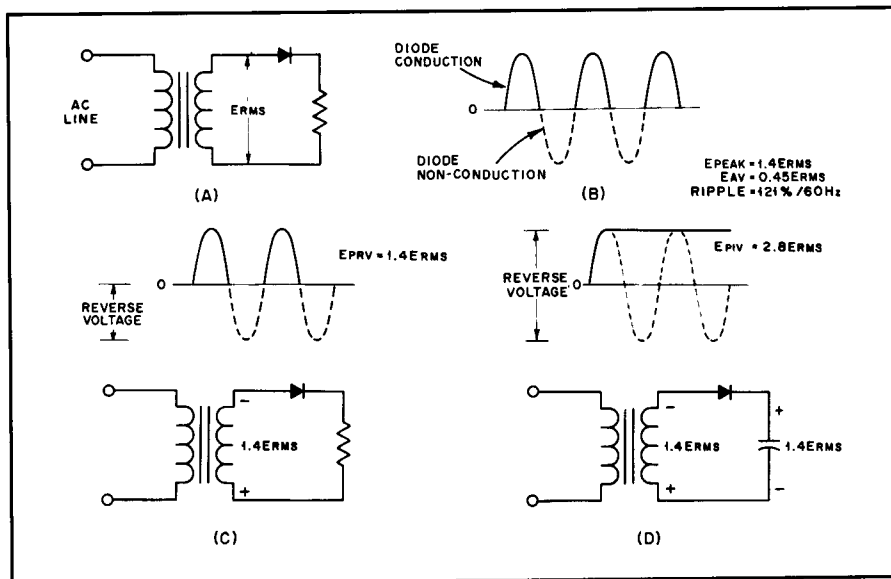

Fig 11.5 shows a simple half-wave rectifier circuit. A rectifier (in this case a semiconductor diode) conducts current in one direction but not the other. During one half of the ac cycle, the rectifier conducts and there is current through the rectifier to the load (indicated by the solid line in Fig 11.5B). During the other half cycle, the rectifier is reverse biased and there is

no current (indicated by the broken line in Fig 11.5B) to the load. As shown, the output is in the form of pulsed dc, and current always flows in the same direction. A filter can be used to smooth out these variations and provide a higher average dc voltage from the circuit. This idea will be covered in the section on filters.

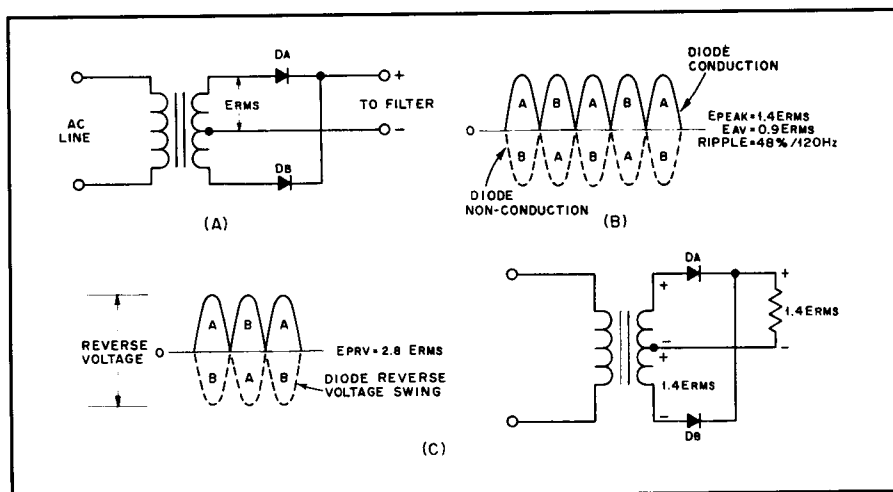

The average output voltage — the voltage read by a dc voltmeter—with this cir-

cuit (no filter connected) is  $0.45 \times E_{RMS}$  of the ac voltage delivered by the transformer secondary. Because the frequency of the pulses is low (one pulse per cycle), considerable filtering is required to provide adequately smooth dc output. For this reason the circuit is usually limited to applications where the required current is small, as in a transmitter bias supply.

The peak inverse voltage (PIV), the

**Fig 11.5 — Half-wave rectifier circuit.** A illustrates the basic circuit, and B displays the diode conduction and nonconduction periods. The peak-inverse voltage impressed across the diode is shown at C and D, with a simple resistor load at C and a capacitor load at D.  $E_{PIV}$  is  $1.4 E_{RMS}$  for the resistor load and  $2.8 E_{RMS}$  for the capacitor load.

**Fig 11.6 — Full-wave center-tap rectifier circuit.** A illustrates the basic circuit. Diode conduction is shown at B with diodes A and B alternately conducting. The peak-inverse voltage for each diode is  $2.8 E_{RMS}$  as depicted at C.

voltage that the rectifier must withstand when it isn't conducting, varies with the load. With a resistive load, it is the peak ac voltage ( $1.4 \times E_{RMS}$ ); with a capacitor filter and a load drawing little or no current, it can rise to  $2.8 \times E_{RMS}$ . The reason for this is shown in parts C and D of Fig 11.5. With a resistive load as shown at C, the voltage applied to the diode is that voltage on the lower side of the zero-axis line, or  $1.4 \times E_{RMS}$ . A capacitor connected to the circuit (shown at D) will store the peak positive voltage when the diode conducts on the positive pulse. If the circuit is not supplying any current, the voltage

across the capacitor will remain at that same level. The peak inverse voltage impressed across the diode is now the sum of the voltage stored in the capacitor plus the peak negative swing of voltage from the transformer secondary. In this case the PIV is  $2.8 \times E_{RMS}$ .

### FULL-WAVE CENTER-TAP RECTIFIER

A commonly-used rectifier circuit is shown in Fig 11.6. Essentially an arrangement in which the outputs of two half-wave rectifiers are combined, it makes use of both halves of the ac cycle. A trans-

former with a center-tapped secondary is required with the circuit.

The average output voltage is  $0.9 \times E_{RMS}$  of half the transformer secondary; this is the maximum that can be obtained with a suitable choke-input filter. The peak output voltage is  $1.4 \times E_{RMS}$  of half the transformer secondary; this is the maximum voltage that can be obtained from a capacitor-input filter.

As can be seen in Fig 11.6C, the PIV impressed on each diode is independent of the type of load at the output. This is because the peak inverse voltage condition occurs when diode A conducts and diode B does not conduct. The positive and negative voltage peaks occur at precisely the same time, a condition different from that in the half-wave circuit. As the cathodes of diodes A and B reach a positive peak ( $1.4 E_{RMS}$ ), the anode of diode B is at a negative peak, also  $1.4 E_{RMS}$ , but in the opposite direction. The total peak inverse voltage is therefore  $2.8 E_{RMS}$ .

Fig 11.6B shows that the frequency of the output pulses is twice that of the half-wave rectifier. Comparatively less filtering is required. Since the rectifiers work alternately, each handles half of the load current. The current rating of each rectifier need be only half the total current drawn from the supply.

### FULL-WAVE BRIDGE RECTIFIER

Another commonly used rectifier circuit is illustrated in Fig 11.7. In this arrangement, two rectifiers operate in series on each half of the cycle, one rectifier being in the lead to the load, the other being the return lead. As shown in Fig 11.7A and B, when the top lead of the transformer secondary is positive with respect to the bottom lead, diodes A and C will conduct while diodes B and D are reverse biased. On the next half cycle, when the top lead of the transformer is negative with respect to the bottom, diodes B and D will conduct while diodes A and C are reverse biased.

The output wave shape is the same as that from the simple full-wave center-tap rectifier circuit. The average dc output voltage into a resistive load or choke-input filter is 0.9 times the RMS voltage delivered by the transformer secondary; with a capacitor filter and a light load, the maximum output voltage is 1.4 times the secondary RMS voltage.

Fig 11.7C shows the inverse voltage to be  $1.4 E_{RMS}$  for each diode. When an alternate pair of diodes (such as  $D_A$  and  $D_C$ ) is conducting, the other diodes are essentially connected in parallel in a reverse-biased direction. The reverse stress is then  $1.4 E_{RMS}$ . Each pair of diodes conducts on alternate half cycles, with the full load

current through each diode during its conducting half cycle. Since each diode is not conducting during the other half cycle the average current is one half the total load current drawn from the supply.

## PROS AND CONS OF THE RECTIFIER CIRCUITS

Comparing the full-wave center-tap rectifier circuit and the full-wave bridge-rectifier circuit, we can see that both circuits have almost the same rectifier requirement, since the center tap has half the number of rectifiers as the bridge. These rectifiers have twice the inverse voltage rating requirement of the bridge diodes, however. The diode current ratings are identical for the two circuits. The bridge makes better use of the transformer's secondary than the center-tap rectifier, since the transformer's full winding supplies power during both half cycles, while each half of the center-tap circuit's secondary provides power only during its positive half-cycle. This is usually referred to as the *transformer utilization factor*, which is unity for the bridge configuration and 0.5 for the full-wave, center-tapped circuit.

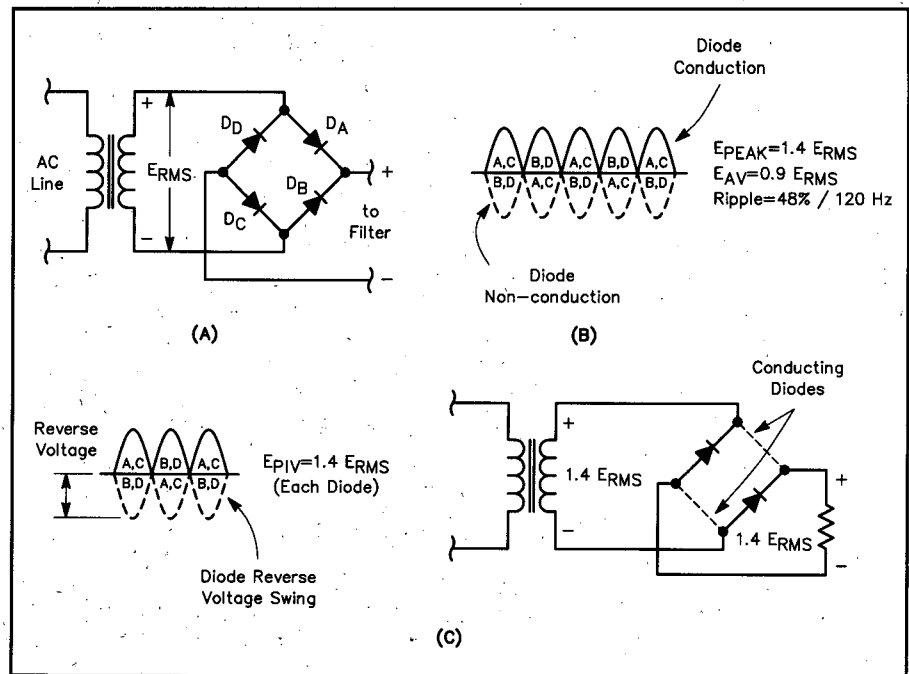

The bridge rectifier often takes second place to the full-wave center tap rectifier in high-current low-voltage applications. This is because the two forward-conducting series-diode voltage drops in the bridge introduce a volt or more of additional loss, and thus more heat to be dissipated, than does the single diode drop of the full-wave rectifier.

The half-wave configuration is rarely used in 60 Hz rectification for other than bias supplies. It does see considerable use, however, in high-frequency switching power supplies in what are called *forward converter* and *flyback converter* topologies.

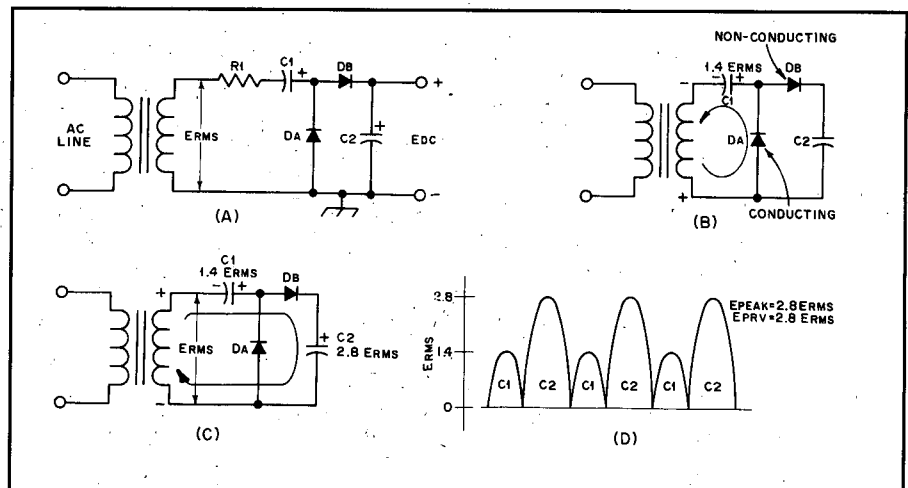

## VOLTAGE MULTIPLIERS

Other rectification circuits of interest are the so-called *voltage multipliers*. These circuits function by the process of charging one or more capacitors on one half cycle of the ac waveform, and then connecting that capacitor or capacitors in series with the opposite polarity of the ac waveform on the alternate half cycle. With full-wave multipliers, this charging occurs during both half-cycles.

Voltage multipliers, particularly doublers, find considerable use in high-voltage supplies. When a doubler is employed, the secondary winding of the power transformer need only be half the voltage that would be required for a bridge rectifier. This reduces voltage stress in the windings and decreases the transformer insulation requirements. It also reduces the chance of corona in the

**Fig 11.7 — Full-wave bridge rectifier circuit.** The basic circuit is illustrated at A. Diode conduction and nonconduction times are shown at B. Diodes A and C conduct on one half of the input cycle, while diodes B and D conduct on the other. C displays the peak inverse voltage for one half cycle. Since this circuit reverse-biases two diodes essentially in parallel, 1.4 E<sub>RMS</sub> is applied across each diode.

**Fig 11.8 — Part A shows a half-wave voltage-doubler circuit. B displays how the first half cycle of input voltage charges C<sub>1</sub>. During the next half cycle (shown at C), capacitor C<sub>2</sub> charges with the transformer secondary voltage plus that voltage stored in C<sub>1</sub> from the previous half cycle. The arrows in parts B and C indicate the conventional current. D illustrates the levels to which each capacitor charges over several cycles.**

windings, prolonging the life of the transformer. This is not without cost, however, because the transformer-secondary current rating has to be correspondingly doubled.

## Half-Wave Doubler

Fig 11.8 shows the circuit of a half-wave voltage doubler. Parts B, C and D illustrate the circuit operation. For clarity, assume the

transformer voltage polarity at the moment the circuit is activated is that shown at B. During the first negative half cycle, D<sub>A</sub> conducts (D<sub>B</sub> is in a nonconductive state), charging C<sub>1</sub> to the peak rectified voltage (1.4 E<sub>RMS</sub>). C<sub>1</sub> is charged with the polarity shown at B. During the positive half cycle of the secondary voltage, D<sub>A</sub> is cut off and D<sub>B</sub> conducts, charging capacitor C<sub>2</sub>. The

Fig 11.9 — Part A shows a full-wave voltage-doubler circuit. One half cycle is shown at B and the next half cycle is shown at C. Each capacitor receives a charge during every input-voltage cycle. D illustrates how each capacitor is charged alternately.

connected to the circuit output, the voltage across C2 drops during the negative half cycle and is recharged up to  $2.8 E_{RMS}$  during the positive half cycle.

The output waveform across C2 resembles that of a half-wave rectifier circuit because C2 is pulsed once every cycle. Fig 11.8D illustrates the levels to which the two capacitors are charged throughout the cycle. In actual operation, the capacitors will not discharge all the way to zero as shown.

### Full-Wave Doubler

Fig 11.9 shows the circuit of a full-wave voltage doubler. The circuit operation can best be understood by following Parts B, C and D. During the positive half cycle of the transformer secondary voltage, as shown at B,  $D_A$  conducts charging capacitor C1 to  $1.4 E_{RMS}$ .  $D_B$  is not conducting at this time.

During the negative half cycle, as shown at C,  $D_B$  conducts, charging capacitor C2 to  $1.4 E_{RMS}$ , while  $D_A$  is nonconducting. The output voltage is the sum of the two capacitor voltages, which will be  $2.8 E_{RMS}$  under no-load conditions. Fig 11.9D illustrates that each capacitor alternately receives a charge once per cycle. The effective filter capacitance is that of C1 and C2 in series, which is less than the capacitance of either C1 or C2 alone.

Resistors R1 and R2 in Fig 11.9A are used to limit the surge current through the rectifiers. Their values are based on the transformer voltage and the rectifier surge-current rating, since at the instant the power supply is turned on, the filter capacitors look like a short-circuited load. Provided the limiting resistors can withstand the surge current, their current-handling capacity is based on the maximum load current from the supply. Output voltages approaching twice the peak voltage of the transformer can be obtained with the voltage doubling circuit shown in Fig 11.9. Fig 11.10 shows how the voltage depends upon the ratio of the series resistance to the load resistance, and the load resistance times the filter capacitance. The peak inverse voltage across each diode is  $2.8 E_{RMS}$ .

Fig 11.10 — DC output voltages from a full-wave voltage doubler circuit as a function of the filter capacitances and load resistance. For the ratio  $R1 / R3$  and for the  $R3 \times C1$  product, resistance is in ohms and capacitance is in microfarads. Equal resistance values for R1 and R2, and equal capacitance values for C1 and C2 are assumed. These curves are adapted from those published by Otto H. Schade in "Analysis of Rectifier Operation," *Proceedings of the I. R. E.*, July 1943.

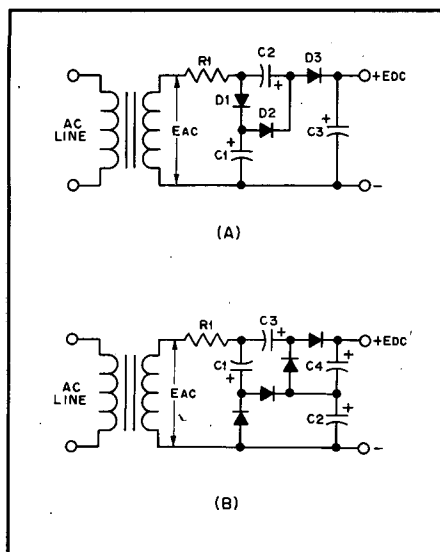

amount of voltage delivered to C2 is the sum of the transformer peak secondary voltage plus the voltage stored in C1 ( $1.4 E_{RMS}$ ). On the next negative half cycle,  $D_B$  is noncon-

ducting and C2 will discharge into the load. If no load is connected across C2, the capacitors will remain charged — C1 to  $1.4 E_{RMS}$  and C2 to  $2.8 E_{RMS}$ . When a load is

### Tripler and Quadrupler

Fig 11.11A shows a voltage-tripling circuit. On one half of the ac cycle, C1 and C3 are charged to the source voltage through  $D1$ ,  $D2$  and  $D3$ . On the opposite half of the cycle,  $D2$  conducts and C2 is charged to twice the source voltage, because it sees the transformer plus the charge in C1 as its source ( $D1$  is cut off during this half cycle.) At the same time,  $D3$  conducts, and with the transformer and the charge in C2 as the source, C3 is charged to three times the transformer voltage.

**Fig 11.11 — Voltage-multiplying circuits with one side of the transformer secondary used as a common connection. A shows a voltage tripler and B shows a voltage quadrupler. Capacitances are typically 20 to 50  $\mu$ F, depending on the output current demand. Capacitor dc ratings are related to  $E_{PEAK}$  ( $1.4 E_{RMS}$ ):**  
**C1 — Greater than  $E_{PEAK}$**   
**C2 — Greater than  $2 E_{PEAK}$**   
**C3 — Greater than  $3 E_{PEAK}$**   
**C4 — Greater than  $2 E_{PEAK}$**

The voltage-quadrupling circuit of Fig 11.11B works in similar fashion. In either of the circuits of Fig 11.11, the output voltage will approach an exact multiple of the peak ac voltage when the output current drain is low and the capacitance values are high.

## RECTIFIER RATINGS VERSUS OPERATING STRESS

Power supplies designed for amateur equipment use silicon rectifiers almost exclusively. These rectifiers are available in a wide range of voltage and current ratings. In peak inverse voltage (PIV) ratings of 600 or less, silicon rectifiers carry current ratings as high as 400 A. At 1000 PIV, the current ratings may be several amperes. It is possible to stack several units in series for higher voltages. Stacks are available commercially that will handle peak inverse voltages up to 10 kV at a load current of 1 A or more.

## RECTIFIER STRINGS OR STACKS

### Diodes in Series

When the PIV rating of a single diode is not sufficient for the application, similar diodes may be used in series. (Two 500 PIV diodes in series will withstand 1000 PIV and so on.) There used to be a general recommendation to place a resistor across each diode in the string to equalize the PIV drops.

With modern diodes, this practice is no longer necessary.

Modern silicon rectifier diodes are constructed to have an avalanche characteristic. Simply put, this means that the diffusion process is controlled so the diode will exhibit a Zener characteristic in the reverse biased direction before destructive breakdown of the junction can occur. This provides a measure of safety for diodes in series. A diode will go into Zener conduction before it self destructs. If other diodes in the chain have not reached their avalanche voltages, the current through the avalanched diode will be limited to the leakage current in the other diodes. This should normally be very low. For this reason, shunting resistors are generally not needed across diodes in series rectifier strings. In fact, shunt resistors can actually create problems because they can produce a low-impedance source of damaging current to any diode that may have reached avalanche potential.

### Diodes in Parallel

Diodes can be placed in parallel to increase current-handling capability. Equalizing resistors should be added as shown in Fig 11.12. Without the resistors, one diode may take most of the current. The resistors should be selected to have several tenths of a volt drop at the expected peak current.

## RECTIFIER PROTECTION

The important specifications of a silicon diode are:

1. PIV, the peak inverse voltage.
2.  $I_0$ , the average dc current rating.
3.  $I_{REP}$ —the peak repetitive forward current.
4.  $I_{SURGE}$ , a nonrepetitive peak half sine wave of 8.3 ms duration (one-half cycle of 60-Hz line frequency).
5. Switching speed.
6. Power dissipation and thermal resistance.

The first two specifications appear in most catalogs.  $I_{REP}$  and  $I_{SURGE}$  often are not specified in catalogs, but they are very important. Because the rectifier never allows current to flow more than half the time, when it does conduct it has to pass at least twice the average direct current. With a capacitor-input filter, the rectifier conducts much less than half the time, so that when it does conduct, it may pass as much as 10 to 20 times the average dc current, under certain conditions. This is shown in Fig 11.13. Part A shows a simple half-wave rectifier with a resistive load. The waveform to the right of the drawing shows the output voltage along with the diode current. Parts B and C show conditions for circuits with "low" capacitance and "high" capacitance to filter the output.

After the capacitor is charged to the peak-rectified voltage, a period of diode nonconduction elapses while the output voltage dis-

**Fig 11.12 — Diodes can be connected in parallel to increase the current-handling capability of the circuit. Each diode should have a series current-equalizing resistor, with a value selected to provide a few tenths of a volt drop at the expected current.**

charges through the load. As the voltage begins to rise on the next positive pulse, a point is reached where the rectified voltage equals the stored voltage in the capacitor. As the voltage rises beyond that point, the diode begins to supply current. The diode will continue to conduct until the waveform reaches the crest, as shown. Since the diode must pass a current equal to that of the load over a short period of a cycle, the current will be high. The larger the capacitor for a given load, the shorter the diode conduction time and the higher the peak repetitive current ( $I_{REP}$ ).

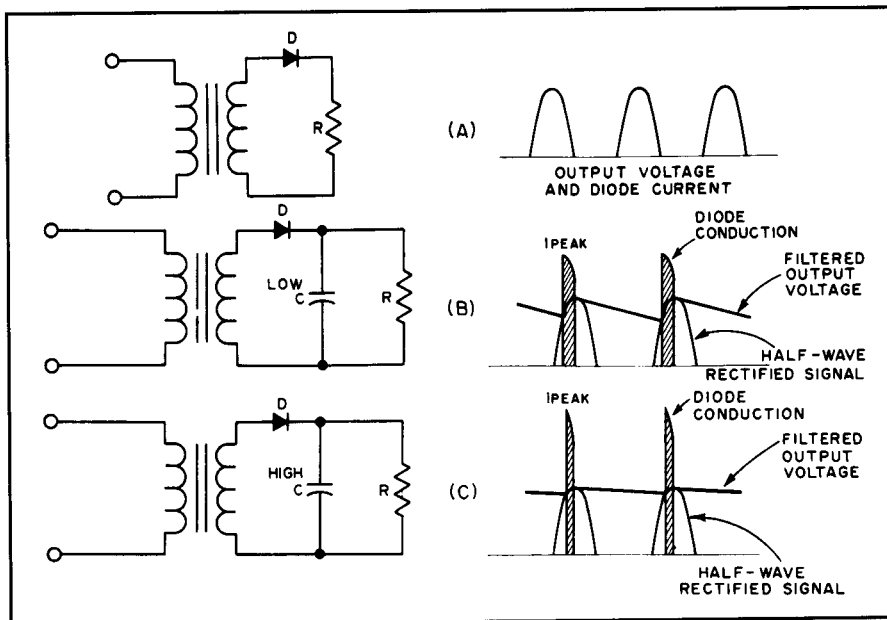

### Current Inrush

When the supply is first turned on, the discharged input capacitor looks like a dead short, and the rectifier passes a very heavy current. This current transient is called  $I_{SURGE}$ . The maximum surge current rating for a diode is usually specified for a duration of one-half cycle (at 60 Hz), or about 8.3 ms. Some form of surge protection is usually necessary to protect the diodes until the input capacitor becomes nearly charged, unless the diodes used have a very high surge-current rating (several hundred amperes). If a manufacturer's data sheet is not available, an educated guess about a diode's capability can be made by using these rules of thumb for silicon diodes commonly used in amateur power supplies:

Rule 1. The maximum  $I_{REP}$  rating can be assumed to be approximately four times the maximum  $I_0$  rating.

Rule 2. The maximum  $I_{SURGE}$  rating can be assumed to be approximately 12 times the maximum  $I_0$  rating. (This figure should provide a reasonable safety factor. Silicon rectifiers with 750-mA dc ratings, for example, seldom have 1-cycle surge ratings of less than 15 A; some are rated up to 35 A or more.) From this you can see that the rectifier should be selected on the basis of  $I_{SURGE}$  and not on  $I_0$  ratings.

Although you can sometimes rely on the dc resistance of the transformer secondary to provide ample surge-current limiting, this is

**Fig 11.13** — The circuit shown at A is a simple half-wave rectifier with a resistive load. The waveform shown to the right is the output voltage and current. B illustrates how the diode current is modified by the addition of a capacitor filter. The diode conducts only when the rectified voltage is greater than the voltage stored in the capacitor. Since this time is usually only a short portion of a cycle, the peak current will be quite high. C shows an even higher peak current. This is caused by the larger capacitor, which effectively shortens the diode conduction period.

seldom true in high-voltage power supplies. Series resistors are often installed between the secondary and the rectifier strings or in the transformer's primary circuit, but these can be a deterrent to good voltage regulation.

## Voltage Spikes

Vacuum-tube rectifiers had little problem with voltage spikes on the incoming power lines — the possibility of an internal arc was of little consequence, since the heat produced was of very short duration and had little effect on the massive plate and cathode structures. Unfortunately, such is not the case with silicon diodes.

Silicon diodes, because of their forward voltage drop of about one volt, create very little heat with high forward currents and therefore have tiny junction areas. Conduction in the reverse direction, however, can cause junction temperatures to rise extremely rapidly with the resultant melting of the silicon and migration of the dopants into the rectifying junction. Destruction of the semiconductor junction is the end result.

To protect semiconductor rectifiers, special surge-absorption devices are available for connection across the incoming ac bus or transformer secondary. These devices operate in a fashion similar to a Zener diode, by conducting heavily when a specific voltage level is reached. Unlike Zener diodes, however, they have the ability to absorb very

high transient energy levels without damage. With the clamping level set well above the normal operating voltage range for the rectifiers, these devices normally appear as open circuits and have no effect on the power-supply circuits. When a voltage transient occurs, however, these protection devices clamp the spike and thereby prevent destruction of the rectifiers.

Transient protectors are available in three basic varieties:

1. Silicon Zener diodes — large junction Zeners specifically made for this purpose and available as single junction for dc (unipolar) and back-to-back junctions for ac (bipolar). These silicon protectors are available under the trade name of TransZorb from General Semiconductor Corporation and are also made by other manufacturers. They have the best transient suppressing characteristics of the three varieties mentioned here, but are expensive and have the least energy absorbing capability per dollar of the group.
2. Varistors — made of a composition metal-oxide material that breaks down at a certain voltage. Metal-oxide varistors, also known as MOVs, are cheap and easily obtained, but have a higher internal resistance, which allows a greater increase of clamped voltage than the Zener variety. Varistors can also degrade with successive transients within their rated power handling limits (this is not usually a prob-

lem in the ham shack where transients are few and replacement of the varistor is easily accomplished).

Varistors usually become short circuited when they fail. Large energy dissipation can result in device explosion. Therefore, it is a good idea to include a fuse that limits the short-circuit current through the varistor, and to protect people and circuitry from debris.

3. Gas tube — similar in construction to the familiar neon bulb, but designed to limit conducting voltage rise under high transient currents. Gas tubes can usually withstand the highest transient energy levels of the group. Gas tubes suffer from an ionization time problem, however. A high voltage across the tube will not immediately cause conduction. The time required for the gas to ionize and clamp the spike is inversely proportional to the level of applied voltage in excess of the device ionization voltage. As a result, the gas tube will let a little of the transient through to the equipment before it activates.

In installations where reliable equipment operation is critical, the local power is poor and transients are a major problem, the usual practice is to use a combination of protectors. Such systems consist of a varistor or Zener protector, combined with a gas-tube device. Operationally, the solid-state device clamps the surge immediately, with the beefy gas tube firing shortly thereafter to take most of the surge from the solid-state device.

## Heat

The junction of a diode is quite small; hence it must operate at a high current density. The heat-handling capability is, therefore, quite small. Normally, this is not a prime consideration in high-voltage, low-current supplies. Use of high-current rectifiers at or near their maximum ratings (usually 2-A or larger stud-mount rectifiers) requires some form of heat sinking. Frequently, mounting the rectifier on the main chassis — directly, or with thin mica insulating washers — will suffice. If insulated from the chassis, a thin layer of silicone grease should be used between the diode and the insulator, and between the insulator and the chassis, to assure good heat conduction. Large, high-current rectifiers often require special heat sinks to maintain a safe operating temperature. Forced-air cooling is sometimes used as a further aid. Safe case temperatures are usually given in the manufacturer's data sheets and should be observed if the maximum capabilities of the diode are to be realized. See the thermal design section in the **Real World Components** chapter for more information.

# Filtration

The pulsating dc waves from the rectifiers are not sufficiently constant in amplitude to prevent hum corresponding to the pulsations. Filters are required between the rectifier and the load to smooth out the pulsations into an essentially constant dc voltage. The design of the filter depends to a large extent on the dc voltage output, the voltage regulation of the power supply and the maximum load current rating of the rectifier. Power-supply filters are low-pass devices using series inductors and shunt capacitors.

## LOAD RESISTANCE

In discussing the performance of power-supply filters, it is sometimes convenient to express the load connected to the output terminals of the supply in terms of resistance. The load resistance is equal to the output voltage divided by the total current drawn, including the current drawn by the bleeder resistor.

## VOLTAGE REGULATION

The output voltage of a power supply always decreases as more current is drawn, not only because of increased voltage drops in the transformer and filter chokes, but also because the output voltage at light loads tends to soar to the peak value of the transformer voltage as a result of charging the first capacitor. Proper filter design can eliminate the soaring effect. The change in output voltage with load is called voltage regulation, and is expressed as a percentage.

$$\text{Percent Regulation} = \frac{(E1 - E2)}{E2} \times 100\% \quad (1)$$

where:

E1 = the no-load voltage

E2 = the full-load voltage.

A steady load, such as that represented by a receiver, speech amplifier or unkeyed stages of a transmitter, does not require good (low) regulation as long as the proper voltage is obtained under load conditions. The filter capacitors must have a voltage rating safe for the highest value to which the voltage will soar when the external load is removed.

A power supply will show more (higher) regulation with long-term changes in load resistance than with short temporary changes. The regulation with long-term changes is often called the static regulation, to distinguish it from the dynamic regulation (short temporary load changes). A load that varies at a syllabic or keyed rate, as represented by some audio and RF amplifiers, usually requires good dynamic

regulation (15% or less) if distortion products are to be held to a low level. The dynamic regulation of a power supply can be improved by increasing the value of the output capacitor.

When essentially constant voltage regardless of current variation is required (for stabilizing an oscillator, for example), special voltage regulating circuits described later in this chapter are used.

## BLEEDER RESISTOR

A bleeder resistor is a resistance connected across the output terminals of the power supply. Its functions are to discharge the filter capacitors as a safety measure when the power is turned off and to improve voltage regulation by providing a minimum load resistance. When voltage regulation is not of importance, the resistance may be as high as 100  $\Omega$  per volt. The resistance value to be used for voltage-regulating purposes is discussed in later sections. From the consideration of safety, the power rating of the resistor should be as conservative as possible, since a burned-out bleeder resistor is dangerous!

## RIPPLE FREQUENCY AND VOLTAGE

Pulsations at the output of the rectifier can be considered to be the result of an alternating current superimposed on a steady direct current. From this viewpoint, the filter may be considered to consist of shunt capacitors that short circuit the ac component while not interfering with the flow of the dc component. Series chokes

will readily pass dc but will impede the flow of the ac component.

The alternating component is called ripple. The effectiveness of the filter can be expressed in terms of percent ripple, which is the ratio of the RMS value of the ripple to the dc value in terms of percentage.

$$\text{Percent Ripple (RMS)} = \frac{E1}{E2} \times 100\% \quad (2)$$

where:

E1 = the RMS value of ripple voltage

E2 = the steady dc voltage.

Any frequency multiplier or amplifier supply in a CW transmitter should have less than 5% ripple. A linear amplifier can tolerate about 3% ripple on the plate voltage. Bias supplies for linear amplifiers should have less than 1% ripple. VFOs, speech amplifiers and receivers may require a ripple no greater than 0.01%.

Ripple frequency refers to the frequency of the pulsations in the rectifier output waveform — the number of pulsations per second. The ripple frequency of half-wave rectifiers is the same as the line-supply frequency — 60 Hz with a 60-Hz supply. Since the output pulses are doubled with a full-wave rectifier, the ripple frequency is doubled — to 120 Hz with a 60-Hz supply.

The amount of filtering (values of inductance and capacitance) required to give adequate smoothing depends on the ripple frequency. More filtering is required as the ripple frequency is reduced.

## CAPACITOR-INPUT FILTERS

Capacitor-input filter systems are shown in Fig 11.14. Disregarding voltage

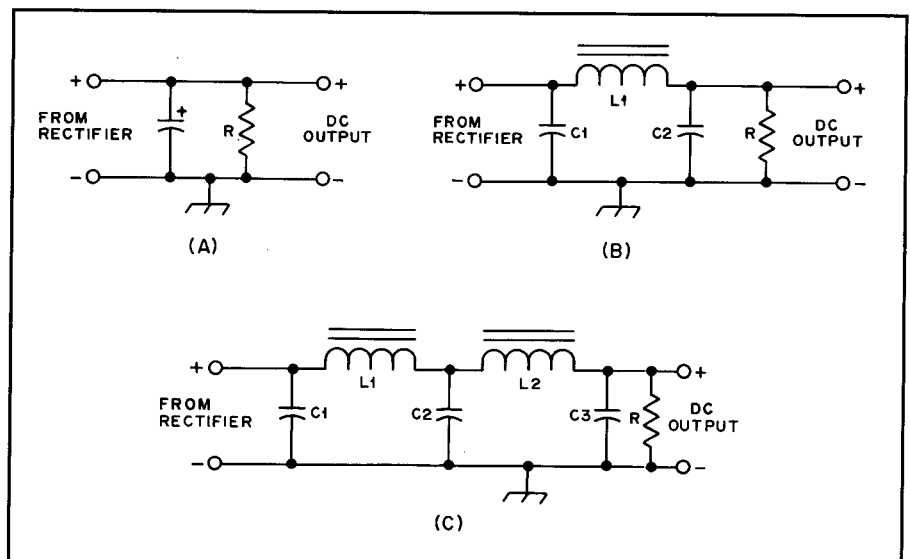

Fig 11.14 — Capacitor-input filter circuits. At A is a simple capacitor filter. B and C are single- and double-section filters, respectively.

drops in the chokes, all have the same characteristics except with respect to ripple. Better ripple reduction will be obtained when LC sections are added as shown in Fig 14B and C.

### Input Versus Output Voltage

The average output voltage of a capacitor-input filter is generally poorly regulated with load-current variations. This is because the rectifier diodes conduct for only a small portion of the ac cycle to charge the filter capacitor to the peak value of the ac waveform. When the instantaneous voltage of the ac passes its peak, the diode ceases to conduct. This forces the capacitor to support the load current until the ac voltage on the opposing diode in the bridge or full wave rectifier is high enough to pick up the load and recharge the capacitor. For this reason, the diode currents are usually quite high.

Since the cyclic peak voltage of the capacitor-filter output is determined by the peak of the input ac waveform, the minimum voltage and, therefore, the ripple amplitude, is determined by the amount of voltage discharge, or "droop," occurring in the capacitor while it is discharging and supporting the load. Obviously, the higher the load current, the proportionately greater the discharge, and therefore the lower the average output voltage will be.

Although not exactly accurate, an easy way to determine the peak-to-peak ripple for a certain capacitor and load is to as-

sume a constant load current. We can calculate the droop in the capacitor by using the relationship:

$$C \times E = I \times t \quad (3)$$

where:

$C$  = the capacitance in microfarads,

$E$  = the voltage droop, or peak-to-peak ripple voltage,

$I$  = the load current in milliamperes and

$t$  = the time between half-cycles of the rectified waveform, in milliseconds.

For 60 Hz full-wave rectifiers,  $t$  is about 7.5 ms.

As an example, let's assume that we need to determine the peak to peak ripple voltage at the dc output of a full-wave rectifier/filter combination that produces 13.8 V dc and supplies a transceiver drawing 2.0 A. The filter capacitor in the power supply is 5000  $\mu$ F. Using the above relationship:

$$C \times E = I \times t$$

$$5000 \mu\text{F} \times E = 2000 \text{ mA} \times 7.5 \text{ ms}$$

$$E = \frac{2000 \text{ mA} \times 7.5 \text{ ms}}{5000 \mu\text{F}} = 3 \text{ V P-P}$$

Obviously, this is too much ripple. A capacitor value of about 20000  $\mu$ F would be better suited for this application. If a linear regulator is used after this rectifier/filter combination, however, and the source voltage raised to produce a dc voltage of about 20 V, the 5000- $\mu$ F capacitor with its 3 V peak-to-peak ripple would

work well, since the regulator would remove the ripple content before the output power was applied to the transceiver.

### CHOKE-INPUT FILTERS

Choke-input filters have become less popular than they once were, because of the high surge current capability of silicon rectifiers. Choke-input filters provide the benefits of greatly improved output voltage stability over varying loads and low peak-current surges in the rectifiers. On the negative side, however, the choke is bulky and heavy, and the output voltage is lower than that of a capacitor-input filter.

As long as the inductance of the choke is large enough to maintain a continuous current over the complete cycle of the input ac waveform, the filter output voltage will be the average value of the rectified output. The average dc value of a full-wave rectified sine wave is 0.637 times its peak voltage. Since the RMS value is 0.707 times the peak, the output of the choke input filter will be  $(0.637 / 0.707)$ , or 0.90 times the RMS ac voltage. For light loads, however, there may not be enough energy stored in the choke during the input waveform crest to allow continuous current over the full cycle. When this happens, the filter output voltage will rise as the filter assumes more and more of the characteristics of a capacitor-input filter.

Choke-input filters see extensive use in the energy-storage networks of switch-mode regulators.

## Regulation

The output of a rectifier/filter system may be usable for some electronic equipment, but for today's transceivers and accessories, further measures may be necessary to provide power sufficiently clean and stable for their needs. Voltage regulators are often used to provide this additional level of conditioning.

Rectifier/filter circuits by themselves are unable to protect the equipment from the problems associated with input-power-line fluctuations, load-current variations and residual ripple voltages. Regulators can eliminate these problems, but not without costs in circuit complexity and power-conversion efficiency.

**Fig 11.15 — Zener-diode voltage regulation.** The voltage from a negative supply may be regulated by reversing the power-supply connections and the diode polarity.

### ZENER DIODES

A Zener diode (named after American physicist Dr. Clarence Zener) can be used to maintain the voltage applied to a circuit at a practically constant value, regardless of the voltage regulation of the power supply or variations in load current. The typical circuit is shown in Fig 11.15. Note that the cathode side of the diode is connected to the positive side of the supply. The electrical characteristics of a Zener diode under conditions of forward and reverse voltage are given in the **Analog Signals and Components** chapter.

Zener diodes are available in a wide variety of voltages and power ratings. The

voltages range from less than two to a few hundred, while the power ratings (power the diode can dissipate) run from less than 0.25 W to 50 W. The ability of the Zener diode to stabilize a voltage depends on the diode's conducting impedance. This can be as low as 1  $\Omega$  or less in a low-voltage, high-power diode or as high as 1000  $\Omega$  in

a high-voltage, low-power diode.

## LINEAR REGULATORS

Linear regulators come in two varieties: series and *shunt*. The shunt regulator is simply an electronic (also called "active") version of the Zener diode. For the most part, the active shunt regulator is rarely

used since the series regulator is a superior choice for most applications. **Fig 11.16B** shows a shunt regulator.

The series regulator consists of a stable voltage reference, which is usually established by a Zener diode, a transistor in series with the power source and the load (called a *series pass transistor*), and an error amplifier. In critical applications a temperature-compensated reference diode would be used instead of the Zener diode. (See Fig 11.16A.)

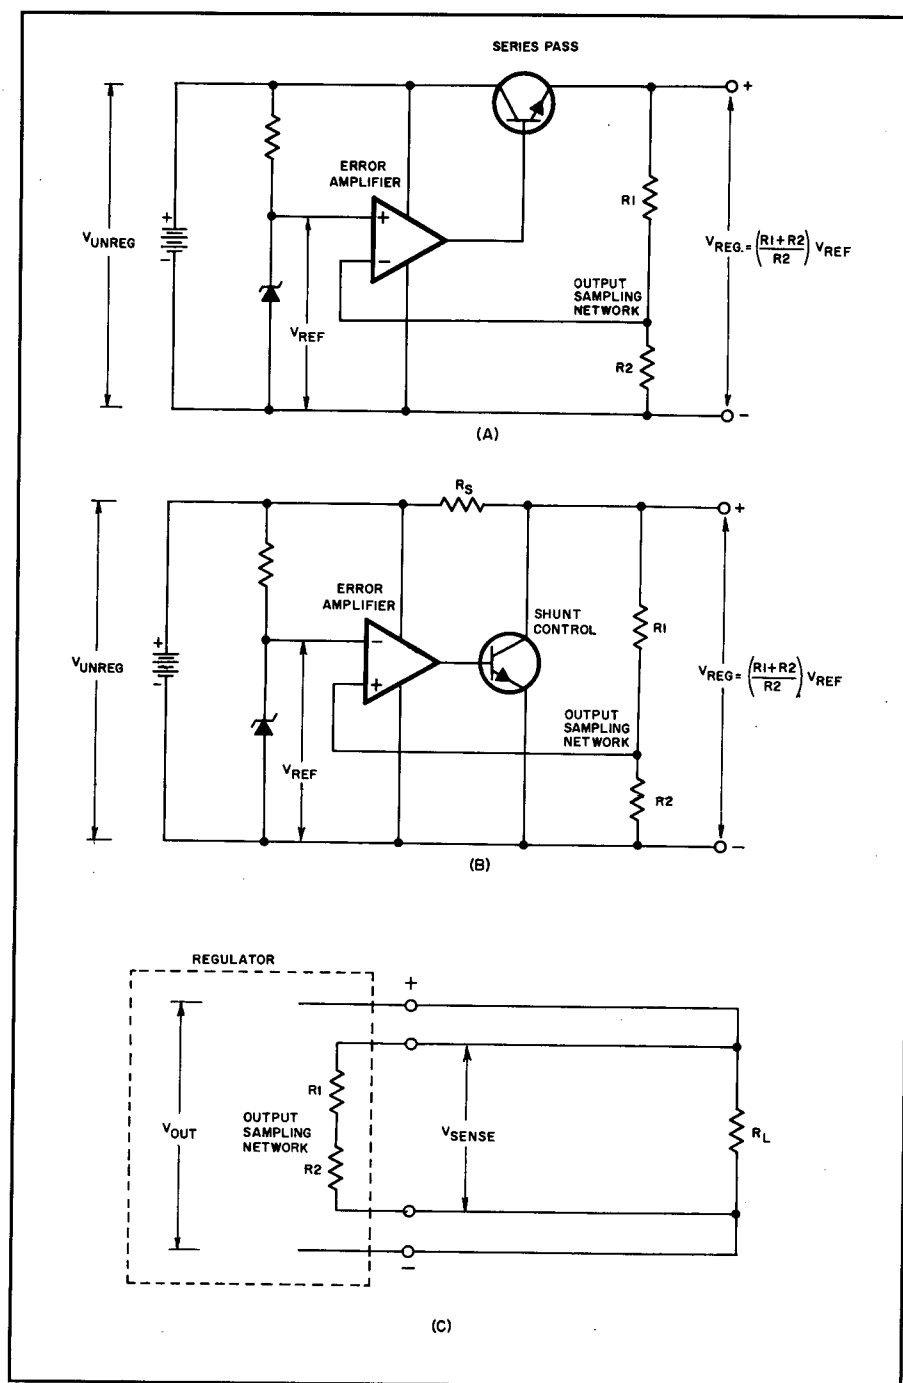

The output voltage is sampled by the error amplifier, which compares the output (usually scaled down by a voltage divider) to the reference. If the scaled-down output voltage becomes higher than the reference voltage, the error amplifier reduces the drive current to the pass transistor, thereby allowing the output voltage to drop slightly. Conversely, if the load pulls the output voltage below the desired value, the amplifier drives the pass transistor into increased conduction.

The "stiffness" or tightness of regulation of a linear regulator depends on the gain of the error amplifier and the ratio of the output scaling resistors. In any regulator, the output is cleanest and regulation stiffest at the point where the sampling network or error amplifier is connected. If heavy load current is drawn through long leads, the voltage drop can degrade the regulation at the load. To combat this effect, the feedback connection to the error amplifier can be made directly to the load. This technique, called *remote sensing*, moves the point of best regulation to the load by bringing the connecting leads inside the feedback loop. This is shown in Fig 11.16C.

### Input Versus Output Voltage

In a series regulator, the pass-transistor power dissipation is directly proportional to the load current and input/output voltage differential. The series pass element can be located in either leg of the supply. Either NPN or PNP devices can be used, depending on the ground polarity of the unregulated input.

The differential between the input and output voltages is a design tradeoff. If the input voltage from the rectifiers and filter is only slightly higher than the required output voltage, there will be minimal voltage drop across the series pass transistor resulting in minimal thermal dissipation and high power-supply efficiency. The supply will have less capability to provide regulated power in the event of power line brownout and other reduced line voltage conditions, however. Conversely, a higher input voltage will provide operation over a wider range of input voltage, but at the

**Fig 11.16 — Linear electronic voltage-regulator circuits.** In these diagrams, batteries represent the unregulated input-voltage source. A transformer, rectifier and filter would serve this function in most applications. Part A shows a series regulator and Part B shows a shunt regulator. Part C shows how remote sensing overcomes poor load regulation caused by the I R drop in the connecting wires by bringing them inside the feedback loop.

expense of increased heat dissipation.

## Pass Transistors

### Darlington Pairs

A simple Zener diode reference or IC op-amp error amplifier may not be able to

Fig 11.17 — At A, a Darlington-connected transistor pair for use as the pass element in a series-regulating circuit. At B, the method of connecting two or more transistors in parallel for high current output. Resistances are in ohms. The circuit at A may be used for load currents from 100 mA to 5 A, and the one at B may be used for currents from 6 A to 10 A.

Q1 — Motorola MJE 340 or equiv.  
Q2 - Q4 — Power transistor such as 2N3055 or 2N3772.

Fig 11.18 — Typical graph of the Safe Operating Area (SOAR) of a transistor. See text for details. Safe operating conditions for specific devices may be quite different from those shown here.

source enough current to a pass transistor that must conduct heavy load current. The Darlington configuration of Fig 11.17A multiplies the pass transistor beta, thereby extending the control range of the error amplifier. If the Darlington arrangement is implemented with discrete transistors, resistors across the base-emitter junctions may be necessary to prevent collector-to-base leakage currents in Q1 from being amplified and turning on the transistor pair. These resistors are contained in the envelope of a monolithic Darlington device.

When a single pass transistor is not available to handle the current required from a regulator, the current-handling capability may be increased by connecting two or more pass transistors in parallel. The circuit of Fig 11.17B shows the method of connecting these pass transistors. The resistances in the emitter leads of each transistor are necessary to equalize the currents.

### Transistor Ratings

When bipolar (NPN, PNP) power transistors are used in applications in which

they are called upon to handle power on a continuous basis, rather than switching, there are four parameters that must be examined to see if any maximum limits are being exceeded. Operation of the transistor outside these limits can easily result in the failure of the device. Unfortunately, not many hams (nor, sometimes, equipment manufacturers) are aware of all these parameters. Yet, for a transistor to provide reliable operation, the circuit designer must be sure not to allow his power supply or amplifier to cause overstress.

The four limits are maximum collector current ( $I_C$ ), maximum collector-emitter voltage ( $V_{CEO}$ ), maximum power and second breakdown ( $I_{SB}$ ). All four of these parameters are graphically shown on the transistor's data sheet on what is known as a Safe Operating Area (SOAR) graph. (See Fig 11.18.) The first three of these limits are usually also listed prominently with the other device information, but it is often the fourth parameter that is responsible for the "sudden death" of the power transistor after an extended operating period.

The maximum current limit of the tran-

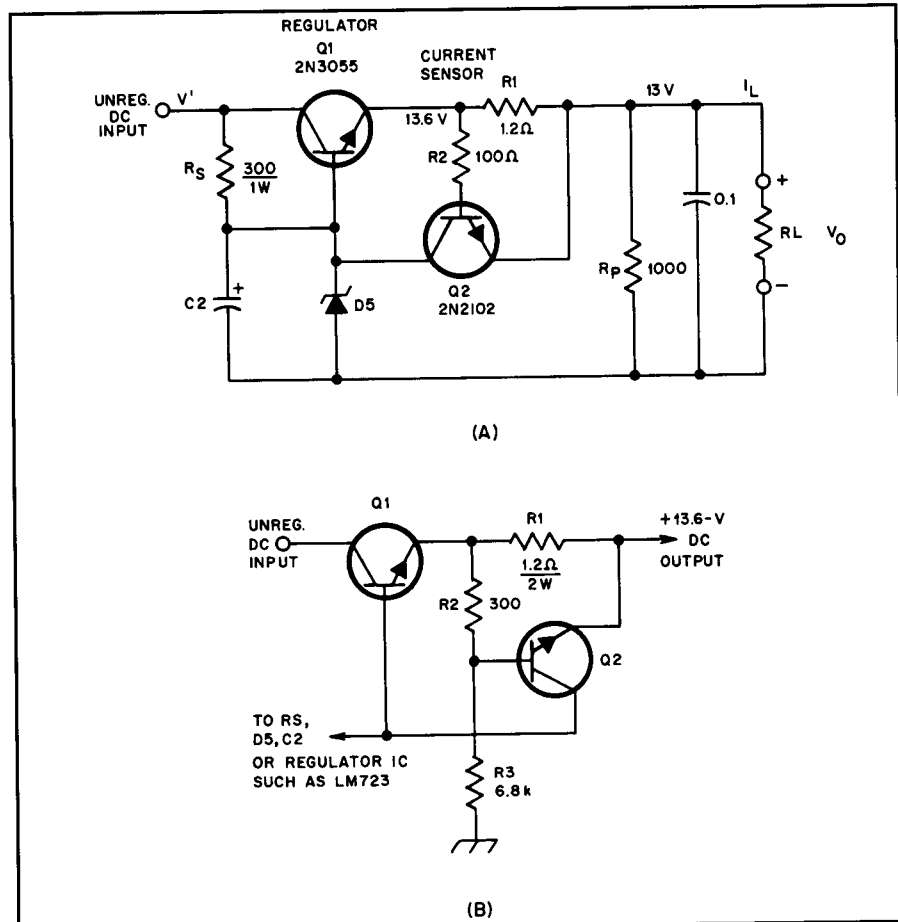

Fig 11.19 — Overload protection for a regulated supply can be implemented by addition of a current-overload-protective circuit, as shown at A. At B, the circuit has been modified to employ current-foldback limiting.

sistor ( $I_C \text{ MAX}$ ) is usually the current limit for fusing of the bond wire connected to the emitter, rather than anything pertaining to the transistor chip itself. When this limit is exceeded, the bond wire can melt and open circuit the emitter. On the operating curve, this limit is shown as a horizontal line extending out from the Y-axis (zero volts between collector and emitter) and ending at the voltage point where the constant power limit begins.

The maximum collector-emitter voltage limit of the transistor ( $V_{CE \text{ MAX}}$ ) is the point at which the transistor can no longer stand off the voltage between collector and emitter.

With increasing collector-emitter voltage drop at maximum collector current, a point is reached where the power in the transistor will cause the junction temperature to rise to a level where the device leakage current rapidly increases and begins to dominate. In this region, the product of the voltage drop and the current would be constant and represent the maximum power ( $P_T$ ) rating for the transistor; that is, as the voltage drop continues to increase, the collector current must decrease to maintain the power dissipation at a constant value.

With most of the higher voltage rated transistors, a point is reached on the constant power portion of the curve whereby, with further increased voltage drop, the maximum power rating is *not* constant, but decreases as the collector to emitter voltage increases. This decrease in power handling capability continues until the maximum voltage limit is reached.

This special region is known as the forward bias second breakdown (FBSB) area. Reduction in the transistor's power handling capability is caused by localized heating in certain small areas of the transistor junction ("hot spots"), rather than a uniform distribution of power dissipation over the entire surface of the device.

The region of operating conditions contained within these curves is called the Safe Operating Area, or SOAR. If the transistor is always operated within these limits, it should provide reliable and continuous service for a long time.

### Overcurrent Protection

Damage to a pass transistor can occur when the load current exceeds the safe amount. Fig 11.19A illustrates a simple current-limiter circuit that will protect Q1. All of the load current is routed through R1. A voltage difference will exist across R1; the value will depend on the exact load current at a given time. When the load current exceeds a predetermined safe value, the voltage drop across R1 will forward-

bias Q2 and cause it to conduct. Because Q2 is a silicon transistor, the voltage drop across R1 must exceed 0.6 V to turn Q2 on. This being the case, R1 is chosen for a value that provides a drop of 0.6 V when the maximum safe load current is drawn. In this instance, the drop will be 0.6 V when  $I_L$  reaches 0.5 A. R2 protects the base-emitter junction of Q2 from current spikes, or from destruction in the event Q1 fails under short-circuit conditions.

When Q2 turns on, some of the current through  $R_S$  flows through Q2, thereby depriving Q1 of some of its base current. This action, depending upon the amount of Q1 base current at a precise moment, cuts off Q1 conduction to some degree, thus limiting the current through it.

### Foldback Current Limiting

Under short-circuit conditions, a constant-current type current limiter must still withstand the full source voltage and limited short circuit current simultaneously, which can impose a very high power dissipation or second breakdown stress on the series pass transistor. For example, a 12-V regulator with current limiting set for 10 A and having a source of 16 V will have a dissipation of 40 W [ $(16 \text{ V} - 12 \text{ V}) \times 10 \text{ A}$ ] at the point of current limiting (knee). But its dissipation will rise to 160 W under short-circuit conditions ( $16 \text{ V} \times 10 \text{ amps}$ ).

A modification of the limiter circuit can cause the regulated output current to decrease with decreasing load resistance after the overcurrent knee. With the output shorted, the output current is only a fraction of the knee current value, which protects the series pass transistor from excessive dissipation and possible failure. Using the previous example of the 12-V, 10-A regulator, if the short-circuit current is designed to be 3 A (the knee is still 10 A), the transistor dissipation with a short circuit will be only  $16 \text{ V} \times 3 \text{ A} = 48 \text{ W}$ .

Fig 11.19B shows how the current limiter example given in the previous section would be modified to incorporate foldback limiting. The divider string formed by R2 and R3 provides a negative bias to the base of Q2, which prevents Q2 from turning on until this bias is overcome by the drop in R1 caused by load current. Since this hold-off bias decreases as the output voltage drops, Q2 becomes more sensitive to current through R1 with decreasing output voltage. See Fig 11.20.

The circuit is designed by first calculating the value of R1 for short-circuit current. For example, if 0.5 A is chosen, the value for R1 is simply  $0.6 \text{ V} / 0.5 \text{ A} = 1.2 \Omega$  (with the output shorted, the amount of hold-off bias supplied by R2 and R3 is very small and can be neglected). The knee

Fig 11.20 — The 1-A regulator shown in Fig 11.19B will fold back to 0.5 A under short-circuit conditions. See text.

current is then chosen. For this example, the selected value will be 1.0 A. The divider string is then proportioned to provide a base voltage at the knee that is just sufficient to turn on Q2 (a value of 13.6 V for 13.0 V output). With 1.0 A flowing through R1, the voltage across the divider will be 14.2 V. The voltage dropped by R2 must then be  $14.2 \text{ V} - 13.6 \text{ V}$ , or 0.6 V. Choosing a divider current of 2 mA, the value of R2 is then  $0.6 \text{ V} / 0.002 \text{ A} = 300 \Omega$ . R3 is calculated to be  $13.6 \text{ V} / 0.002 \text{ A} = 6800 \Omega$ .

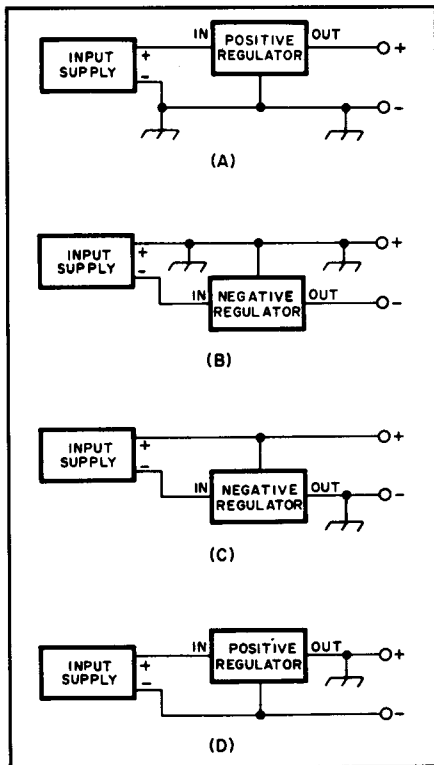

### "Crowbar" Circuits

Electronic components *do* fail from time to time. In a regulated power supply, the only component standing between an elevated dc source voltage and your rig is one transistor, or a group of transistors wired in parallel. If the transistor, or one of the transistors in the group, happens to short internally, your rig could suffer lots of damage.

To safeguard the rig or other load equipment against possible overvoltage, some power-supply manufacturers include a circuit known as a crowbar. This circuit usually consists of a silicon-controlled rectifier (SCR) connected directly across the output of the power supply, with a voltage-sensing trigger circuit tied to its gate. In the event the output voltage exceeds the trigger set point, the SCR will fire, and the output is short circuited. The resulting high current in the power supply (shorted output in series with a series pass transistor failed short) will blow the power supply's line fuses.

### IC VOLTAGE REGULATORS

The modern trend in regulators is toward the use of three-terminal devices commonly referred to as *three-terminal regulators*. Inside each regulator is a voltage reference, a high-gain error amplifier, temperature-compensated voltage sensing

**Fig 11.21** — Parts A and B illustrate the conventional manner in which three-terminal regulators are used. Parts C and D show how one polarity regulator can be used to regulate the opposite-polarity voltage.

**Fig 11.22** — Effects of input-output differential voltage on three-terminal regulator current.

**Fig 11.23** — By varying the ratio of R2 to R1 in this simple LM317 schematic diagram, a wide range of output voltages is possible. See text for details.

resistors and a pass element. Many currently available units have thermal shutdown, overvoltage protection and current foldback, making them virtually destruction-proof.

Three-terminal regulators (a connection for unregulated dc input, regulated dc output and ground) are available in a wide range of voltage and current ratings. Fairchild, National and Motorola are perhaps the three largest suppliers of these regulators at present. It is easy to see why regulators of this sort are so popular when you consider the low price and the number of individual components they can replace. The regulators are available in several different package styles, depending on current ratings. Low-current (100 mA) devices frequently use the plastic TO-92 and DIP-style cases. TO-220 packages are popular in the 1.5-A range, and TO-3 cases house the larger 3-A and 5-A devices.

Three-terminal regulators are available as positive or negative types. In most cases, a positive regulator is used to regulate a positive voltage and a negative regulator a negative voltage. Depending on the system ground requirements, however, each regulator type may be used to regulate the "opposite" voltage.

Fig 11.21A and B illustrate how the regulators are used in the conventional mode. Several regulators can be used with a common-input supply to deliver several voltages with a common ground. Negative regulators may be used in the same manner. If no other common supplies operate off the input supply to the regulator, the circuits of Fig 11.21C and D may be used to regulate positive voltages with a negative regulator and vice versa. In these configurations the input supply is floated; neither side of the input is tied to the system ground.

Manufacturers have adopted a system of family numbers to classify three-terminal regulators in terms of supply polarity, output current and regulated voltage. For example, National Semiconductor uses the number LM7805C to describe a positive 5-V, 1.5-A regulator; the comparable unit from Texas Instruments is a UA7805KC. LM7812C describes a 12-V regulator of similar characteristics. LM7905C denotes a negative 5-V, 1.5-A device. There are many such families with widely varied ratings available from manufacturers. Fixed-voltage regulators are available with output ratings in most common values between 5 and 28 V. Other families include devices that can be adjusted from 1.25 to 50 V.

## Regulator Specifications

When choosing a three-terminal regula-

tor for a given application, the most important specifications to consider are device output voltage, output current, input-to-output differential voltage, line regulation, load regulation and power dissipation. Output voltage and current requirements are determined by the load with which the supply will ultimately be used.

Input-to-output differential voltage is one of the most important three-terminal regulator specifications to consider when designing a supply. The differential value (the difference between the voltage applied to the input terminal and the voltage on the output terminal) must be within a specified range. The minimum differential value, usually about 2.5 V, is called the dropout voltage. If the differential value is less than the dropout voltage, no regulation will take place. At the other end of the scale, maximum input-output differential voltage is generally about 40 V. If this differential value is exceeded, device failure may occur.

Increases in either output current or differential voltage produce proportional increases in device power consumption. By employing a safety feature called current foldback, some manufacturers ensure that maximum dissipation will never be exceeded in normal operation. Fig 11.22 shows the relationship between output current, input-output differential and current limiting for a three-terminal regulator nominally rated for 1.5-A output current. Maximum output current is available with differential voltages ranging from about 2.5 V (dropout voltage) to 12 V. Above 12 V, the output current decreases, limiting the device dissipation to a safe value. If the output terminals are accidentally short circuited, the input-output differential will rise, causing current foldback, and thus preventing the power-supply components from being over stressed. This protective feature makes three-terminal regulators particularly attractive in simple power supplies.

When designing a power supply around a particular three-terminal regulator, input-output voltage characteristics of the regulator should play a major role in selecting the transformer-secondary and filter-capacitor component values. The unregulated voltage applied to the input of the three-terminal device should be higher than the dropout voltage, yet low enough that the regulator does not go into current limiting caused by an excessive differential voltage. If, for example, the regulated output voltage of the device shown in Fig 11.22 was 12, then unregulated input voltages of between 14.5 and 24 would be acceptable if maximum output current is desired.

In use, all but the lowest current regulators generally require an adequate external heat sink because they may be called on to dissipate a fair amount of power. Also, because the regulator chip contains a high-gain error amplifier, bypassing of the input and output leads is essential for stable operation.

Most manufacturers recommend bypassing the input and output directly at the leads where they protrude through the heat sink. Solid tantalum capacitors are usually recommended because of their good high-frequency capabilities.

External capacitors used with IC regulators may discharge through the IC junctions under certain circuit conditions, and high current discharges can harm ICs. Look at the regulator data sheet to see whether protection diodes are needed, what diodes to use and how to place them in any particular application.

In addition to fixed-output-voltage ICs, high-current, adjustable voltage regulators are available. These ICs require little more than an external potentiometer for an adjustable output range from 5 to 24 V at up to 5 A. The unit price on these items is only a few dollars, making them ideal for test-bench power supplies. A very popular low current, adjustable output voltage three terminal regulator, the LM317, is shown in Fig 11.23. It develops a steady 1.25-V reference,  $V_{REF}$ , between the output and adjustment terminals. By installing  $R_1$  between these terminals, a constant current,  $I_1$ , is developed, governed by the equation:

$$I_1 = \frac{V_{REF}}{R_1} \quad (4)$$

Both  $I_1$  and a 100- $\mu$ A error current,  $I_2$ , flow through  $R_2$ , resulting in output voltage  $V_O$ .  $V_O$  can be calculated using the equation:

$$V_O = V_{REF} \left( 1 + \frac{R_2}{R_1} \right) + I_2 \times R_2 \quad (5)$$

Fig 11.24 — The basic LM317 voltage regulator is converted into a constant-current source by adding only one resistor.

Any voltage between 1.2 and 37 V may be obtained with a 40-V input by changing the ratio of  $R_2$  to  $R_1$ . At lower output voltages, however, the available current will be limited by the power dissipation of the regulator.

Fig 11.24 shows one of many flexible applications for the LM317. By adding only one resistor with the regulator, the voltage regulator can be changed into a constant-current source capable of charging NiCd batteries, for example. Design equations are given in the figure. The same precautions should be taken with adjustable regulators as with the fixed voltage units. Proper heat sinking and lead bypassing are essential for proper circuit operation.

### Increasing Regulator Output Current

When the maximum output current from an IC voltage regulator is insufficient to operate the load, discrete power transistors may be connected to increase the current capability. Fig 11.25 shows two methods for boosting the output current of a positive regulator, although the same techniques can be applied to negative regulators.

In A, an NPN transistor is connected as an emitter follower, multiplying the output current capacity by the transistor beta. The shortcoming of this approach is that the base-emitter junction is not inside the feedback loop. The result is that the output voltage is reduced by the base-emitter drop, and the load regulation is degraded by variations in this drop.

The circuit at B has a PNP transistor "wrapped around" the regulator. The regulator draws current through the base-emitter junction, causing the transistor to conduct. The IC output voltage is unchanged by the transistor because the collector is connected directly to the IC output (sense point). Any increase in output voltage is detected by the IC regulator, which shuts

off its internal pass transistor, and this stops the boost-transistor base current.

### HIGH-PRECISION SERIES REGULATOR LOOP DESIGN

This regulator-loop-design material was contributed by William E. Sabin, WØIYH. (A similar discussion appears in May 1991 *QEX*, pp 3-9.) The discussion here concerns some of the important factors in the design and testing of a series regulator feedback loop. These techniques were used to design "A Series Regulated 4.5- to 25-V 2.5-A Power Supply," which appears later in this chapter. The values and measurements discussed here are from that circuit. Fig 11.26 is a simplified version of that supply, which is adequate for this discussion.

The series regulator is a good example of a feedback control system. Open-loop gain and bandwidth, the phase and gain margins and the transient response are important factors. The goal of the design is to maximize the regulator closed-loop performance. One approach is to use a high value of open-loop gain and establish the open-loop frequency response in two ways: (1) an RC low-pass filter consisting of  $C_6$ ,  $R_2$ ,  $R_3$ ,  $\frac{1}{2} R_e$  and the output resistances of  $Q_1$  and  $Q_2$ ; and (2) a single small capacitor ( $C_4$ ) at the regulator IC. Note that the voltage drop across  $R_2$  and  $R_3$  is applied to pins 2 and 3 of the LM723 regulator IC, which are used for current limiting.  $R_2$  sets the current limit value, and  $R_3$ 's value affects the RC filter.

### Test Circuits

Fig 11.26 shows three test circuits. One is an adjustable Load Test Circuit that can be modulated linearly (almost) by: (1) a sine or triangle wave from a function generator with a dc-offset adjustment (so that the waveform always has positive polarity), or (2) by a bidirectional square wave. This circuit is used to test the loop response to various load fluctuations. It has

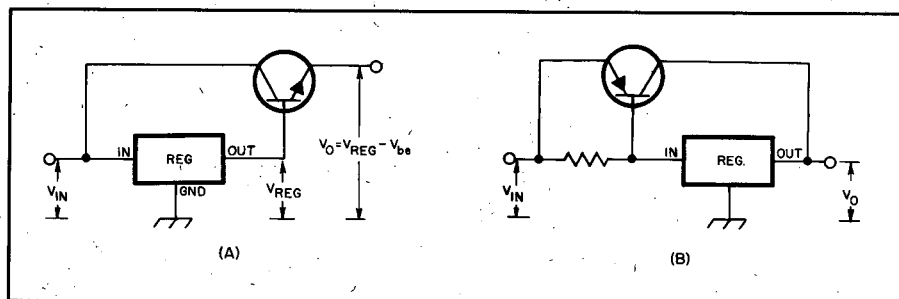

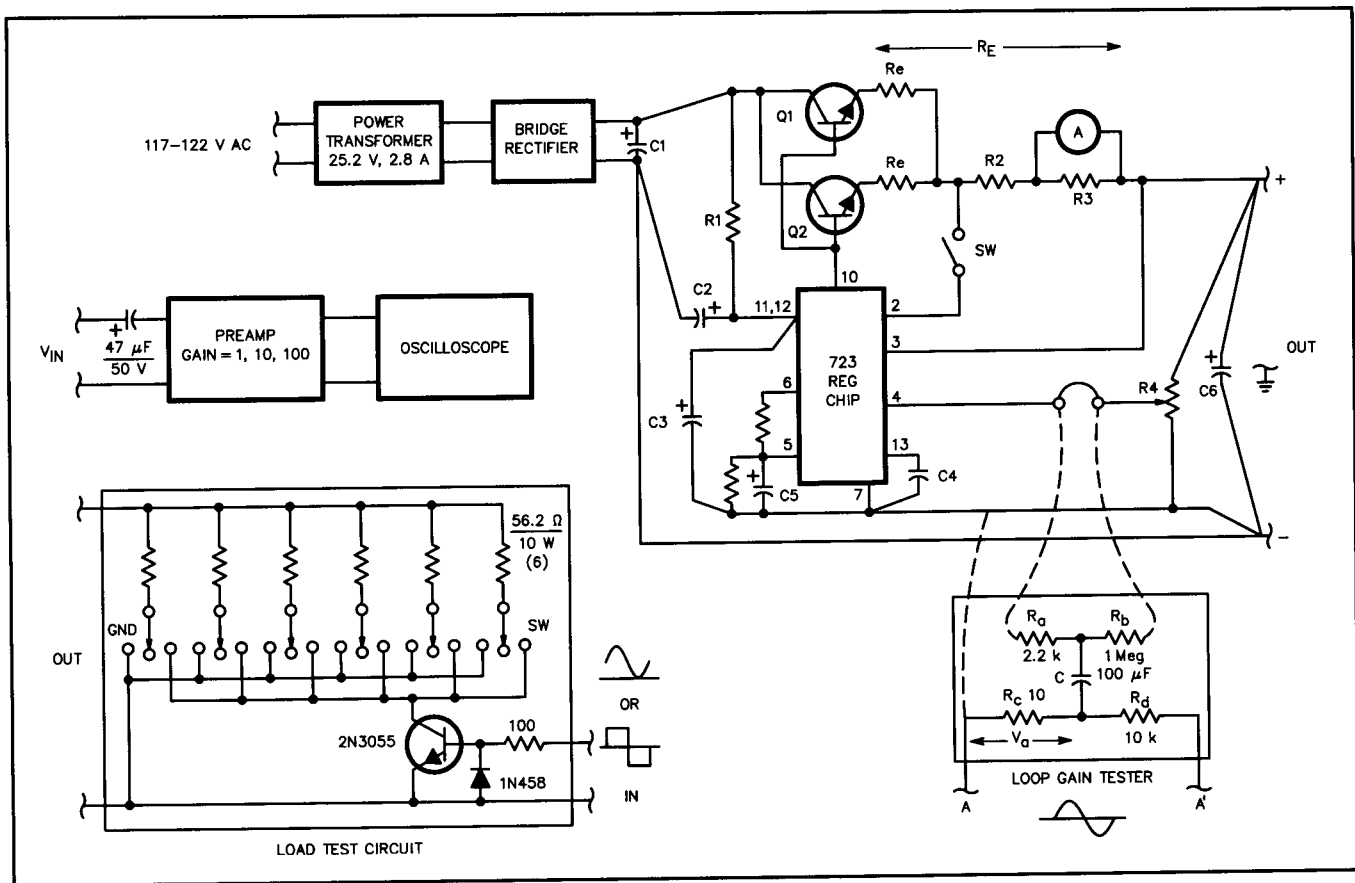

Fig 11.25 — Two methods for boosting the output-current capacity of an IC voltage regulator. Part A shows an NPN emitter follower and B shows a PNP "wrap-around" configuration. Operation of these circuits is explained in the text.

**Fig 11.26 — A simplified voltage-regulator feedback loop. The Loop Gain Tester, Load Tester, Load Test Circuit and oscilloscope circuits are used to test open-loop response and gain. the heavy lines indicate critical low-impedance circuit paths.**

proved to be very informative, as discussed later.

The second test circuit (Loop Gain Tester) is inserted into the regulator loop so that a test signal can be injected into the loop, in order to measure the open-loop gain and frequency response. Notice that the loop is closed through the feedback path of R4, R<sub>b</sub> and R<sub>a</sub> at dc and very low frequencies (less than 0.5 Hz), and the dc output voltage is pretty well regulated (which is essential to loop testing). By observing the magnitude (and rate of change) of the frequency response, it is possible to deduce information about phase shift.<sup>1</sup> With this information available, the gain and phase margins (and therefore the regulation, stability, transient response and output impedance) of the closed-loop regulator can be estimated.

The third test circuit is a two-stage op amp preamplifier and oscilloscope. It is used to measure very small signals in

the 0.1-Hz to 400-kHz range.

### Open-Loop Tests

The test signal applied to points A and A' is reduced 60 dB by a voltage divider: R<sub>d</sub> and R<sub>c</sub>. (The voltage division converts convenient input voltages, which we can measure with ordinary equipment, to microvolt levels in the loop.) Capacitor C couples V<sub>a</sub>, the voltage across R<sub>c</sub>, to the '723 through R<sub>a</sub>. R<sub>a</sub> is roughly the resistance that the '723 sees in normal operation. The test signal is amplified by at most 74 dB on its way (clockwise around the loop and through the regulator) to the right-hand end of R<sub>b</sub>. It is then attenuated 100 dB by R<sub>b</sub> and R<sub>c</sub>. This means that the "leak-through" back to the '723 input is much smaller, than the V<sub>a</sub> that we started with, if the frequency is 2 Hz or greater. At dc (and very low frequencies) the regulator functions somewhat normally. Above 2 Hz, then, the magnitude of the open-loop gain at the test frequency is very nearly the ratio  $|V_{out}| / |V_a|$ .

The first benefit of this test circuit was that it isolated an instability in the '723. The oscillation, at several hundred kHz, was cured by adding C4 (33 pF) and C3

(100 μF / 50 V with very short leads). Normally, one would suspect an oscillation to involve the overall loop, but this was not the case. This kind of instability is common in feedback control systems: Everything appears to function (usually not to full specification), but an embedded element is not stable.

### Open-Loop Frequency Response

Refer to Fig 11.26. The open-loop gain is the product of three factors. The test signal is:

1. Voltage amplified by the regulator IC (about 74 dB for the '723) on its way (clockwise) to the emitters of Q1 and Q2.
2. Low-pass filtered by C6 and R<sub>E</sub> (the combination of  $\frac{1}{2} R_E + R_2 + R_3$ ).
3. Divided by potentiometer R4.

For the 2.5-A supply, the greatest open-loop gain values are 59 dB at 25 V output and 74 dB at 4.5 V.

Fig 11.27 shows the open-loop frequency response to the top of R4 when R<sub>E</sub> is set for a 2.5-A current limit. At very low frequencies, the drop off is due to the gradual closure of the feedback loop, as mentioned above. At higher frequencies,

<sup>1</sup>Van Valkenburg, M.E., *Introduction to Modern Network Synthesis*, Chapter 8, New York: John Wiley & Sons, 1967.

**Fig 11.27 — The open-loop frequency response curves of the voltage-regulator feedback loop. Point A is 120 Hz; point B is 280 Hz; point C is 1.2 kHz (above 1.2 kHz, C6 is no longer effective).**

the roll off results from the combined effects of C4 and C6; it occurs at a 6-dB-per-octave rate (within the errors of instrumentation). The cutoff frequency is about 280 Hz, which is:

$$f_{co} = \frac{1}{2 \times \pi \times R_E \times C6} \quad (6)$$

where:

$f_{co}$  = cutoff frequency in Hz

$R_E = 0.57 \Omega$

$C6 = 1000 \mu F$

For comparison, a reference curve (6 dB per octave at the high and low ends) is superimposed. At about 1.2 kHz or so, the reactance of C6 is roughly equal to its equivalent series resistance (ESR), which is about  $0.13 \Omega$  for a small 1000- $\mu F$  aluminum-electrolytic capacitor. Beyond this frequency the impedance of C6 does not diminish, and C4 takes over (thereby maintaining the 6-dB-per-octave roll-off rate). Careful measurements and computer simulations of the regulator loop verified that C4 and C6 do, in fact, collaborate pretty well in this manner.

This characteristic is the desired effect. At 120 Hz (the major ripple frequency) the loop gain is maximum, so the regulator loop works hard to suppress output ripple. At higher frequencies, the roll-off rate implies a loop phase shift in the neighborhood of  $90^\circ$ , which assures closed-loop stability and good transient response. Closed-loop transient response tests (using a square-wave signal injected into the Load Test Circuit) verify the absence of ringing or large overshoot.

When  $R_E$  is increased to limit at smaller currents, the cutoff frequency decreases.

In the example supply, the 0.5-A and 0.1-A range cutoff frequencies are 58 Hz and 12 Hz, respectively, and the roll-off rate remains 6 dB per octave as before. Hence, the loop gain at 120 Hz is reduced. The ripple voltage across C1, however, is also greatly reduced at lighter load currents. In the end, output ripple remains very low.

### Closed-Loop Response

The closed-loop gain of the regulator is:

$$G_{CL} = 20 \log \left( \frac{V_{out}}{V_{ref}} \right) \quad (7)$$

where:

$G_{CL}$  = closed-loop gain, in dB

$V_{out}$  = output voltage

$V_{Ref}$  = reference voltage.

Here,  $V_{out}$  is 4.5 V, minimum (25.0 V, maximum) and  $V_{Ref}$  is 4.5 V. Fig 11.27 shows the locations of the minimum and maximum gain values and also the corresponding closed-loop bandwidths. By locating the 280-Hz cutoff frequency fairly close to the 120-Hz ripple frequency, the closed-loop bandwidth is minimized, which is desirable in a voltage regulator.

Another important regulator parameter is closed-loop output impedance. Fig 11.28 shows a computer simulation of this parameter. Mathematical analysis and actual measurements using the Load Test Circuit with a sine-wave test signal corroborate the simulations quite well. Two results are shown. For curve A, the C6 component (of Fig 11.26) is removed from the circuit, and C4 is increased so that the 280-Hz cutoff frequency is main-

**Fig 11.28 — Output impedance magnitude for the voltage-regulator feedback loop.**

tained, as we discussed before. At low frequencies the output impedance should be  $R_E$  ( $0.57 \Omega$ ) divided by the open-loop voltage gain (5000 maximum), about  $0.11 m\Omega$ . Above 280 Hz, though, the output impedance increases rapidly because the open-loop gain is decreasing. It will eventually reach the value of  $R_E$ .

For curve B, the original values of C6 and C4 are used, and the output impedance remains low up to about 1.2 kHz. It then increases, but remains much lower than curve A. This happens because C4 is smaller than in curve A and C4 mainly determines the frequency characteristic. In other words, the impedance of C6 (its reactance plus its ESR) is in parallel with the relatively small output impedance of a high-gain feedback amplifier. Therefore, C4 is much less influential in determining the power-supply output impedance. This situation gradually changes as frequency increases.

This discussion shows that the output-impedance characteristic of the power supply is reduced at frequencies that are significant in certain applications. Furthermore, it can be reduced by feedback to levels that are impossible with practical capacitors. To take advantage of this lower impedance, the regulator must be located extremely close to the load (remote sensing is another possibility).

When extremely tight regulation and low output impedance are important, the leads to the load must be very short, heavy straps. Multiple loads should be connected in parallel directly at the binding posts: A "daisy-chain" connection scheme does not assure equal regulation for each load; it counteracts precision regulation.

# High-Voltage Techniques

The construction of high-voltage supplies poses special considerations in addition to the normal design and construction practices used for lower-voltage supplies. In general, the constructor needs to remember that physical spacing between leads, connections, parts and the chassis must be sufficient to prevent arcing. Also, the series connection of components such as capacitor and resistor strings needs to be done with consideration for voltage stresses in the components.

## CAPACITORS

Capacitors will usually need to be connected in series strings to form an equivalent capacitor with the capability to withstand the applied voltage. When this is done, equal-value bypassing resistors need to be connected across each capacitor in the string in order to distribute the voltage equally across the capacitors. The *equalizing resistors* should have a value low enough to equalize differences in capacitor leakage resistance between the capacitors, while high enough not to dissipate excessive power. Also, capacitor bodies need to be insulated from the chassis and from each other by mounting them on insulating panels, thereby preventing arcing to the chassis or other capacitors in the string.

For high voltages, oil-filled paper-dielectric capacitors are superior to

electrolytics because they have lower internal impedance at high frequencies, lower leakage resistance and are available with higher working voltages. These capacitors are available in values of several microfarads and have working voltage ratings of thousands of volts. Avoid older oil-filled capacitors. They may contain polychlorinated biphenyls (PCBs), a known cancer-causing agent. Newer capacitors have eliminated PCBs and have a notice on the case to that effect.

## BLEEDER RESISTORS

Bleeder resistors should be given careful consideration. These resistors provide protection against shock when the power supply is turned off and dangerous wiring is exposed. A general rule is that the bleeder should be designed to reduce the output voltage to 30 V or less within 2 seconds of turning off the power supply. Take care to ensure that the maximum voltage rating of the resistor is not exceeded. The bleeder will consist of several resistors in series. One additional recommendation is that two separate bleeder strings be used, to provide safety in the event one of the strings fails.

## METERING TECHNIQUES

Special considerations should be observed for metering of high-voltage supplies, such as the plate supplies for linear

amplifiers. This is to provide safety to both personnel and also to the meters themselves.

To monitor the current, it is customary to place the ammeter in the supply return (ground) line. This ensures that both meter terminals are close to ground potential, as compared to the hazard created by placing the meter in the positive output line—in which case the voltage on each meter terminal would be near the full high-voltage potential. Also, there is the strong possibility that an arc could occur between the wiring and coils inside the meter and the chassis of the amplifier or power supply itself. This hazardous potential cannot exist with the meter in the negative leg. Another good safety practice is to place a low-voltage Zener diode across the terminals of the ammeter. This will bypass the meter in the event of an internal open circuit in the meter.

For metering of high voltage, the builder should remember that resistors to be used in multiplier strings have voltage breakdown ratings. Usually, several resistors need to be used in series to reduce voltage stress across each resistor. A basic rule of thumb is that resistors should be limited to a maximum of 200 V, unless rated otherwise. Therefore, for a 2000-V power supply, the voltmeter would have a string of 10 resistors connected in series to distribute the voltage equally.

# Batteries and Charging

The availability of solid-state equipment makes it practical to use battery power under portable or emergency conditions. Hand-held transceivers and instruments are obvious applications, but even fairly powerful transceivers (100 W or so output) may be practical users of battery power (for example, emergency power for the home station for ARES operation).

Lower-power equipment can be powered from two types of batteries. The "primary" battery is intended for one-time use and is then discarded; the "storage" (or "secondary") battery may be recharged many times.

A battery is a group of chemical cells, usually series-connected to give some desired multiple of the cell voltage. Each assortment of chemicals used in the cell gives a particular nominal voltage. This must be taken into account to make up a

particular battery voltage. For example, four 1.5-V carbon-zinc cells make a 6-V battery and six 2-V lead-acid cells make a 12-V battery. The **DC Theory and Resistive Components** chapter has more information about energy storage in batteries. In addition, the **Real World Component Characteristics** chapter has information about battery capacity and charge/discharge rates.

## PRIMARY BATTERIES

One of the most common primary-cell types is the carbon-zinc, or Leclanche flashlight type, in which chemical oxidation occurs during discharge. This chemical oxidation converts the zinc into salts, and produces electricity. When there is no current, the oxidation essentially stops until current is required. A slight amount of chemical action does continue, however, so stored batteries eventually will

degrade or dry out to the point where the battery will no longer supply the desired current. The time taken for degradation without battery use is called *shelf life*.

The carbon-zinc battery has a nominal voltage of 1.5 V. Larger cells are capable of producing more milliampere hours and less voltage drop than smaller cells. Heavy-duty and industrial batteries usually have a longer shelf life. The carbon-zinc cell is now largely being supplanted by the alkaline cell, which has better discharge characteristics and will retain more capacity at low temperatures. The alkaline cell typically has an ampere hour capacity of about twice that of the carbon-zinc cell. Its nominal voltage is also 1.5 V.

Lithium primary batteries have a nominal voltage of about 3 V per cell and by far the best capacity, discharge, shelf-life and temperature characteristics. Their disadvantages are high cost and the fact that they

cannot be readily replaced by other types in an emergency.

The lithium-thionyl-chloride battery is a primary cell, and should not be recharged under any circumstances. The charging process vents hydrogen, and a catastrophic hydrogen explosion can result. Even accidental charging caused by wiring errors or a short circuit should be avoided.

Silver oxide (1.5 V) and mercury (1.4 V) batteries are very good where nearly constant voltage is desired at low currents for long periods. Their main use (in subminiature versions) is in hearing aids, though they may be found in other mass-produced devices such as household smoke alarms.

## SECONDARY OR RECHARGEABLE BATTERIES

Many of the chemical reactions in primary batteries are theoretically reversible if current is passed through the battery in the reverse direction. For instance, zinc may be plated back onto the negative electrode of a carbon-zinc battery.

Primary batteries should not be recharged for two reasons: It may be dangerous because of heat generated within sealed cells, and even in cases where there may be some success, both the charge and life are limited. In the carbon-zinc example, the zinc may not replating in the locations that had been oxidized. Pinholes in the case result, with consequent fluid leakage that will damage the equipment powered by the batteries. (One type of alkaline battery is rechargeable, and is so marked).

### Nickel Cadmium

The most common type of smaller rechargeable battery is the nickel-cadmium (NiCd), with a nominal voltage of 1.2 V per cell. Carefully used, these are capable of 500 or more charge and discharge cycles. For best life, the NiCd battery must not be fully discharged. Where there is more than one cell in the battery, the most-discharged cell may suffer polarity reversal, resulting in a short circuit, or seal rupture. All storage batteries have discharge limits, and NiCd types should not be discharged to less than 1.0 V per cell.

Nickel cadmium cells are not limited to "D" cells and smaller sizes. They also are available in larger varieties ranging to mammoth 1000 Ah units having carrying handles on the sides and caps on the top for adding water, similar to lead-acid types. These large cells are sold to the aircraft industry for jet-engine starting, and to the railroads for starting locomotive diesel engines. They also are used extensively for uninterruptible power supplies. Although expensive, they have very long life. Surplus cells are often available through surplus electronics dealers, and

these cells often have close to their full rated capacity.

Advantages for the ham in these vented-cell batteries lie in the availability of high discharge current to the point of full discharge. Also, cell reversal is not the problem that it is in the sealed cell, since water lost through gas evolution can easily be replaced. Simply remove the cap and add distilled water. By the way, tap water should never be added to either nickel cadmium or lead-acid cells, since dissolved minerals in the water can hasten self discharge and interfere with the electrochemical process.

### Lead Acid

The most widely used high-capacity rechargeable battery is the lead-acid type. In automotive service, the battery is usually expected to discharge partially at a very high rate, and then to be recharged promptly while the alternator is also carrying the electrical load. If the conventional auto battery is allowed to discharge fully from its nominal 2 V per cell to 1.75 V per cell, fewer than 50 charge and discharge cycles may be expected, with reduced storage capacity.

The most attractive battery for extended high-power electronic applications is the so-called "deep-cycle" battery, which is intended for such use as powering electric fishing motors and the accessories in recreational vehicles. Size 24 and 27 batteries furnish a nominal 12 V and are about the size of small and medium automotive batteries. These batteries may furnish between 1000 and 1200 W-hr per charge at room temperature. When properly cared for, they may be expected to last more than 200 cycles. They often have lifting handles and screw terminals, as well as the conventional truncated-cone automotive terminals. They may also be fitted with accessories, such as plastic carrying cases, with or without built-in chargers.

Lead-acid batteries are also available with gelled electrolyte. Commonly called *gel cells*, these may be mounted in any position if sealed, but some vented types are position sensitive.

Lead-acid batteries with liquid electrolyte usually fall into one of three classes — conventional, with filling holes and vents to permit the addition of distilled water lost from evaporation or during high-rate charge or discharge; maintenance-free, from which gas may escape but water cannot be added; and sealed. Generally, the deep-cycle batteries have filling holes and vents.

## PROS AND CONS

### Chemical Hazards of Each Battery Type

In addition to the precautions given above, the following precautions are rec-

ommended. (Always follow the manufacturer's advice.)

Gas escaping from storage batteries may be explosive. Keep flames or lighted tobacco products away.

Dry-charged storage batteries should be given electrolyte and allowed to soak for at least half an hour. They should then be charged at about a 15 A rate for 15 minutes or so. The capacity of the battery will build up slightly for the first few cycles of charge and discharge, and then have fairly constant capacity for many cycles. Slow capacity decrease may then be noticed.

No battery should be subjected to unnecessary heat, vibration or physical shock. The battery should be kept clean. Frequent inspection for leaks is a good idea. Electrolyte that has leaked or sprayed from the battery should be cleaned from all surfaces. The electrolyte is chemically active and electrically conductive, and may ruin electrical equipment. Acid may be neutralized with sodium bicarbonate (baking soda), and alkalis may be neutralized with a weak acid such as vinegar. Both neutralizers will dissolve in water, and should be quickly washed off. Do not let any of the neutralizer enter the battery.

Keep a record of the battery use, and include the last output voltage and (for lead-acid storage batteries) the hydrometer reading. This allows prediction of useful charge remaining, and the recharging or procuring of extra batteries, thus minimizing failure of battery power during an excursion or emergency.

### Internal Resistance

Cell internal resistance is very important to handheld-transceiver users. This is because the internal resistance is in series with the battery's output and therefore reduces the available battery voltage at the high discharge currents demanded by the transmitter. The result is reduced transmitter output power and power wasted in the cell itself by internal heating. Because of cell-construction techniques and battery chemistry, certain types of cells typically have lower internal resistance than others.

The NiCd cell is the undisputed king of cell types for high discharge current capability. Also, the NiCd maintains this low internal resistance throughout its discharge curve, because the specific gravity of its potassium hydroxide electrolyte does not change.

Next in line is probably the alkaline primary cell. When these cells are used with handheld transceivers, it is not uncommon to have lower output power, and often to have the low battery indicator come on, even with fresh cells.

The lead-acid cell, which is finding

**Fig 11.29 — Output capacity as a function of discharge rate for two sizes of lead-acid batteries.**

popularity in belt-hung battery packs, is pretty close to the alkaline cell for internal resistance, but this is only at full charge. Unlike the NiCd, the electrolyte in the lead-acid cell enters into the chemical reaction. During discharge, the specific gravity of the electrolyte gradually drops as it approaches water, and the conductivity decreases. Therefore, as the lead-acid cell approaches a discharged state, the internal resistance increases. For the belt pack, larger cells are used (approximately 2 Ah) and the internal resistance is consequently reduced.

The worst cell of all is the common carbon-zinc flashlight cell. With the transmit current demand levels of handheld radios, these cells are pretty much useless.

## BATTERY CAPACITY

The common rating of battery capacity is ampere hours (Ah), the product of current drain and time. The symbol "C" is commonly used; C/10, for example, would be the current available for 10 hours continuously. The value of C changes with the discharge rate and might be 110 at 2 A but only 80 at 20 A. Fig 11.29 gives capacity-to-discharge rates for two standard-size lead-acid batteries. Capacity may vary from 35 mAh for some of the small hearing-aid batteries to more than 100 Ah for a size 28 deep-cycle storage battery.

Sealed primary cells usually benefit from intermittent (rather than continuous) use. The resting period allows completion of chemical reactions needed to dispose of by-products of the discharge.

The output voltage of all batteries drops as they discharge. "Discharged" condition

for a 12-V lead-acid battery, for instance, should not be less than 10.5 volts. It is also good to keep a running record of hydrometer readings, but the conventional readings of 1.265 charged and 1.100 discharged apply only to a long, low-rate discharge. Heavy loads may discharge the battery with little reduction in the hydrometer reading.

Batteries that become cold have less of their charge available, and some attempt to keep a battery warm before use is worthwhile. A battery may lose 70% or more of its capacity at cold extremes, but it will recover with warmth. All batteries have some tendency to freeze, but those with full charges are less susceptible. A fully charged lead-acid battery is safe to  $-30^{\circ}\text{F}$  ( $-26^{\circ}\text{C}$ ) or colder. Storage batteries may be warmed somewhat by charging. Blow-torches or other flame should never be used to heat any type of battery.

A practical discharge limit occurs when the load will no longer operate satisfactorily on the lower output voltage near the "discharged" point. Much gear intended for "mobile" use may be designed for an average of 13.6 V and a peak of perhaps 15 V, but will not operate well below 12 V. For full use of battery charge, the gear should operate well (if not at full power) on as little as 10.5 V with a nominal 12 to 13.6-V rating.

Somewhat the same condition may be seen in the replacement of carbon-zinc cells by NiCd storage cells. Eight carbon-zinc cells will give 12 V, while 10 of the same size NiCd cells are required for the same voltage. If a 10-cell battery holder is used, the equipment should be designed for 15 V in case the carbon-zinc units are plugged in.

## Discharge Planning

Transceivers usually drain a battery at two or three rates: one for receiving, one for transmit standby and one key-down or average voice transmit. Considering just the first and last of these (assuming the transmit standby is equal to receive), average two-way communication would require the low rate  $\frac{3}{4}$  of the time and the high rate  $\frac{1}{4}$  of the time. The ratio may vary somewhat with voice. The user may calculate the percentage of battery charge used in an hour by the combination (sum) of rates. If, for example, 20% of the battery capacity is used in an hour, the battery will provide five hours of communications per charge. In most actual traffic and DX-chasing situations the time spent listening should be much greater than that spent transmitting.

## Charging/Discharging Requirements

The rated full charge of a battery, C, is expressed in ampere-hours. No battery is perfect, so more charge than this must be offered to the battery for a full-charge. If, for instance, the charge rate is 0.1 C (the 10-hour rate), 12 or more hours may be needed for the charge.

Basically NiCd batteries differ from the lead-acid types in the methods of charging. It is important to note these differences, since improper charging can drastically shorten the life of a battery. NiCd cells have a flat voltage-versus-charge characteristic until full charge is reached; at this point the charge voltage rises abruptly. With further charging, the electrolyte begins to break down and oxygen gas is generated at the positive (nickel) electrode and hydrogen at the negative (cadmium) electrode.

Since the cell should be made capable of accepting an overcharge, battery manufacturers typically prevent the generation of hydrogen by increasing the capacity of the cadmium electrode. This allows the oxygen formed at the positive electrode to reach the metallic cadmium of the negative electrode and reoxidize it. During overcharge, therefore, the cell is in equilibrium. The positive electrode is fully charged and the negative electrode less than fully charged, so oxygen evolution and recombination "wastes" the charging power being supplied.

In order to ensure that all cells in a NiCd battery reach a fully charged condition, NiCd batteries should be charged by a constant current at about a 0.1-C current level. This level is about 50 mA for the AA-size cells used in most hand-held radios. This is the optimum rate for most NiCds since 0.1 C is high enough to provide a full charge, yet it is low enough to prevent over-charge damage and provide good charge efficiency.

Although fast-charge-rate (3 to 5 hours typically) chargers are available for hand-held transceivers, they should be used with care. The current delivered by these units is capable of causing the generation of large quantities of oxygen in a fully charged cell. If the generation rate is greater than the oxygen recombination rate, pressure will build in the cell, forcing the vent to open and the oxygen to escape. This can eventually cause drying of the electrolyte, and then cell failure. The cell temperature can also rise, which can shorten cell life. To prevent overcharge from occurring, fast-rate chargers should have automatic charge-limiting circuitry that will switch or taper the charging current to a safe rate as the battery reaches a fully-charged state.

Gelled-electrolyte lead-acid batteries provide 2.4 V/cell when fully charged. Damage results, however, if they are overcharged. (Avoid constant-current or trickle charging unless battery voltage is monitored and charging is terminated when a full charge is reached.) Voltage-limited charging is best for these batteries. A proper charger maintains a safe charge-current level until 2.3 V/cell is reached (13.8 V for a 12-V battery). Then, the charge current is tapered off until 2.4 V/cell is reached. Once charged, the battery may be safely maintained at the "float" level, 2.3 V/cell. Thus, a 12-V gel-cell battery can be "floated" across a regu-

lated 13.8-V system as a battery backup in the event of power failure.

Deep-cycle lead-acid cells are best charged at a slow rate, while automotive and some NiCd types may safely be given quick charges. This depends on the amount of heat generated within each cell, and cell venting to prevent pressure build-up. Some batteries have built-in temperature sensing, used to stop or reduce charging before the heat rise becomes a danger. Quick and fast charges do not usually allow gas recombination, so some of the battery water will escape in the form of gas. If the water level falls below a certain point, acid hydrometer readings are no longer reliable. If the water level falls to

plate level, permanent battery damage may result.

Overcharging NiCds in moderation causes little loss of battery life. Continuous overcharge, however, may generate a voltage depression when the cells are later discharged. For best results, charging of NiCd cells should be terminated after 15 hours at the slow rate. Better yet, circuitry may be included in the charger to stop charging, or reduce the current to about 0.02 C when the 1.43-V-per-cell terminal voltage is reached. For lead-acid batteries, a timer may be used to run the charger to make up for the recorded discharge, plus perhaps 20%. Some chargers will switch over automatically to an acceptable standby charge.

## Emergency Operations

### CARE AND FEEDING OF GENERATORS

For long term emergency operation, a generator is a must, as anyone who has operated field day can attest to. The generator will provide power as long as the fuel supply holds out. Proper care is necessary to keep the generator operating reliably, however.

When the generator runs out of fuel, the operator may be tempted to rush over with the gasoline can and begin refueling. This is very hazardous, since the engine's manifold and muffler are at temperatures that can ignite spilled gasoline. The operator should wait a few minutes to allow hot surfaces to cool sufficiently to ensure safety. For these periods when the generator is shut down, plan on having battery

power available to support station operation until the generator can be brought back on line.

Check the level of the engine's lubricating oil from time to time. If the oil sump becomes empty, the engine can seize, putting the station out of operation and necessitating costly engine repairs.

Remember that the engine will produce carbon monoxide gas while it is running. The generator should never be run indoors, and should be placed away from open windows and doors to keep exhaust fumes from coming inside.

### INVERTERS

For battery-powered operation of alternating-current loads, inverters are avail-

able. An inverter is a dc-to-ac converter, switching at 60 Hz to provide 120 V ac to the loads.

Inverters come in varying degrees of sophistication. The simplest, as mentioned above, produces a square-wave output. This is no problem for lighting and other loads that don't care about the input waveform. Lots of equipment using motors will work poorly or not at all when supplied with square wave power. Therefore, many higher-power inverters use waveform shaping to approximate a sine-wave output. The simplest of these methods is a resonant inductor and capacitor filter. Higher-power units employ pulse-width modulation of the converter switches to create a sinusoidal output waveform.

## Power-Supply Projects

Construction of a power supply can be one of the most rewarding projects undertaken by a radio amateur. Whether it's a charger for the NiCds in a VHF hand-held transceiver, a low-voltage, high-current monster for a new 100-W solid-state transceiver, or a high-voltage supply for a new linear amplifier, a power supply is basic to all of the radio equipment we operate and enjoy. Final testing and adjustment of most power-supply projects requires only a voltmeter, and perhaps an oscilloscope — tools commonly available to most amateurs.

General construction techniques that may be helpful in building the projects in this chapter are outlined in the **Circuit**

**Construction** chapter. Earlier chapters in this *Handbook* contain basic information about the components that make up power supplies.

Safety must always be carefully considered during design and construction of any power supply. Power supplies contain potentially lethal voltages, and care must be taken to guard against accidental exposure. For example, electrical tape, insulated tubing (spaghetti) or heat-shrink tubing is recommended for covering exposed wires, component leads, component solder terminals and tie-down points. Whenever possible, connectors used to mate the power supply to the outside world should be of an insulated type designed to

prevent accidental contact.

Connectors and wire should be checked for voltage and current ratings. Always use wire with an insulation rating higher than the working voltages in the power supply. Special high-voltage wire is available for use in B+ supplies. The **Component Data** chapter contains a table showing the current-carrying capability of various wire sizes. Scrimping on wire and connectors to save money could result in flashover, meltdown or fire.

All fuses and switches should be placed in the hot leg(s) only. The neutral leg should not be interrupted. Use of a three-wire (grounded) power connection will greatly reduce the chance of accidental

shock. The proper wiring color code for 120-V circuits is: black — hot; white — neutral; and green — ground. For 240-V circuits, the second hot lead generally uses a red wire.

### Power-supply Primary Circuit Connector Standard

The International Commission on Rules for the Approval of Electrical Equipment (CEE) standard for power-supply primary-circuit connectors for use with detachable cable assemblies is the CEE-22 (see Fig 11.30). The CEE-22 has been recognized by the ARRL and standards agencies of many countries. Rated for up to 250 V, 6 A at 65°C, the CEE-22 is the most commonly used three-wire (grounded), chassis-mount primary circuit connector

**Fig 11.30 — CEE-22 connectors are available with built-in line filters and fuse holders.**

for electronic equipment in North America and Europe. It is often used in Japan and Australia as well.

When building a power supply requiring 6 A or less for the primary supply, a builder would do well to consider using a CEE-22 connector and an appropriate

cable assembly, rather than a permanently installed line cord. Use of a detachable line cord makes replacement easy in case of damage. CEE-22 compatible cable assemblies are available with a wide variety of power plugs including most types used overseas.

Some manufacturers even supply the CEE-22 connector with a built-in line filter. These connector/filter combinations are especially useful in supplies that are operated in RF fields. They are also useful in digital equipment to minimize conducted interference to the power lines.

CEE-22 connectors are available in many styles for chassis or PC-board mounting. Some have screw terminals; others have solder terminals. Some styles even contain built-in fuse holders.

## A SERIES-REGULATED 4.5- TO 25-V, 2.5-A POWER SUPPLY

For home-laboratory requirements, a series-regulator supply is simpler and less expensive than a switching power supply. Series-regulated supplies are also free of electrical switching noise, which is a problem with some switching supplies. During tests of sensitive low-level circuitry, the power supply output should be pure dc; it should not contribute to problems in the circuit under test.

The power supply in Fig 11.31 was de-

signed and built by William E. Sabin, WØIYH. See “High-Precision Series Regulator Loop Design,” earlier in this chapter, for a discussion of the design, analysis and tests of the feedback control loop used in this power supply.

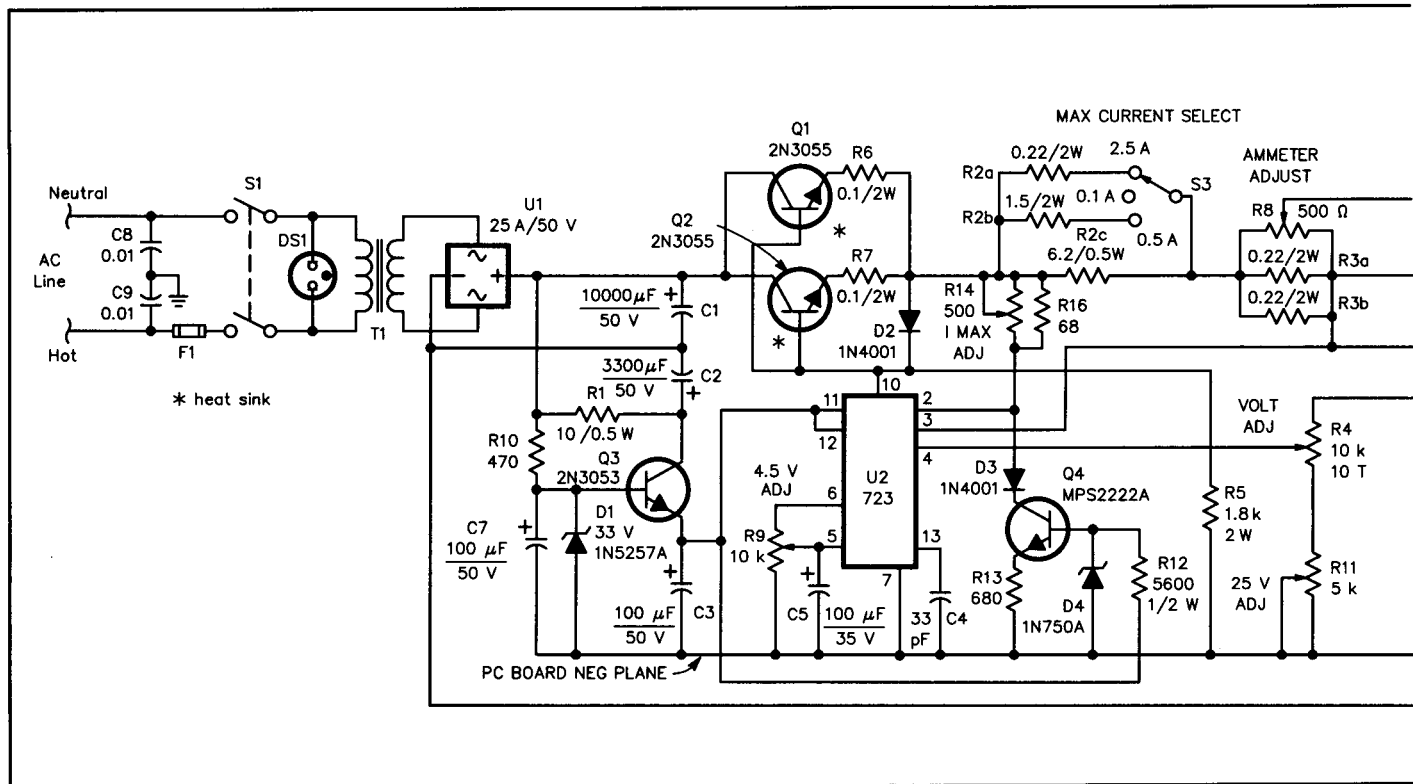

### Features

This supply was designed to meet the following objectives:

- Continuously variable output voltage

from 4.5 to 25.0 V.

- Tight load voltage regulation, better than 0.03%, for load currents from 0 to 2.0 A, 0.1% to 2.5 A; 0.01% into a 2.0-A load for ac-line voltages from 117 to 122 V.
- Excellent response to load fluctuations and transients (low output impedance).
- Very low ac ripple, less than 2  $\mu$ V RMS with a 2.0-A load.
- Very low random noise, less than 2  $\mu$ V RMS from 0.1 Hz to 500 kHz.

- Use an off-the-shelf transformer and other easily obtainable parts.
- Load currents up to 2.5 A, continuous duty.
- Switch selectable current limiting, at 0.1, 0.5 or 2.5 A, to protect delicate circuits under test.

### The Circuit

Fig 11.32 is a schematic of the power-supply circuit. An LM723 regulator was selected because it's simple, and its reference voltage is available (pin 6) for filtering. Reference noise (typical of zener diodes) is reduced to a very low level via C5, as suggested in the data sheet for the '723. The current-limiting circuitry is also accessible (at pins 2 and 3). It senses the voltage drop across R2 and R3.

The combination of R2 and R3 sets the current limit at  $0.62 / (R2 + R3)$  A. R3 (R3a and R3b together) forms an 0.11- $\Omega$ , 4-W resistor, which acts as a shunt for the digital meter that measures load current. R8 provides meter adjustment without affecting R3 significantly. S3 selects from three values of R2 to set current limits at approximately 0.1, 0.5 or 2.5 A.

C1 has a large value to reduce output ripple voltage. Smaller values would increase ripple and require a higher transformer voltage to prevent regulator drop out. Other voltage drops between the Q1/Q2 emitters and the output terminal are minimized to assure that a standard 25.2-V transformer can do the job. The R1-C2 combination reduces ac ripple at the '723 by a factor of 25; this eliminates the need for an extremely large value of C1.

The circuitry of Q3, R10, C7 and D1 prevents the voltage on pins 11 and 12 of U2 from exceeding the 40-V maximum rating of the '723 (especially with light loads and high line voltage). C7 eliminates a very small ac ripple at the dc output. As load current increases, the voltage at C1 decreases and Q3 is saturated.

When R4 is adjusted to reduce output voltage, U2 and Q1/Q2 are switched off until C6 discharges to the lower voltage. This caused the emitter-base junctions of Q1 and Q2 to break down

Fig 11.31 — An exterior view of the 2.5-A power supply. The DMM is mounted on the control panel as the output meter.

(at about 2.0 V) so that C6 could discharge through R5. D2 provides an alternate path and prevents this breakdown. R5 provides a minimum load for U2.

The foldback circuit is interesting: Q4, D4 and R13 provide a constant current through, and therefore a constant voltage drop across, R16. This voltage makes the current limiting (pins 2 and 3 of U2) work properly over the entire 4.5- to 25.0-V range. As the current limiting action pulls the voltage at the top of R16 below about 4.0 V, D3 quickly stops conducting, the voltage across R16 approaches zero and the load current is limited at about 1.9 A. This limits Q1/Q2 and T1 dissipation and provides short-circuit protection. This is a regenerative positive feedback process. R14 sets the current at which foldback begins, 2.6 A.

Fig 11.32 — Schematic of the 4.5 to 25-V, 2.5-A regulated dc power supply. Heavy lines indicate critical low-impedance conductors; use short conductors with large surface areas. "RS" signifies a Radio Shack part number; "CDE" is Cornell Dubilier Electric.

C1 — 10000  $\mu$ F, 50 V (CDE 10000-50-AC, or equiv).  
 C2 — 3300  $\mu$ F, 50 V (CDE 3300-50-M, or equiv).  
 C3, C7 — 100  $\mu$ F, 50 V (RS 272-1044, or equiv).  
 C4 — 33 pF, 50 V.  
 C5 — 100  $\mu$ F, 35 V (RS 272-1028, or equiv).  
 C6 — 1000  $\mu$ F, 35 V (RS 272-1032, or equiv).  
 C8, C9 — 0.01  $\mu$ F, ac-rated capacitor.  
 D1 — 1N5257A 33-V Zener diode.  
 D2, D3 — 1N4001 (RS 276-1101, or equiv).  
 D4 — 1N750A.  
 DS1 — Neon lamp, 120-V ac (RS 272-704, or equiv).  
 F1 — 1.5 A slow-blow (RS 270-1284, or equiv).  
 M1 — DMM (Heath SM-2300-A, or equiv).  
 P1 — Three-wire power cord and plug.  
 Q1, Q2 — 2N3055 (RS 276-2041, or equiv).  
 Q3 — 2N3053 (RS 276-2030, or equiv).  
 Q4 — MPS2222A (RS 276-2009, or equiv).  
 R1 — 10  $\Omega$ , 0.5 W.  
 R2a — 0.22  $\Omega$ , 2 W.  
 R2b — 1.5  $\Omega$ , 2 W.  
 R2c — 6.2  $\Omega$ , 5%, 0.5 W.

R3 — 0.15  $\Omega$ , 2 W.  
 R4 — 10 k $\Omega$ , 10-turn potentiometer (Bourns 3540S, or equiv).  
 R5 — 1.8 k $\Omega$ , 2 W.  
 R6, R7 — 0.1  $\Omega$ , 2 W.  
 R8, R14 — 500  $\Omega$  potentiometer (RS 271-226, or equiv).  
 R9 — 10 k $\Omega$  potentiometer.  
 R10 — 470  $\Omega$ , 0.25 W.  
 R11 — 5 k $\Omega$  potentiometer.  
 R12 — 5.6 k $\Omega$ , 0.5 W.  
 R13 — 680  $\Omega$ , 0.25 W.  
 R16 — 68  $\Omega$  0.25 W.  
 S1, S2 — DPDT (RS 275-652, or equiv).  
 S3 — SPDT (center off) (RS 275-654, or equiv).  
 S4 — Normally open, momentary-contact, push-button switch (RS 275-1547, or equiv).  
 T1 — 120-V primary, 25.2-V, 2.8-A secondary (Stancor P-8388, or equiv).  
 U1 — Rectifier bridge, 25 A, 50 V (RS 276-1185, or equiv).  
 U2 — LM723 regulator (RS 27-1740, or equiv).  
 Heat sink — Wakefield 403A, or equiv (two required).

There is further discussion of foldback circuitry earlier in this chapter.

An inexpensive Heath SM-2300-A auto ranging DMM (mounted on the front panel) displays the supply output levels. The dedicated DMM can display very small output changes. S2 selects either voltage or current (divided by ten) for display. (The DMM is left in its voltage range for both measurements.) The voltage across R3 is 0.11 times the load current. R8 provides the required ammeter adjustment without significantly affecting R3. The meter shows 0.2 for 2 A. Ordinary wire-wound resistors are adequate for R3 because they do not heat significantly at 2.5 A.

R9 sets the reference voltage on pin 5 of U2 at 4.5 V to establish the minimum output voltage. R11 sets the 25.0-V upper limit. A three-wire line cord assures that the supply chassis is always tied to the ac-line ground, for safety reasons. The dc output is not referenced to chassis ground, and performance is independent of the ac-ground connection. If the load current is very small, it may take a long time for C6 to discharge when the power is switched off; a press of S2 quickly discharges the capacitors (through R15) after turnoff. The mechanical construction emphasizes heat removal, so a cooling fan is not needed.

## Construction

Several areas are critical to good performance. Pay particular attention to these:

- Wire C1 with short, heavy leads to present a minimum impedance to ac ripple. Also, connect C1 directly to the negative binding post with a heavy lead. This provides a low inductance path for load-current fluctuations and keeps them off the PC-board ground plane.

- Connect C2 directly to the negative lead of C1.
- Connect C6 directly across the binding posts.
- Connect R4 to R11 with a low-impedance lead and connect R11 directly to the PC board ground plane.
- Connect the regulator PC board ground plane to the negative binding post at a single point.
- Use heavy-duty binding posts to reduce a small but significant voltage drop (from the rear to the front) at the front panel.

Fig 11.33 shows the general construction. (Fig 11.35 also shows the front-panel layout.) The cabinet and chassis surface are  $\frac{1}{16}$ -in aluminum plates connected by aluminum angle stock, drilled and tapped for #6-32 screws. Ventilation screens at the top and rear provide an excellent chimney effect. The chassis plate is tightly joined to the side plates for good heat transfer. Construction of the cabinet shown is somewhat labor intensive; it involves a lot of metal work. Any enclosure of similar size with good ventilation is suitable. For example, a 7×11×2-inch chassis with a bottom cover and rubber feet, a  $7\frac{1}{2}$ ×6-inch front panel and a U-shaped perforated metal cover would serve well.

Q1 and Q2 each have a Wakefield 403A heat sink. The sinks were selected according to the thermal design discussion in the **Real-World Component Characteristics** chapter. The worst-case 2N3055 junction temperature was calculated to be 145°C, based on a measured case temperature of 95°C and dissipation of 32 W (each) for Q1 and Q2. This temperature is a little higher than recommended, but it's acceptable for intermittent lab use.

The DMM is epoxied to a narrow alumi-

num strip, which is then screwed to the front panel. This allows easy removal to replace the DMM battery.

Fig 11.33B shows the supply underside. The PC board is mounted on standoff insulators and positioned so that the positive and negative outputs are close to the binding posts.

Fig 11.34 is a parts-placement diagram for the regulator board. A full-size etching pattern is available from ARRL — send an SASE to the Technical Department Secretary with your request for the “*Handbook* Sabin Power Supply Template.” All components and wiring are on the etched side of the board (with the help of a few jumper wires). The other side is entirely ground plane. The components are surface mounted by bending a section of each lead and soldering it to the surface of the appropriate copper pad. The socket for U2 is mounted by bending the pins out 90° and soldering pins 11 and 12 to the pad for C3. Some leads pass through holes (marked with cross hairs in Fig 11.34) in the PC board and solder to the ground plane. The emitter and base leads of Q1 and Q2 are isolated from ground; use insulated-wire to pass from the PC-board pads through holes in the PC board and chassis to the transistors.

Fig 11.35 shows the placement of major parts in front, top and side views. Silastic and pieces of Kraft paper cover any exposed 120-V wiring.

C1, C2 and R1 are mounted on a  $\frac{1}{8}$ -in thick plastic board as shown in Fig 11.35. In the supply shown, it's a piece of  $\frac{1}{8}$ -in PC board with wide traces. A piece of angle stock mounts the board to the chassis.

The main voltage control, R4, is a ten-turn potentiometer, for ease of adjustment. C8 and C9 are ceramic capacitors rated for ac-line use. Once the supply is complete, double check all wiring and connections.

Fig 11.33 — A shows a top view of the open power-supply chassis. The  $\frac{1}{8}$ -in plate holding C1 is visible at the left edge of the heat sinks. B shows a bottom view. Notice that the components are mounted on the etched side of the board. The circuit pattern is simple enough for freehand layout. The front panel is at right in both views.

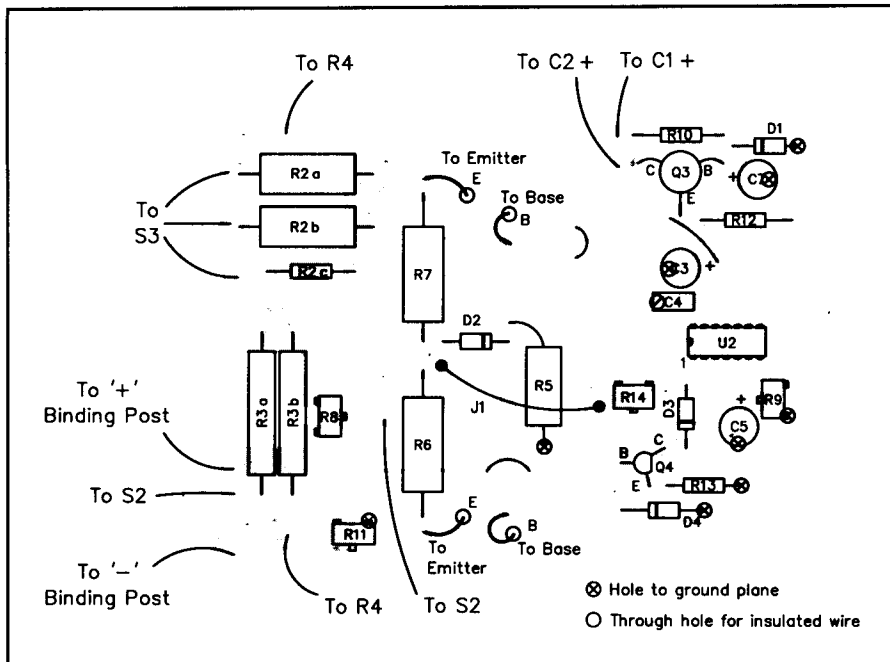

Fig 11.34 — A parts-placement diagram for the 2.5-A power supply. The component side is shown, and the etching is on the component side. Cross hairs indicate holes through the board. Component leads that terminate at cross hairs are grounded on the far side of the board. The emitter and base leads of Q1 and Q2 do not connect to the ground plane. Use insulated wire to pass through the PC board and holes in the chassis to the transistors on the heat sinks. Wire Jumper J1 is soldered to the pad surfaces without drilling holes. If you do drill holes for the jumper be sure to remove the ground plane around the holes on the non-component side. A full-size etching pattern is available from ARRL Headquarters (see text).

Fig 11.35 — This three-view drawing shows the panel layout and locations of major power-supply components.

## Adjustments

Several adjustments are needed: the dedicated AMMETER ADJUST (R8), the foldback limit (R14, I MAX ADJ), the lower (R9, 4.5 VOLT ADJ) and upper (R11, 25 V ADJ) voltage limits. First, obtain an accurate external ammeter and a test load that can draw at least 3 A at 12 V or so (automobile sealed beam headlights work well). Series connect the load and external meter to the supply binding posts. Set S3 to the 2.5-A range; set R4 for minimum output; set S2 to A and switch on the power. Advance R4 until the ammeter reads 2.0 A, and adjust R8 until the panel meter also

reads 0.200. Next, increase R4 until the current slightly exceeds 2.6 A, and adjust R14 so that current begins to decrease (foldback). Switch off the supply and remove the external meter and load.

Adjust the voltage limits with no load connected and S2 set to v. Switch on the supply, set R4 for minimum voltage and adjust R9 until the meter reads 4.5. Increase R4 to maximum voltage and adjust R11 so that the meter reads 25. The supply is ready for use.

## Performance and Use

The example supply met the design

goals: When the line voltage was varied from 117 to 122 V (with a 25-V dc 2.0-A load), the output voltage varied less than 0.01%. When the dc load was varied from 0 to 2.0 A, the output voltage changed less than 0.03%.

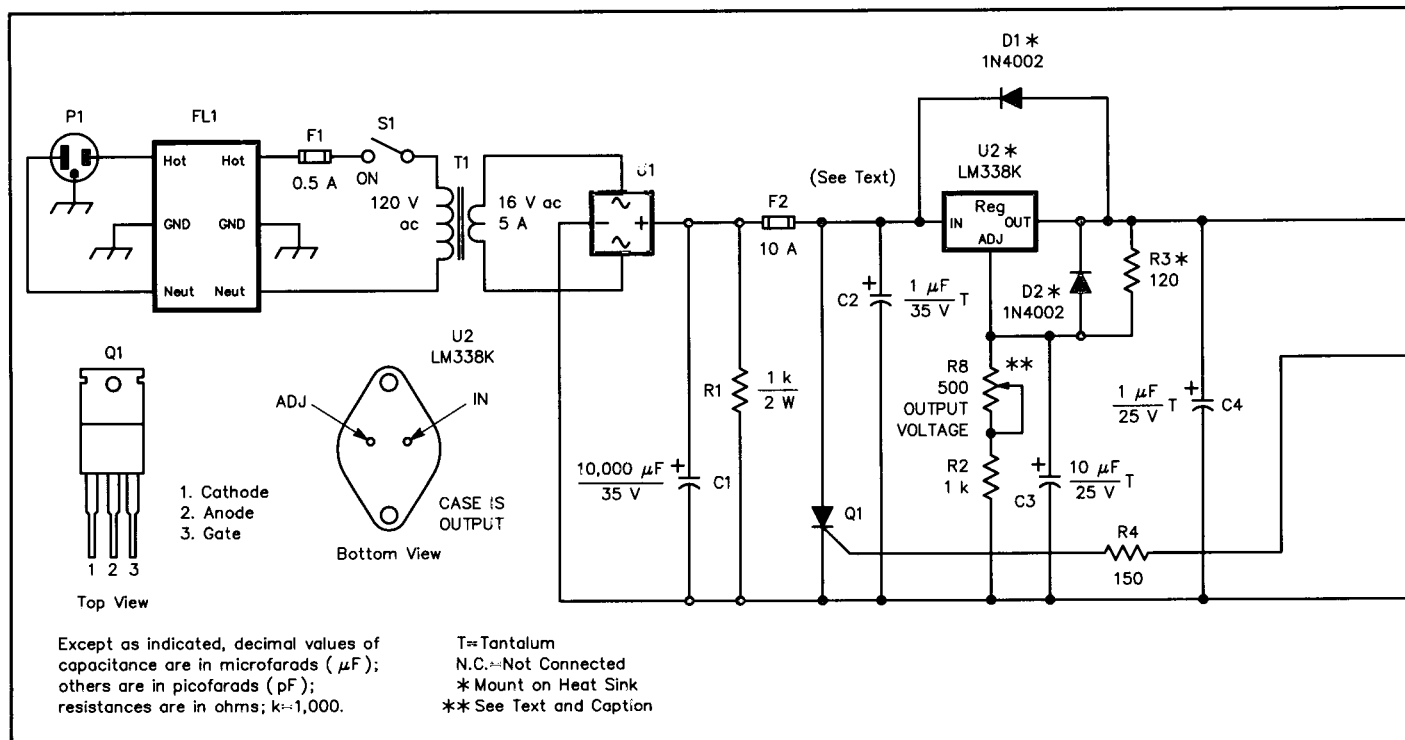

When extremely tight regulation and low output impedance are important, the leads to the load must be very short, heavy straps. Multiple loads should be parallel-connected directly at the binding posts: A "Daisy chain" connection scheme does not assure equal regulation for each load; it counteracts the precision regulation of this supply.

## A 13.8-V, 5-A POWER SUPPLY

Ben Spencer, G4YNM, built this project, which was originally published in the November 1993 issue of *QST*. Many commercially built 13.8-V power supplies are available. Some are robust and equipped with protection circuits; others have clearly been "built down" to meet a specific selling price. Most hams and electronics hobbyists want a well-designed power supply — but at the lowest price. Cheap power supplies, however, usually have no protection circuitry and exhibit poor regulation. Worse, regulator failure can damage the equipment to which the supply is connected. Think about it: With

**Fig 11.36 — Physical layout of the power supply.** On the rear panel, left, are the ac-line filter and F1. The regulator's heat sink is at the middle of the panel and F2 is to the right. At the bottom of the enclosure, in front of T1, is the diode bridge rectifier. Because C1 is too tall to mount vertically within the Hammond #14260 cabinet, its mounting clamp is secured to the inside rear panel. Immediately to the right of C1 is the FAR Circuits PC board. On the front panel are the ON/OFF switch, LED power-on indicator and output-voltage binding posts. (Photo by Kirk Kleinschmidt, NT0Z.)

the gear you have attached to the supply, is it worth taking a risk like that?

The power supply shown in Fig 11.36 provides 13.8 V dc at 5 A. It features time-dependent current limiting and short-circuit protection, thermal-overload protection within the safe operating area of the regulator IC and overvoltage protection for the equipment it powers.

Construction, testing and calibration are straightforward, requiring no special skills or equipment. Many of the components can be found in junk boxes, or purchased at hamfests or from mail-order suppliers.<sup>2</sup>

## Circuit Description

Fig 11.37 is the power-supply sche-

matic. Incoming ac-line current is filtered by a chassis-mounted line filter (FL1) and, after passing through the fuse (F1), is routed via ON/OFF switch S1 to T1.

U1 rectifies, and C1 filters, the ac output of T1. U2 is an LM338K voltage regulator. This IC features a continuous output of 5 A, with a guaranteed peak output of 7 A, on-chip thermal and safe-operating-area protection for itself, and current limiting. U2's output voltage is set by two resistors (R2 and R3) and a trimmer potentiometer (R8), which allows for adjustment over a small range. U2's input and output are bypassed by C2, C3 and C4. D1 and D2 protect U2 against these capacitors discharging into it.

Overvoltage protection is provided by an SCR, Q1, across the regulator input. Normally, Q1 presents an open circuit, but under fault conditions, it's triggered and short-circuits the unregulated dc input to ground. This discharges C1 and blows F2, reducing the possibility of damage to any connected equipment.

Overvoltage-protection IC U3 continuously monitors the output voltage. When the output voltage rises above a predetermined level, U3 starts charging C5. If the overvoltage duration is sufficiently long, U3 triggers Q1. This built-in delay (about 1 ms) allows short transient noise spikes on the output voltage to be safely ignored while still triggering the SCR if a true fault occurs. The monitored voltage is set by R5, R6 and trimmer potentiometer R9, which allows for adjustment over a limited range.

D3 protects the supply from reverse-polarity discharge from connected equipment. The presence of output voltage is indicated by an LED, DS1. R7 is a current limiting-resistor for DS1.

## Construction

How you construct your supply depends on the size of the components and enclosure you use. General physical layout is not important, although there are a couple of areas that require some attention. In the unit shown in Fig 11.36, FL1, the fuse holders, S1, the heat sink, DS1 and the binding posts are mounted on the front and rear enclosure panels. T1 and the PC board<sup>3</sup> are secured to the enclosure's bottom plate. C1's mounting clamp is attached to the rear panel. Bleeder resistor R1 is connected directly across C1's terminals. D3 is soldered directly across the output binding posts.

<sup>2</sup>See the **References** chapter for the Address List. Here are some places to shop for transformers and other components used in this project: T1 can consist of two #15724 transformers. These transformers have a 120-V primary and dual 18-V, 3.1-A and 24-V ct, 3.5-A secondary windings; connect the two 18-V windings in parallel to produce an 18-V, 6.2-A secondary.

Mendelson Electronics Co, Inc: For T1, a #600-0190F transformer can be used (120-V primary, 35-V c.t. 10-A secondary).

Fair Radio Sales Co, Inc: For T1, a #5608798 transformer with a 120-/240-V primary and 19.5-V, 6-A secondary. Connect the primary windings in parallel (observe proper phasing) for 120-V operation, or in series for use with 240-V lines. This is the transformer used in the unit shown in the accompanying photographs.

<sup>3</sup>PC boards and overvoltage protection ICs are available from FAR Circuits. Price: PC board, \$3.50, plus \$1.50 shipping; MC3423P1 overvoltage IC, \$3 (prices subject to change). The PC board has mounting holes and pads to allow for handling different trimmer-potentiometer footprints.

A PC-board template package is available free from the ARRL. Address your request for the SPENCER 13.5-V, 5-A POWER SUPPLY TEMPLATE and send it to the ARRL Technical Department Secretary. Please enclose a business-size SASE.

Fig 11.37 — Schematic of the power supply. Part numbers in parentheses are Radio Shack; equivalent parts can be substituted. Unless otherwise specified, resistors are 1/4-W, 5%-tolerance carbon-composition or film units.

C1 — 10000-μF, 35-V electrolytic.

C2, C4 — 1-μF, 35-V tantalum (272-1434).

C3 — 10-μF, 35-V tantalum.

C5 — 0.1-μF, 25-V ceramic disc (272-135).

D1-D3, include — 1N4002 (276-1102 suitable).

DS1 — Red LED (276-041).

F2 — Fast-acting 10-A fuses; three required — see text (270-1325).

F1 — Fast-acting 0.5-A fuse (270-1271).

FL1 — AC-line filter.

Q1 — BT152 400-V, 25-A SCR in TO-220A package (ECG 5554).

R1 — 1 kΩ, 2 W.

R8 — 500-Ω, single-turn trimmer potentiometer.

R9 — 500-Ω or 1-kΩ, single-turn trimmer potentiometer (see Note 4).

S1 — SPST panel-mount switch (275-634).

T1 — 120-V primary, 16- to 20-V, 5-A

secondary (see Note 2).

U1 — 100-PIV, 6-A bridge rectifier (276-1181 suitable).

U2 — LM338K 5-A adjustable power regulator in a TO-3 package; available from Digi-Key and other sources.

U3 — MC3423P1 overvoltage protection IC (see Note 3).

Misc: two panel-mount fuse holders (270-364, 270-365, 270-367, or 270-368); IEC line cord; heat sinks for TO-3 case transistors; TO-3 mounting kit and heat-sink grease (276-1371 and 276-1372); two binding posts, one red, one black (274-662); chassis or cabinet, PC board (see Note 3), hardware, rubber hoods, heat-shrink tubing or electrical tape for F1 and FL1, hook-up wire.

**Fig 11.38** — Here's the regulator's heat-sinking arrangement, showing U2, D1, D2 and R3. U2 is electrically isolated from the heat sink by a TO-3 mounting kit.

U2, D1, D2, and R3 are all mounted on the heat sink as shown in **Fig 11.38**. (It's important to keep R3 attached as closely as possible to U2's terminals to prevent instability.) Use a TO-3 mounting kit and heat-conductive grease to electrically isolate U2 from the heat sink.

Cover all ac-input wiring (use insulated wire and heat-shrink tubing) to prevent electrical shock, and route the ac wiring away from the dc wiring. Mount U2, C1 and the PC board close to each other; keep the wire runs between these components as short as possible. Excessively long wire runs may lead to unpredictable behavior.

### Test and Calibration

An accurate analog or digital multimeter, covering ranges of 30 V dc and 10 A dc, is required. A variable resistive load with a power rating of 100 W is also needed; this can be made using a heat-sink-mounted 2N3055 power transistor and a couple of components as shown in **Fig 11.39**.

First, set R8 (OUTPUT VOLTAGE) fully clockwise and R9 (OVERVOLTAGE) fully counterclockwise. Insert a fuse in the dc line at F2. Connect the ac line, turn on

S1 and check that DS1 lights. Measure the output voltage; it should be about 12; adjust R8 counterclockwise until you obtain 14.2 V output; this sets the trip voltage.

While monitoring the output voltage, gradually adjust R9 clockwise until the voltage suddenly falls to zero.<sup>4</sup> This indicates that the SCR has triggered and blown F2. Disconnect the ac line cord from the wall socket. *Don't make any adjustment to R9!* Instead, adjust R8 fully clockwise.

With the ac line cord removed, check that F2 is open. Replace F2 with a new fuse (now you know why two of the three fuses are called for). Reconnect the ac line cord, and while continually monitoring the output voltage, gradually adjust R8 until Q1 again triggers at 14.2 V, blowing F2.

Again, disconnect the line cord from the wall socket, set R8 fully clockwise, replace F2 and reset R8 for 13.8 V. This completes the voltage calibration and overvoltage protection tests. The power supply is now set to 13.8 V output, with

<sup>4</sup>If you find the adjustment of R9 to be too sensitive, use a 500- $\Omega$  potentiometer in its place and reduce the value of R5 (if necessary) to provide the required adjustment range.

**Fig 11.39** — An active resistive load to use in testing the supply. Adjustment of R11 is sensitive.

**M1**—Multimeter or ammeter capable of measuring 10 A.

**Q2**—2N3055 (Radio Shack 276-2041); mount on heat sink.

**R10**—100- $\Omega$ , 1/2-W carbon composition or film resistor (271-012).

**R11**—10-k $\Omega$ , 2-W wire-wound potentiometer.

the overvoltage protection set for 14.2 V.

Adjust the variable resistive load to maximum resistance and connect it to the power-supply output in series with the ammeter. Turn on the power supply and gradually adjust R10 until there is a 5-A current. Decrease the resistance further and check that the current limits between 5.5 A and 6.5 A.

Finally, be thoroughly unpleasant and apply a short circuit via the ammeter. Check that the current-limiting feature operates correctly. My prototype limited at approximately 3.5 A. Disconnect the ac line cord and test equipment, close up the case and your power supply is ready for service.

# A SMART CHARGER FOR NICKEL-CADMIUM BATTERIES

This article, written by Steven Avritch, WB1EOB, first appeared in the September 1994 issue of *QST*. Trickle charging NiCd batteries takes forever, but speeding up the process can damage batteries by overcharging. This article describes a simple yet sophisticated NiCd battery "quick" charger. This Smart Charger is based on the MAX713 single-chip battery charger. The unit continuously monitors the battery during fast charge and automatically switches over to trickle charge when the battery is full — eliminating any possibility of overcharge.

## MAX713 Single-Chip Battery Charger

The MAX713 single-chip charger can fast charge and trickle charge any NiCd battery pack containing from 1 to 16 cells (battery-pack voltages ranging from 1.2 to 19.2 V). The charger in this article, however, is limited to packs having a maximum of nine cells, because of the 12-V wall adapter power supply. Charge rates are programmable from 4C (20-minute charge) to  $C \div 3$  (4-hour charge), where C is the capacity of the battery in milliamperes-hours (mAh). The trickle charge rate is fixed at  $C \div 16$ . (The charge rate is calculated as the battery capacity, C, in mAh, divided by the expected charge time, in hours. The actual charge time will be longer than the expected charge time because the charging process is less than 100% efficient.) The MAX713 uses three different techniques to determine when to end the fast charge and switch over to trickle. These techniques are:

- Voltage-peak detection
- Battery temperature
- Time

Voltage-peak detection is the best method to determine when a NiCd battery is fully charged. As NiCd batteries charge, the voltage across the battery slowly increases. This voltage peaks when the battery is fully charged and then drops off slightly (see Fig 11.40). The MAX713 continuously samples the battery voltage and shuts down when the voltage peak is detected. Also, if the battery voltage does not peak within a preset timeout period, fast charge is terminated.

The MAX713 also has provision for thermally protecting the battery during the charge cycle. A high-temperature shutoff will terminate the charge cycle if the battery temperature exceeds a preset limit. In addition, a low (cold) temperature shutoff will not allow fast charging until the battery temperature reaches another preset limit. The temperature-detection features

**Fig 11.40** — The terminal voltage of a NiCd cell increases as the cell is charged. Once the cell is fully charged, though, the terminal voltage drops slightly. The Smart Charger detects this drop and automatically switches to trickle charging. Because all the cells in a battery may not reach the full-charge point at the same time, it is a good idea to leave the battery on trickle charge for several hours to ensure a full battery charge.

are optional and require the addition of three thermistors and a few other parts. One of the thermistors must be in contact with the battery, which is not practical with sealed battery packs. To simplify the project, the Smart Charger does not use temperature detection. Note that temperature detection is recommended if the charge rate selected is greater than 2C.

## Design Overview

This charger is capable of charging battery packs from one to nine cells (1.2 to 10.8 V). The number of cells in the pack to be charged must be programmed into the MAX713 by connecting the PGM pins of the 713 as defined in Table 11.1. This design assumes the battery pack(s) to be charged will always have the same number of cells. If you wish to build a charger capable of charging battery packs with varying numbers of cells, switches must be added to change the PGM pin connections according to the battery to be charged.

The charging section is simply the MAX713 and a few external components (see Fig 11.41). The entire circuit is powered by an inexpensive 12-V dc wall adapter. The current capacity of the adapter should be at least 50 mA greater than the preprogrammed fast-charge rate current. For example, if the fast-charge-rate current is 250 mA, then the wall adapter should be rated for at least 300 mA.

## Designing a Charger

A few decisions must be made before

**Table 11.1**

### Maxim MAX713 Programming for 1- to 16-Cell Packs

Number of Cells	PGM1	PGM0
1	V+	V+
2	OPEN	V+
3	REF	V+
4	BATT-	V+
5	V+	OPEN
6	OPEN	OPEN
7	REF	OPEN
8	BATT-	OPEN
9	V+	REF
10	OPEN	REF
11	REF	REF
12	BATT-	REF
13	V+	BATT-
14	OPEN	BATT-
15	REF	BATT-
16	BATT-	BATT-
OPEN	Not connected	
BATT-	Connect to pin 12	
REF	Connect to pin 16	
V+	Connect to pin 15	

the design can begin:

- Wall adapter voltage (minimum)
- Number of cells in pack to be charged
- Fast charge rate
- Time out period (maximum time in fast charge).

The following charger design is for a 7.2-V, 500-mAh battery pack, the kind that come with many hand-held radios. The wall adapter voltage should be at least 1 V higher than the battery being charged. The number of cells in the pack is determined by dividing the pack voltage by 1.2; the 7.2-V pack contains 6 cells. The charge rate is selected to be  $C \div 2$  (250 mA), which will result in a charge time of approximately 2.5 hours. The charge time is calculated by:

$$\text{Charge time} = C \div (\text{charge rate} \times 0.8) \quad (8)$$

The 0.8 accounts for the fact that the charging process is only about 80% efficient.

Therefore, for this design:

- Number of cells = 6
- Charge rate =  $C \div 2 \text{ hr} = 500 \text{ mAh} \div 2 \text{ hr} = 250 \text{ mA}$
- Time out = 2.5 hours (150 minutes)
- The wall adapter is 12 V dc, rated at 300 mA.

There are four steps in the charger design:

1. Calculate the power dissipation in Q1
2. Calculate the value of R1
3. Calculate the value of  $R_{\text{SENSE}}$
4. Determine the PGM pin connections.

time out is reached the charger reverts to trickle charge.

### Construction and Checkout

Wire the circuit according to the schematic.

Connect a milliammeter in line at the positive battery terminal. Also connect a voltmeter across the positive and negative battery terminals. Place a half-charged battery in the charger and turn on the power; the POWER and FAST CHARGE indicators should light.

The voltage will slowly rise and the milliammeter should indicate the maximum charge rate as designed (250 mA in

our example). After the battery voltage peaks or the fast charge timeout (2.5 hours) has passed, whichever comes first, the FAST CHARGE light should go out and the charge rate should decrease to approximately  $C \div 16$  (approximately  $500 \div 16$ , or 31 mA).

### Getting the Parts

All parts except the MAX713 can be obtained from Radio Shack. The 1-W resistor is available from Radio Shack in a package with many resistors of different values. Some parts were selected only because they are standard Radio Shack stock. For example, the 100-W PNP tran-

sistor (Q1) is overkill; it could be replaced with a smaller device.

The MAX713 chip or a complete set of parts including the chip are available from the author.<sup>5</sup>

<sup>5</sup>The following parts are available from Simple Design Implementations. See the **References** chapter Address List.

1. Maxim MAX713CPE single chip battery charger: \$10 + \$1.50 shipping and handling.

2. Complete kit of parts including perforated board, case, wall adaptor: \$30 + \$3 shipping and handling. Connecticut residents, please add 6% sales tax. Prices subject to change.

## THE SOLARSWITCH

This article, written by Michael Bryce, WB8VGE, originally appeared in the October 1993 issue of *QST*. It is a simple, low-cost and easy-to-use charge controller you can build. Then you'll be ready to charge and protect your batteries when the sun comes out!

You can power your radio, boat, RV or cottage by the lake using solar power. You can even charge batteries using a commer-

cial ac-line-operated power supply.

Small enough to fit in the palm of your hand, the SolarSwitch uses two power MOSFETS to control the array current from a solar panel to a battery. The SolarSwitch is a series controller, and uses pulse charging techniques. With the two FETs specified, this controller handles array currents of up to 6 A—that's enough to tackle two 48-W photovoltaic (PV)

panels.<sup>7</sup> If you don't plan on controlling that much current, you can build a 3-A version and save a few dollars. Or, you can easily increase the SolarSwitch's current-handling capacity, as you'll see later.

<sup>7</sup>For periods of less than one hour, an unmodified PC-board-based SolarSwitch can handle over 8 A. PC-board trace size is the limiting factor.

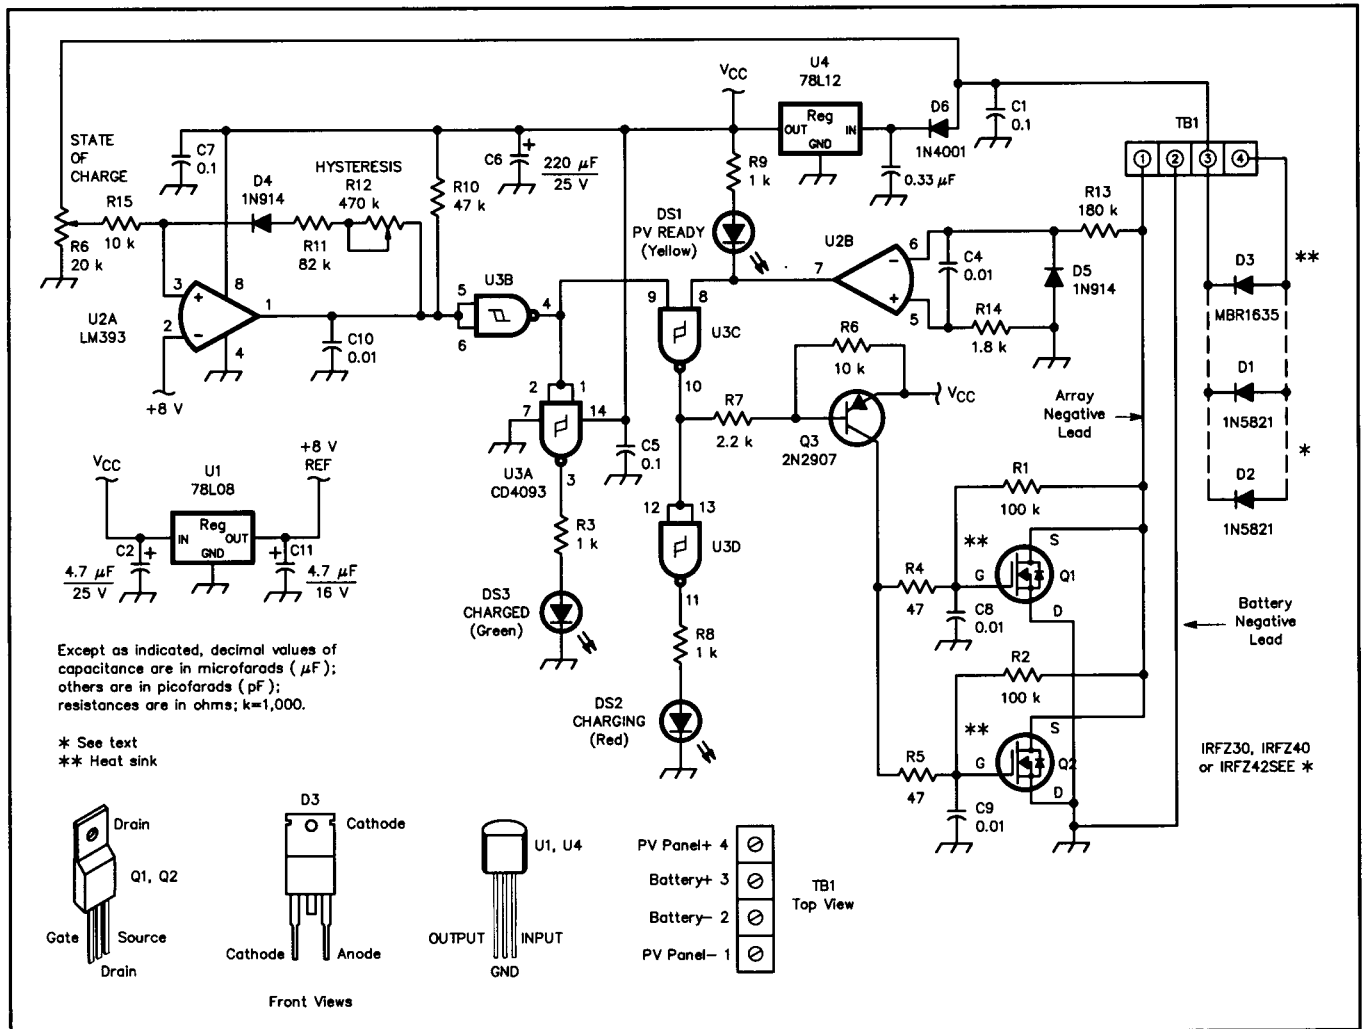

Fig 11.46 — Schematic of the SolarSwitch circuit. Part numbers in parentheses are Mouser or Active Electronics; equivalent parts can be substituted. Unless otherwise specified, resistors are  $\frac{1}{4}$ -W, 5%-tolerance, carbon-composition or film units. Mouser Electronics and Active Electronics both have several locations throughout the US.

D1, D2 — 1N5821 30-V, 3-A rectifier (Mouser #333-1N5821).  
D3 — MBR1635 35-V, 16-A Schottky diode (Mouser #584-18TQ045 or Active Electronics #MBR1635).  
D4, D5 — 1N914 silicon switching diode.  
D6 — 1N4001 50-PIV, 1-A diode.  
DS1 — Yellow rectangular LED; see text (Mouser #ME3516231).  
DS2 — Red rectangular LED (Mouser #35BL510).

DS3 — Green rectangular LED (Mouser #ME3516221).  
Q1, Q2 — IRFZ30 50-V HEXFET (Mouser #584-IRFZ30; see text) or 584-IRFZ40; Active Electronics #26058.  
Q3 — 2N2907 PNP switching transistor.  
R6 — 20-k $\Omega$  multiturn pot (Mouser #594-64W203).  
R12 — 470-k $\Omega$  trimmer pot (Mouser #324-CP10H-470K).  
U1 — MC78L08, 8-V, 100-mA three-terminal positive voltage regulator

(Mouser #333-78L008AP).  
U2 — LM393 dual voltage comparator (Mouser #511-LM393N).  
U3 — CD4093 quad two-input NAND Schmitt trigger (Mouser #570-CD4093BE).  
U4 — LM78L12 12-V, 100-mA three-terminal positive voltage regulator (Mouser #333-78L012AP).  
Misc: Terminal block (Mouser #506-4PCV-04), heat sinks (Mouser #567-7-199BA), enclosure.

Three LEDs monitor circuit operation and keep you informed of what's going on. A four-position terminal block makes it a snap to connect the photo-voltaic (PV) array and battery. Because it's easy to build and adjust, this may be the perfect *first* project for newcomers to building. A wide part-selection tolerance makes this project junk-box friendly. At \$40 — even less with the help of your (or a friend's) junk box — the SolarSwitch is affordable. To make things ultra convenient, PC boards and complete kits are available. And, if you don't like to bend and drill metal, a punched and silk-screened enclosure is available, too.<sup>8</sup>

## How It Works

Refer to **Fig 11.46**. The battery under charge supplies the current to run the SolarSwitch. In standby mode, the SolarSwitch draws 15 mA. D6 provides reverse-polarity protection for the ICs. U4 has two functions: (1) It serves as the SolarSwitch's voltage regulator; (2) in case of operator error (such as mistakenly hooking the array to the BATTERY terminals), the regulator protects the ICs from array overvoltage. You can even use the SolarSwitch in a 24-V system: U4 keeps the circuit supply voltage at 12 and the ICs happy.

Because the normal battery voltage of 12.6 is insufficient overhead for the 78L12 input, U4's output runs at about 10.5 V, but that's more than ample for the CMOS chips. When the battery is charging and its terminal voltage is near 14.3, U4 supplies a steady 12 V to the ICs.

A second regulator, U1, serves as a stable 8-V reference for the voltage comparator, U2. Capacitors connected to U1's input and output lines ensure stability.

Battery voltage is sampled by a 20-k $\Omega$  trimmer potentiometer R6 (STATE OF CHARGE), which sets the battery's state of charge. U2A, half of an LM393 dual-voltage comparator, monitors the battery's terminal voltage. U2 pin 2 connects to the 8-V reference. R10 pulls the output of

U2A high. When the battery voltage is low, and while the battery is charging, U2A's output is pulled low. This low is applied to U3B. C10, at the output of U2A, keeps the chip stable.

As the battery charges, its terminal voltage increases. When the battery voltage increases to the charger's off point (14.3 V), U2A switches states and pin 1 goes high. A small amount of this output is fed back to the comparator's input. A 470-k $\Omega$  trimmer potentiometer, R12 (HYSTERESIS) adjusts the circuit hysteresis, which provides the basics for pulse charging. When the battery voltage reaches the off point, FETs Q1 and Q2 are turned off. The battery voltage then begins to fall. But — because of the hysteresis — the comparator won't switch the charger on until the battery voltage drops to a preset value, lower than the turn-on point set by R6. When this occurs, the comparator turns on the FETs and the cycle repeats. Then, the battery charging is pulsed on and off. Pulsing is controlled by the HYSTERESIS control setting, the rate of charge and the battery capacity.

U2B monitors the PV array output. When the PV array is active, there is a small current in the array's negative lead. U2B detects the current and its output switches states from low to high. At night, when there is no array output, U2B's output is low. This low causes DS1 (PV READY) to glow when the array is inactive. During battery charging, U3C pin 10 is low. This low turns on Q3, which drives FETs Q1 and Q2. FET gate drive is 10 V.

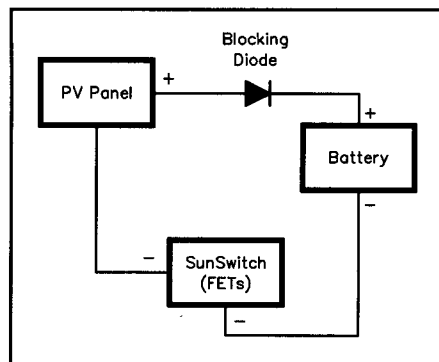

## A Complete Charging Sequence

When the sun comes up, the solar-panel array starts producing current. This is sensed by U2B, which switches states and produces a high at pin 7. DS1 goes dark. Because the battery voltage is low, the output of U2A is also low and its output is inverted by U3B.

U3B's output at pin 4 is routed in two directions: (1) It is applied to pins 1 and 2 of U3A and inverted again. Because a high is applied to its inputs, the output is low and DS3, the charged LED, remains dark; (2) U3B's output also goes to U3C pin 9. Since we now have highs on both inputs of U3C, the gate switches states and the result is a low at pin 10. This low is inverted by U3D. The result is a high, which lights DS2, the CHARGING LED.

U3 pin 10 supplies a low to the base of Q3. The transistor saturates and supplies gate voltage to Q1 and Q2. The FETs conduct and connect the negative lead of the PV array to the negative side of the battery.

When the battery is almost fully charged, U2A pin 1 goes high. This high is

**Fig 11.47 — A block diagram of a typical SolarSwitch system. The blocking diode is physically mounted on the SolarSwitch PC board.**

**Fig 11.48 — The SolarSwitch PC board. (Photo by Kirk Kleinschmidt, NT0Z.)**

inverted by U3B. U3A sees this as a low and outputs a high to illuminate DS3, the CHARGED LED. Because U3C pin 9 is now low, U3C pin 10 goes high, turning off Q3 and removing gate drive from the FETs. DS2, the CHARGING LED, goes dark because U3D pin 11 is no longer high.

With the FETs off, the battery voltage starts to drop. Because of the hysteresis provided by R12, the voltage can be adjusted to drop almost 1.5 V before the comparator switches states. When the battery voltage does drop below the hysteresis point, the comparator switches and the cycle repeats. As the battery charge nears 100%, DS2 and DS3 blink on and off as the SolarSwitch sends current pulses to the battery.

Towards dusk, the current pulses begin to lengthen. Finally, DS2 remains on. When U2B no longer detects output from the PV array, its output goes low. This fires DS1, the PV READY LED, and turns off the FETs by way of U3C pin 8. At dusk, DS2

<sup>8</sup>Kits for the SolarSwitch are available from SunLight Energy Systems. See the Address List in the **References** chapter. A complete parts kit including the 3 1/2 x 4-inch PC board (but not the enclosure): \$40 plus \$2.50 shipping.

A punched, drilled and silk-screened enclosure: \$12. PC board only: \$8.50 plus \$1 shipping. PC boards are also available from FAR Circuits.

A PC-board pattern and part-overlay template is available free from the ARRL. Address your request for the BRYCE SOLARSWITCH PC-BOARD TEMPLATE to the ARRL Technical Department Secretary. Please enclose a business-size SASE.

extinguishes and DS1 lights.

Even though the FETs have been turned off, they still allow current to flow from the batteries back to the array. D3, an MBR1635 16-A Schottky diode, prevents this nighttime current leakage. D3 also protects the FETs in the event you reverse-connect the array to the SolarSwitch.

### A Word About Power MOSFETS

For your SolarSwitch, you have a wide selection of suitable FETs from which to choose. IRFZ30s can handle a drain current of over 50 A (more than three times the maximum this circuit can handle). The  $R_{DS(on)}$  is a scant 0.045  $\Omega$ . IRFZ30s are inexpensive and easy to obtain. Other good choices are the IRFZ42 and the IRFZ44.

The IRFZ44 or IRFZ42 have an  $R_{DS(on)}$  of 0.028  $\Omega$ . If you plan on running just 1 or 2 A of charging current, then an IRF531 or IRF511 can be substituted. Although more expensive and a bit difficult to obtain, the Siliconix SMP60N06 is an excellent power MOSFET for use in the SolarSwitch.

### Different Switching Methods

Q1 and Q2 are in the battery's negative lead. There is, however, one drawback to this scheme: You can't connect the negative side of the array and the negative side of the battery and then ground them. If you do, you'll defeat the SolarSwitch and overcharge your batteries. Fig 11.47 details where the FETs are located in the circuit, along with the array and the battery. The blocking diode is in the positive side of the array and battery.

### Three Amps or Six?

Do you want to build the 3- or 6-A version of the SolarSwitch? In the 3-A version, D3, the 15-A blocking diode, is replaced by two 1N5821 Schottky diodes, D1 and D2. If the current you'll be controlling is less than 1 A, you can use two 1N4001 diodes. With the 3-A version, there is no need to use two FETs, so you can eliminate one. The basic operation of either version is the same.

### Putting It Together

There is nothing critical about the SolarSwitch assembly — you can build it on perfboard, if you choose. Using a PC board, however, is the easiest and neatest way to build your SolarSwitch. Take precautions to avoid static build-up and discharge when handling U3 (the CMOS 4093) and, of course, the FETs. Use a wrist ground strap. Use IC sockets for the chips. Once the devices are mounted on the PC board, they'll withstand a lot of abuse.

With all the parts on hand, you should be able to assemble and test the SolarSwitch in a few hours.

Start by stuffing the PC board with the IC sockets and then the resistors. Install U1 before you mount C2 and C11; it's a tight fit there! Install U4 and Q3. Don't forget the wire jumper (W1) near Q3. Finish the PC board by mounting the terminal block.

Note: If you're going to use the 15-A Schottky diode at D3, you must follow one of these mounting methods to avoid shorting PC-board traces: Don't drill through the PC board to mount the TO-220 case and heat-sink combination. Attach the diode to a heat sink with #4-40 hardware; be certain to use thermal compound between the diode and heat sink. Bend the diode leads toward the PC board. While holding the heat sink level on the PC board, solder D3's leads to the board. Next, place a small square of double-stick foam tape beneath the heat sink. Push the heat sink onto the foam tape. That holds the heat sink to the PC board without the need to drill any holes. Otherwise, you must use insulating hardware (such as nylon) to secure the diode/heat-sink assembly.

Bend the leads of one FET 90°, apply some thermal compound to its heat sink and bolt the combination to the PC board in the Q1 position. Follow the same procedure for Q2. Solder both FETs in place.

### Testing and Adjustment

To adjust the SolarSwitch, you'll need a variable-voltage power supply, a battery and an accurate digital VOM (you can use an analog VOM, but you'll lose some resolution). Set the power supply to 14.3 V. Adjust R6 and R12 to midrange. Connect the power supply to the battery terminals on TB1. DS1 (PV READY) should light. DS3 may be on; DS2 should be off. If it's on, you've either got a solder bridge at the 4093 or LM393 pins, or one (or both) of the chips is defective.

Check for +12 volts at U3 pin 14. Check for +8 V at U2 pin 2. Monitor the voltage at U2 pin 3 while adjusting R6, the STATE OF CHARGE pot. Verify that the voltage increases and decreases as you rotate the control shaft for R6.

With the power supply still set to 14.3 V, adjust R6 until DS3 glows. Drop the supply voltage to 12, then very slowly increase the voltage to 14.3. At that point, DS3 should light again. (You may want to repeat this step, as you'll encounter the effect of the hysteresis circuit.)

For the rest of the testing, use a small battery. (A 6.5-Ah lead-acid battery works well.) Connect the battery to your SolarSwitch. Adjust the power supply for

an output of 16 to 19 V. Connect the power supply to the TB1 ARRAY INPUT terminals and turn on the power supply. DS1 (PV READY) will extinguish and DS2 (CHARGING) will light. If possible, monitor the charging current as well as the battery voltage. When the battery terminal voltage hits 14.3, DS3 should light and DS2 extinguish. With DS2 off, the current going into the battery must be zero! If not, you may have an oscillating FET, or a solder bridge in the FET area.

If the current drops to zero with DS2 off, the SolarSwitch sends current pulses to the battery. The pulse length is determined by the charge current, battery condition, and, of course, the setting of the HYSTERESIS control, R12. (Don't worry, the setting of R12 is not critical.)

If all's fine so far, slowly reduce the power-supply voltage. At about 13 V, DS1 lights and DS2 goes dark. This completes the testing and adjustments. If everything works as outlined, you're ready to hook the SolarSwitch to your solar panels!

### Hooking It Up

First, connect the battery to the SolarSwitch, then connect the array. Be sure to use adequately sized wire. Charging is fully automatic and requires no action on your part. At dawn and dusk, DS1 and DS2 may light simultaneously. This is normal, as the comparator monitors the output of the array. With a full 6 A of array current, the heat sinks become warm to the touch.

The full state-of-charge voltage of 14.3 is about right for just about everyone. If you have a high charge current (6 A) and a small-capacity battery (1.2 Ah), however, you may want to increase the set point a bit. Likewise, if you're charging a 105-Ah battery with only 600 mA, you'll need to reduce the set point to 14 V or so.

You can also use the SolarSwitch to charge small lead-acid batteries. Use your variable-voltage power supply as the current source. Set the power-supply output for 16 to 19 V and connect it to the ARRAY positions on the terminal block. It is best if you use a current-limiting power supply — one that can safely limit its output to a preset value. (A really dead battery draws all the current it can handle! You could toast the power supply if the current drain is excessive.) The SolarSwitch is happy with currents of up to 7 A.

### Problems

The most common failure of the SolarSwitch is sloppy soldering around U1. It's close quarters there and a solder bridge is easy to make. If DS3 lights, but current is still flowing into the battery,

check for a solder bridge near the FETs. When DS3 is on, the base of Q3 must be high. Ensure that you installed C10; it keeps U2 stable.

If there is no charging current when DS2 is on, check for +10 V at the FET gates. Work your way back toward Q3. Did you remember to install the jumper wire (W1)? Did you install the blocking diode (D3) backwards?

If DS1 doesn't extinguish, check for the proper placement of D5. Also, it's possible to have both DS1 and DS2 on at dusk when the SolarSwitch is connected to a solar panel. Long runs of too-small-gauge wire between the SolarSwitch and the array may keep DS1 on. The SolarSwitch will still function if this happens. Mistakenly swapping the 1.8-k $\Omega$  and the 180-k $\Omega$  resistors is quite easy to do.

### Part Substitutions

Not everyone has junk boxes or part bins overflowing with the exact parts for every project. The SolarSwitch is quite tolerant of part substitutions. Your local Radio Shack outlet can supply almost every part you need. You can use IRF510 or IRF511 FETs at Q1 and Q2 for currents of 1 to 3 A, if you don't mind them running a bit hotter than the FETs specified.

If you can't obtain the 8-V regulator, an LM78L05 5-V regulator can be substituted. In fact, you can use just about any regulator in place of the LM78L08 as long as its output is below 9 V and you can

squeeze it into the available board space. Also, just about any PNP switching transistor will work at Q3.

If you can't find — or just want to eliminate — the HYSTERESIS pot, use a 470-k $\Omega$  pot and adjust the hysteresis to your liking. Then, remove the pot, measure its value and install a fixed-value resistor in its place.

You don't need to use the commercial heat sinks listed, either. They fit the board nicely, but a bent-up piece of aluminum works just fine. If you mount the two FETs and the diode on the heat sink, insulate the diode from the heat sink. The cases of the diode and the tabs of the FET are electrically "hot." Don't allow any other wires to touch them. Fig 11.48 shows the assembled SolarSwitch circuit board.

A ready-to-go case is available for the SolarSwitch. Because the case requires a different method of mounting the board, you can't use round LEDs; they won't fit the case — it's designed for rectangular LEDs. Solder the LEDs to the board from the foil side, spacing them about 1/4 inch from the board. Because the case has silk-screened panel labels, the LEDs can all be of one color, although the color variations are attractive.

### Increasing SolarSwitch Current Capacity

Three factors limit the current capacity of the SolarSwitch: (1) The capacity of the

heat sinks to keep the active devices cool; (2) the PC-board traces carrying the current to and from the battery; and (3) the FETs. The PC-board traces can carry a little over 7 A before they become rather warm. To increase the current-carrying capacity of the SolarSwitch, you'll need to reinforce the current-carrying PC-board traces with some solid copper wire; #14 solid wire works well. Four places need to be beefed up — they're the main circuit traces. They are easy to spot, as they go to the FETs and back to the terminal block. By doing this — and increasing the heat-sink capacity — the SolarSwitch can handle up to 14 A of array current, the current-handling limit of the blocking diode, D3.

If you choose to use the IRF510 or IRF511 FET instead of the IRFZ30, you'll not be able to draw 14 A, as these FETs won't handle the current without meltdown.

### Odds and Ends

Although the SolarSwitch is designed for use with 12-V lead-acid batteries, you can use it to charge wet pocket NiCds, too. A wet pocket NiCd requires up to 16 V or so before it's fully charged. Simply adjust the SolarSwitch to reflect the higher turn-off voltage. You can also use the SolarSwitch in a 24-V lead-acid system. Increase the value of R12 to, say 50 k $\Omega$ , and adjust the state of charge to your needs.

## 28-V, HIGH-CURRENT POWER SUPPLY

Many modern high-power transistors used in RF power amplifiers require 28-V dc collector supplies, rather than the traditional 12-V supply. By going to 28 V (or even 50 V), designers significantly reduce the current required for an amplifier in the 100-W or higher output class. The power supply shown in Fig 11.49 through Fig 11.53 is conservatively rated for 28 V at 10 A (enough for a 150-W output amplifier) — continuous duty! It was designed with simplicity and readily-available components in mind. Mark Wilson, AA2Z, built this project in the ARRL lab.

### Circuit Details

The schematic diagram of the 28-V supply is shown in Fig 11.50. T1 was designed

by Avatar Magnetics specifically for this project. The primary requires 120-V ac, but a dual-primary (120/240 V) version is available. The secondary is rated for 32 V at 15 A, continuous duty. The primary is bypassed by two 0.01- $\mu$ F capacitors and protected from line transients by an MOV.

U1 is a 25-A bridge module available from Radio Shack or a number of other suppliers. It requires a heat sink in this application. Filter capacitor C1 is a computer-grade 22000- $\mu$ F electrolytic. Bleeder resistor R1 is included for safety because of the high value of C1; bleeder current is about 12 mA.

There is a tradeoff between the transformer secondary voltage and the filter-capacitor value. To maintain regulation,

Fig 11.49 — The front panel of the 28-V power supply sports only a power switch, pilot lamp and binding posts for the voltage output. There is room for a voltmeter, should another builder desire one.

the minimum supply voltage to the regulator circuitry must remain above approximately 31 V. Ripple voltage must be taken into account. If the voltage on the bus drops below 31 V in ripple valleys, regulation may be lost.

In this supply, the transformer secondary voltage was chosen to allow use of a commonly available filter value. The builder found that 50-V electrolytic capacitors of up to about 25000  $\mu\text{F}$  were common and the prices reasonable; few dealers stocked capacitors above that value, and the prices increased dramatically. If you have a larger filter capacitor, you can use a transformer with a lower secondary voltage; similarly, if you have a

transformer in the 28- to 35-V range, you can calculate the size of the filter capacitor required. Equation 3, earlier in this chapter, shows how to calculate ripple for different filter-capacitor and load-current values.

The regulator circuitry takes advantage of commonly available parts. The heart of the circuit is U3, a 723 voltage regulator IC. The values of R8, R9 and R10 were chosen to allow the output voltage to be varied from 20 to 30 V. The 723 has a maximum input voltage rating of 40 V, somewhat lower than the filtered bus voltage. U2 is an adjustable 3-terminal regulator; it is set to provide approximately 35 V to power U3. U3 drives the base of Q1,

which in turn drives pass transistors Q2-Q5. This arrangement was selected to take advantage of common components. At first glance, the number of pass transistors seems high for a 10-A supply. Input voltage is high enough that the pass transistors must dissipate about 120 W (worst case), so thermal considerations dictate the use of four transistors. See the **Real World Component Characteristics** chapter for a complete discussion of thermal design. If you use a transformer with a significantly different secondary potential, refer to the thermal-design tutorial to verify the size heat sink required for safe operation.

R9 is used to adjust supply output voltage. Since this supply was designed pri-

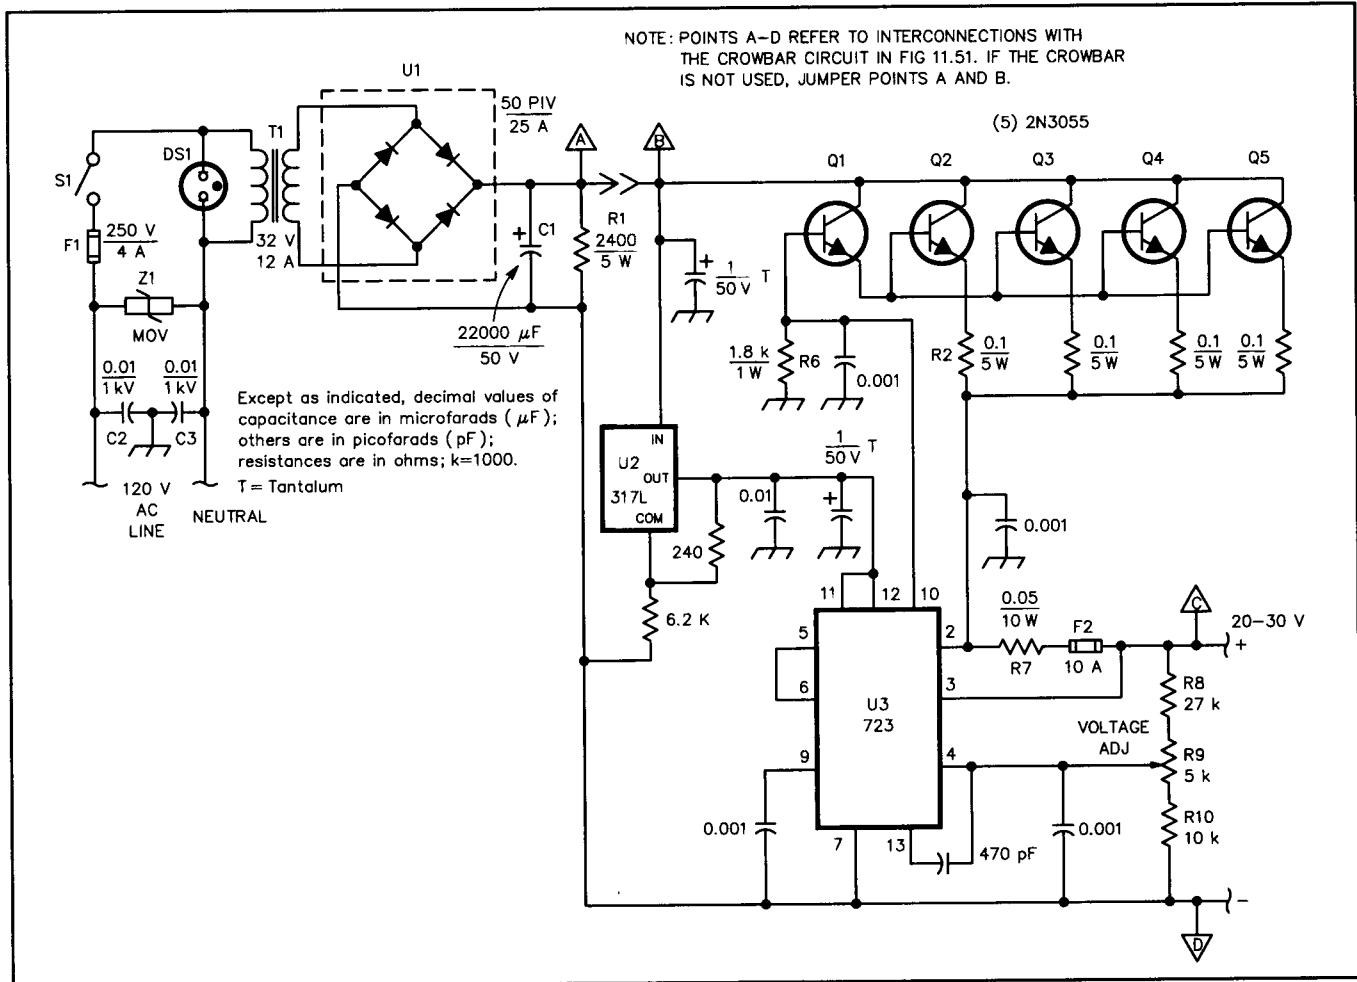

Fig 11.50 — Schematic diagram of the 28-V, high-current power supply. Resistors are  $\frac{1}{4}$ -W, 5% types unless otherwise noted. Capacitors are disc ceramic unless noted; capacitors marked with polarity are electrolytic. Parts numbers given in parentheses that are preceded by the letters RS are Radio Shack catalog numbers.

C1 — Electrolytic capacitor, 22000  $\mu\text{F}$ , 50 V (Mallory CGS223U050X4C or equiv., available from Mouser Electronics).  
C2, C3 — AC-rated bypass capacitors.  
DS1 — Pilot lamp, 120-V ac (RS 272-705).  
Q1-Q5 — NPN power transistor, 2N3055 or equiv. (RS 276-2041).

R2-R5 — Power resistor, 0.1  $\Omega$ , 5 W (or greater), 5% tolerance.  
R7 — Power resistor, 0.05  $\Omega$ , 10 W (or greater), made from two 0.1- $\Omega$ , 5-W resistors in parallel.  
T1 — Power transformer. Primary, 120-V ac; secondary, 32 V, 15 A. (Avatar Magnetics AV-430 or equiv. Dual primary version is part #AV-431. Available from Avatar Magnetics.)

U1 — Bridge rectifier, 50 PIV, 25 A (RS 276-1185).  
U2 — Three-terminal adjustable voltage regulator, 100 mA (LM-317L or equiv.). See text.  
U3 — 723-type adjustable voltage regulator IC, 14-pin DIP package (LM-723, MC1723, etc. RS 276-1740).  
Z1 — 130-V MOV (RS 276-570).

marily for 28-V applications, R9 is a “set and forget” control mounted internally. A 25-turn potentiometer is used here to allow precise voltage adjustment. Another builder may wish to mount this control, and perhaps a voltmeter, on the front panel to easily vary the output voltage.

The 723 features current foldback if the load draws excessive current. Foldback current, set by R7, is approximately 14 A, so F2 should blow if a problem occurs. The output terminals, however, may be shorted indefinitely without damage to any power-supply components.

If the regulator circuitry should fail, or if a pass transistor should short, the unregulated supply voltage will appear at the output terminals. Most 28-V RF transistors would fail with 40-plus volts on the collector, so a prospective builder might wish to incorporate the overvoltage protection circuit shown in **Fig 11.51** in the power supply. This circuit is optional. It connects across the output terminals and may be added or deleted with no effect on the rest of the supply. If you choose to use the “crowbar,” make the interconnections as shown. Note that R11 and F3 of **Fig 11.67** are added between points A and B of **Fig 11.66**. If the crowbar is not used, place a wire jumper between points A and B of **Fig 11.66**.

This crowbar circuit is taken from Motorola application notes for the MC3423 overvoltage sensor IC. The chip contains a 2.5-V reference and two comparators. When the voltage at pins 2 (sense terminal) reaches 2.5 V, the output goes high (from 0.0 V to the positive bus voltage) to drive the gate of Q6, a high-current SCR. Q6 turns on, shorting the supply output terminals. This circuit is inexpensive and easy to implement, yet it allows the builder to precisely set the trip voltage. It provides excellent gate drive to the SCR, and is somewhat quicker and more reliable than crowbar circuits that use Zener diodes. R11 and F3 protect the pass transistors from damage in case of high-current transients.

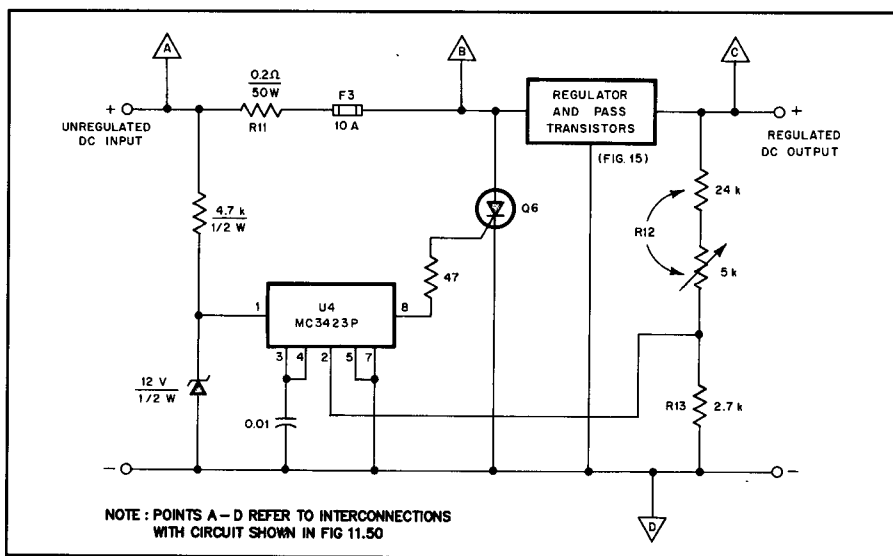

The trip voltage is determined from the equation:

$$V_{\text{TRIP}} = 2.5 \left( 1 + \frac{R11}{R12} \right)$$

The application notes recommend that R13 be less than 10 k $\Omega$  for minimum drift and suggest a value of 2.7 k $\Omega$ . In this version, R12 is preset with a 24-k $\Omega$  resistor, and a 5-k $\Omega$ , 10-turn potentiometer dials in the precise trip point.

### Construction

**Fig 11.52** shows the interior of the 28-V supply. It is built in a Hammond

**Fig 11.51** — Schematic diagram of the overvoltage protection circuit. Resistors are 1/4-W, 5% carbon types unless noted.

Q6 — 20-A, 100-V stud-mount SCR (RCA SK6502 or equiv.).

R12 — 5-k $\Omega$ , 10-turn potentiometer in

series with a 24-k $\Omega$ , 1/4-W resistor.  
U4 — Overvoltage sensor IC, Motorola MC3423 (RS 276-1717).

**Fig 11.52** — Interior of the 28-V, high-current power supply. The cooling fan is necessary only if the pass transistors and heat sink are mounted inside the cabinet. See text.

**Fig 11.53 — Parts placement diagram for the 28-V power supply. A full-size etching pattern is available from ARRL.**

1401K enclosure. All parts mount inside the box. The regulator components are mounted on a small PC board attached to the rear of the front panel. See **Fig 11.53**. Most of the parts were purchased at local electronics stores or from suppliers listed in the **References** chapter. Many parts, such as the heat sink, pass transistors, 0.1- $\Omega$  power resistors and filter capacitor can be obtained from scrap computer power supplies found at flea markets.

Q2-Q5 are mounted on a Wakefield model 441K heat sink. The transistors are mounted to the heat sink with insulating washers and thermal heat-sink compound to aid heat transfer. Radio Shack TO-3 sockets make electrical connections easier. The heat-sink surface under the transistors must be absolutely smooth. Carefully deburr all holes after drilling and lightly sand the edges with fine emery cloth.

A five-inch fan circulates air past the heat sink inside the cabinet. Forced-air cooling is necessary only because the heat sink is mounted inside the cabinet. If the heat sink was mounted on the rear panel with the fins vertical, natural convection would provide adequate cooling and no fan would be required.

U1 is mounted to the inside of the rear panel with heat-sink compound. Its heat

sink is bolted to the outside of the rear panel to take advantage of convection cooling.

U2 may prove difficult to find. The 317L is a 100-mA version of the popular 317-series 1.5-A adjustable regulator. The 317L is packaged in a TO-92 case, while the normal 317 is usually packaged in a larger TO-220 case. Many of the suppliers listed in the **References** chapter sell them, and RCA SK7644 or Sylvania ECG1900 direct replacements are available from many local electronics shops. If you can't find a 317L, you can use a regular 317 (available from Radio Shack, among others).

R7 is made from two 0.1- $\Omega$ , 5-W resistors connected in parallel. These resistors get warm under sustained operation, so they are mounted approximately  $\frac{1}{16}$  inch above the circuit board to allow air to circulate and to prevent the PC board from becoming discolored. Similarly, R6 gets warm to the touch, so it is mounted away from the board to allow air to circulate. Q1 becomes slightly warm during sustained operation, so it is mounted to a small TO-3 PC board heat sink.

Not obvious from the photograph is the use of a single-point ground to avoid ground-loop problems. The PC-board ground connection and the minus lead of the supply are tied directly to the minus

terminal of C1, rather than to a chassis ground.

The crowbar circuit is mounted on a small heat sink near the output terminals. Q6 is a stud-mount SCR and is insulated from the heat sink. An RCA replacement SCR was used here because it was readily available, but any 20-A or greater SCR that can handle at least 50 V will work. The other components are mounted on a small circuit board attached to the heat sink with angle brackets. U4 is available from Radio Shack.

Although the output current is not extremely high, #14 or #12 wire should be used for all high-current runs, including the wiring between C1 and the collectors of Q2-Q5; between R2-R5 and R7; between F2 and the positive output terminal; and between C1 and the negative output terminal. Similar wire should be used between the output terminals and the load.

## Testing

First, connect T1, U1 and C1 and verify that the no-load voltage is approximately 44 V dc. Then, connect unregulated voltage to the PC board and pass transistors. Leave the gate lead of Q6 disconnected from pin 8 of U4 at this time. You should be able to adjust the output voltage between approximately 20 and 30 V. Set the output to 28 V.

Next, set the crowbar to fire at 29 V or whatever trip voltage you desire. Set the potentiometer of R12 for maximum resistance. Connect a voltmeter to U4, pin 8. The voltmeter should indicate 0.0 V. Increase supply voltage to 29 V and adjust R12 until pin 8 goes high, to approximately 28 V. Back off the supply voltage; pin 8 should go low again. Connect the gate lead of Q6 and again increase supply voltage to 29 V. The crowbar should fire, shorting the supply output. Slight adjustment of R12 may be necessary. Remove power and turn R9 to reduce supply voltage below the trip point. Apply power and reset the output voltage to 28 V.

Next, short the output terminals to verify that the current foldback is working. Voltage should return to 28 when the shorting wire is disconnected. This completes testing and setup.

The supply shown in the photographs dropped approximately 0.1 V between no load and a 12-A resistive load. During testing in the ARRL lab, this supply was run for four hours continuously with a 12-A resistive load on several occasions, without any difficulty.

## A 3200-V POWER SUPPLY

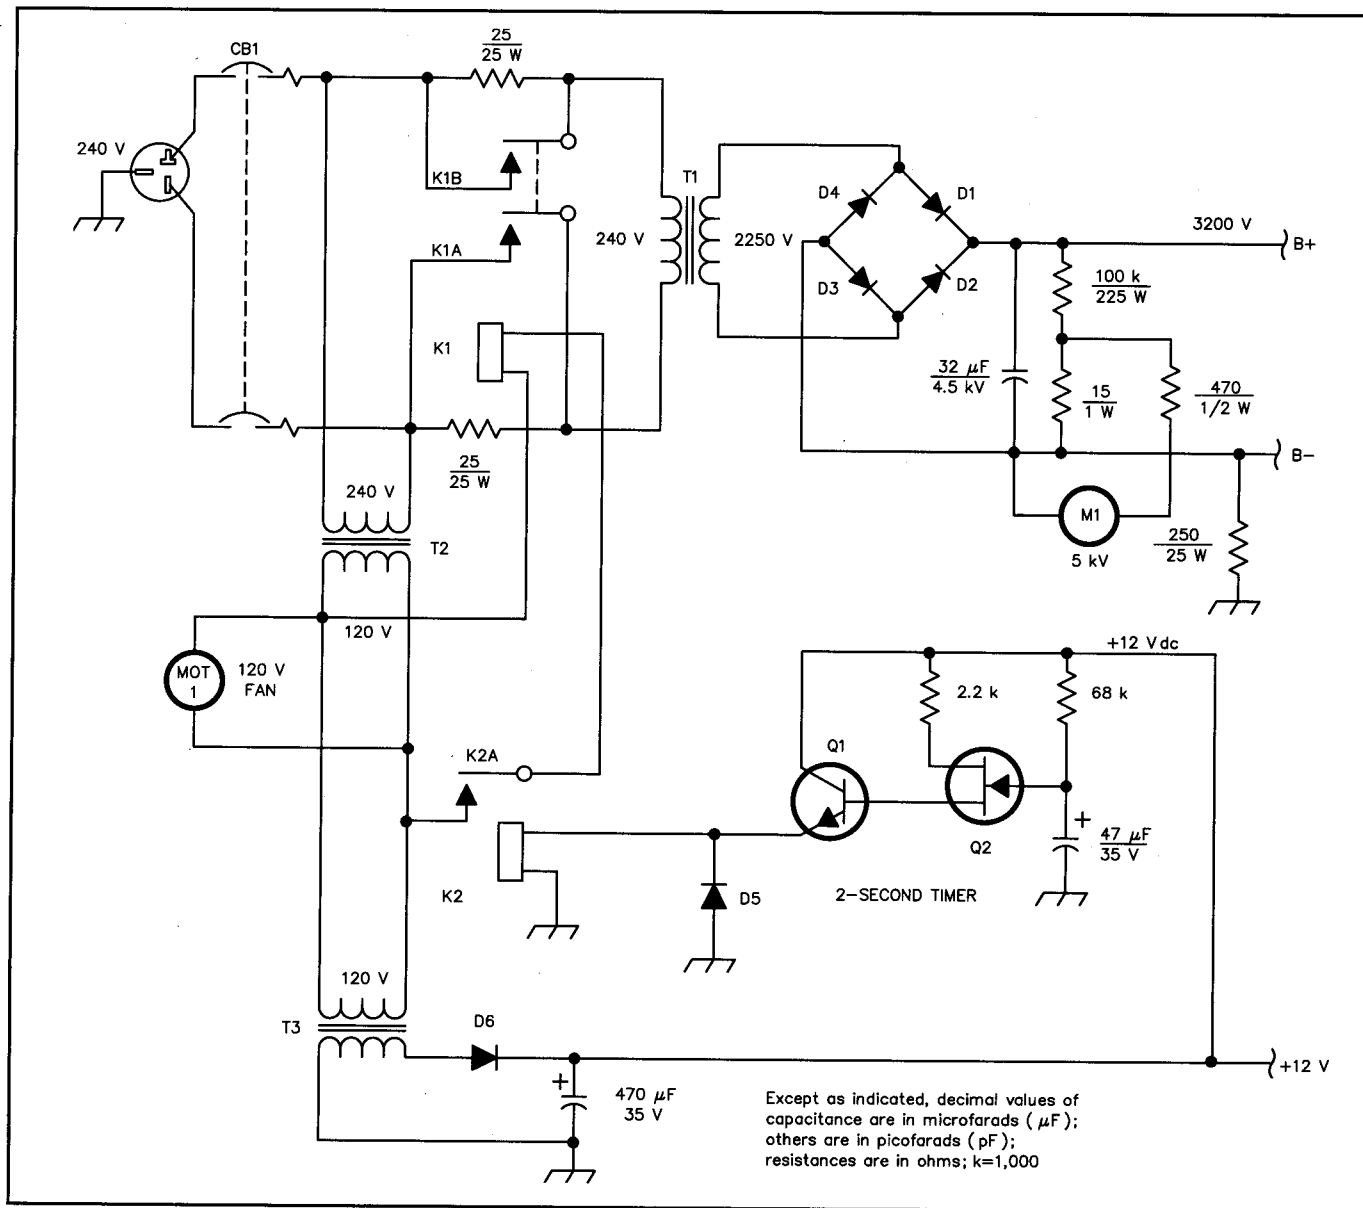

This high-voltage power supply was described by Russ Miller, N7ART, in December 1994 *QST* for use with a 2-m, 1-kW amplifier using the 3CX1200Z7 triode. The supply is rated at 3200 V, at a continuous output current of 1.2 A, and an intermittent peak current of 2 A. The power supply also has a 12 V, 1 A output,

used to power the control circuitry in the N7ART 2-meter amplifier. See the **RF Power Amplifiers** chapter for details.

A simple, effective step/start circuit is incorporated to ensure that the rectifier diodes are not over stressed by the heavy surge current into the output capacitor when the power supply is first turned on.

A 5 kV meter is used to monitor high-voltage output.

**Fig 11.54** is a schematic diagram of the supply. A power supply for a high-power linear amplifier should operate from a 240-V circuit, for best line regulation. A special, hydraulic/magnetic circuit breaker doubles as the main power switch.

**Fig 11.54—Schematic diagram of the high-voltage power supply.**

**D1-D4—Strings of 5 each, 1000-PIV, 3-A diodes, 1N5408 or equiv. A commercial diode block assembly is also suitable: K2AW HV14-1, from K2AW's Silicon Alley.**

**K1—DPST relay, 120-V ac coil, 240-V-ac, 20-A contacts (Midland Ross 187-321200 or equiv).**

**K2—SPDT miniature relay, 12-V dc coil  
(Radio Shack 275-248 or equiv).**

**M1—High-voltage meter, 5 kV dc full scale (1-mA meter movement used with series resistors shown in drawing).**

**MOT1—Cooling fan, Torin TA-300 or equiv.**

**Q1—2N2222A or equiv.**

**Q2—MPF102 or equiv.**

**CB1—20-A hydraulic/magnetic circuit breaker (Potter and Brumfield W68X2Q12-20 or equiv).**

**T1—High-voltage power transformer, 240-V primary, 2250-V, 1.2-A secondary (Avatar AV-538 or equiv).**

**T2—Stepdown transformer, Jameco 112125, 240-V to 120-V, 100 VA.**

**T3**—Power transformer, Jameco 104379, 120-V primary; 16.4 V, 1-A secondary (half used).

Don't substitute a regular switch and fuses for this breaker; fuses won't operate quickly enough to protect the amplifier in case of an operating abnormality. The bleeder resistor dissipates about 100 W, so a small fan is included to remove the excess heat.

### **Power Supply Construction**

The power supply can be built into a

17×13×10-inch cabinet. The power transformer is quite heavy, so use 1/8-inch aluminum for the cabinet bottom, and reinforce it with aluminum angle for extra strength. The diode bridge consists of four legs, each containing five diodes.

### **Power Supply Operation**

When the front-panel breaker is turned on, two 25- $\Omega$  resistors in the primary circuit limit inrush current as the filter ca-

pacitor charges. After two seconds, step-start relay K1 activates, shorting both resistors and allowing full line voltage to be applied to the transformer.

As with all high-voltage power supplies, be extremely careful! Before opening the cabinet, remove the ac-line plug from its receptacle, and confirm that the filter capacitor is discharged before working on the supply.

# Modulation Sources (What and How We Communicate)

## 12

**M**odulation Sources—what does that mean? An engineer might simply call this chapter *Baseband*. Engineers use that term to distinguish information before it's used to modulate a carrier. So, this chapter covers the various kinds of information we impress on RF (audio, video, digital, remote control) before that information has been moved to some intermediate frequency (IF) or the desired RF.

Baseband carries the connotation "at or near dc" because the final RF is usually much higher than the baseband frequency, yet that is misleading. For example, a baseband ATV signal usually extends up to 5 MHz, which is hardly dc. Nonetheless, compared to the operating frequencies (52 to 806 MHz for broadcast, 420 MHz and higher for amateur) it is practically dc.

Here we will discuss characteristics of the information (such as bandwidth), how we prepare it for transmission, optimize the transfer and process it after reception.

Nearly all of the processing discussed in this chapter can be implemented with the emerging digital-signal-processing (DSP) technology. For example, the

CLOVER-II system described later in this chapter uses DSP to vary the modulation scheme as required by propagation conditions. Look to the **Digital Signal Processing** chapter for further information about DSP techniques.

### BANDWIDTH

Whenever information is added to a carrier (we say the carrier is *modulated*), sidebands are produced. Sidebands are the frequency bands on both sides of a carrier resulting from the baseband signal varying some characteristic of the carrier. The modulation process creates two sidebands: the upper sideband (USB) and the lower sideband (LSB). The width of each sideband is generally equal to the highest frequency component in the baseband signal. In some modulation systems, the width of the sidebands may greatly exceed the highest baseband frequency component.

The USB and LSB are mirror images of each other and carry identical information. Some modulation systems transmit only one sideband and partially or completely suppress the other in order to conserve bandwidth.

According to FCC Rules, *occupied bandwidth* is:

The frequency bandwidth such that, below its lower and above its upper frequency limits, the mean powers radiated are each equal to 0.5 percent (−23 dB) of the total mean power radiated by a given emission.

In some cases a different relative power level may be specified; for example, −26 dB (0.25%) is used to define bandwidth in §97.3(a)(8) of the FCC rules.

Occupied bandwidth is not always easy for amateurs to determine. It can be measured on a spectrum analyzer, which is not available to most amateurs. Occupied bandwidth can also be calculated, but the calculations require an understanding of the mathematics of information theory and are not covered in this book.

The FCC has defined *necessary bandwidth* as:

For a given class of emission, the minimum value of the occupied bandwidth sufficient to ensure the transmission of information at the rate and with the quality required for the system employed, under specified conditions.

# Voice Modes

## AMPLITUDE MODULATION (AM)

AM voice was the second mode used in Amateur Radio (after Morse code). AM techniques are the basis for several other modes, such as single-sideband voice and AFSK. This material was supplied by Jeff Bauer, WA1MBK.

AM is a mixing process. When RF and AF signals are combined in a standard AM modulator, four output signals are generated: the original RF signal (carrier), the original AF signal, and two sidebands, whose frequencies are the sum and difference of the original RF and AF signals, and whose amplitudes are proportional to that of the original AF signal. The sum component is called the upper sideband (USB). It is erect: A frequency increase of the modulating AF causes a frequency increase in the RF output. The difference component is called the lower sideband (LSB), which is inverted: A frequency increase in the modulating AF produces a decrease in the output frequency. The amplitude and frequency of the carrier are unchanged by the modulation process, and the original AF signal is rejected by the RF output network. The RF envelope (sum of sidebands and carrier), as viewed

on an oscilloscope, has the shape of the modulating waveform.

Fig 12.1B shows the envelope of an RF signal that is 20% modulated by an AF sine wave. The envelope varies in amplitude because it is the vector sum of the carrier and the sidebands. A spectrum analyzer or selective receiver will show the carrier to be constant. The spectral photograph also shows that the bandwidth of an AM signal is twice the highest frequency component of the modulating wave.

An AM signal cannot be frequency multiplied without special processing because the phase/frequency relationship of the modulating-waveform components would be severely distorted. For this reason, once an AM signal has been generated, its frequency can be changed only by heterodyning.

All of the information in an AM signal is contained in the sidebands, but two-thirds of the RF power is in the carrier. If the carrier is suppressed in the transmitter and reinserted (in the proper phase) in the receiver, significant advantages accrue. When the reinserted carrier is strong compared to the incoming double-sideband signal (DSB), exalted carrier reception is achieved, and distortion from selective fading is reduced greatly. A refinement called synchronous detection uses a PLL to reject interference. Suppressing the carrier also eliminates the heterodyne inter-

ference common with adjacent AM signals. More important, eliminating the carrier increases overall transmitter efficiency. Transmitter power requirements are reduced by 66%, and the remaining 34% has a light duty cycle.

### Mathematics of AM

AM can happen at low levels (as in a driver or predriver stages of a transmitter) or high levels, in the final output stage. The numbers are consistent for both methods.

For example, to 100% modulate a 10 W RF carrier, 5 W of clean AF is required from the modulator. Good engineering calls for a 25% overdesign; thus 6.25 W of AF allows plenty of system headroom. The circuitry can then "loaf along" at the 100% level.

### Overmodulation

Overmodulation occurs when more audio is impressed on a carrier than is needed for 100% modulation. It is also known as *flattopping*. Overmodulation causes distortion of the information conveyed and produces *splatter* (spurious emissions) on adjacent frequencies. Splatter interferes with others sharing our already-crowded bands: Prevent overmodulation at all times.

Years ago amateurs used ingenious ways to detect and prevent or control overmodulation. Nowadays with solid-state, large-scale integration (LSI) chips and microprocessor control, bullet-proof overmodulation prevention can be designed into transmitters. The most familiar method is called ALC, for automatic level control.

Although modern use of full-carrier AM on the amateur bands is very limited, there is a core group of AM aficionados experimenting with pulse duration modulation (PDM). This system was pioneered in AM broadcast transmitters.

This form of high-level modulation differs from conventional AM in that the PDM modulator operates in switching mode, with audio information contained during on-pulses. The audio amplitude is therefore determined by the duty cycle of the modulator or switching tube. Those interested in further reading on the topic should look in William Orr's (W6SAI) *Radio Handbook* (published by Howard W. Sams and Co) and the *AM Press/Exchange* (for contact information, see the Address List in the **References** chapter).

### Balanced Modulators

The carrier can be suppressed or nearly eliminated by using a balanced modulator or an extremely sharp filter. Contemporary amateur transmitters often use both methods.

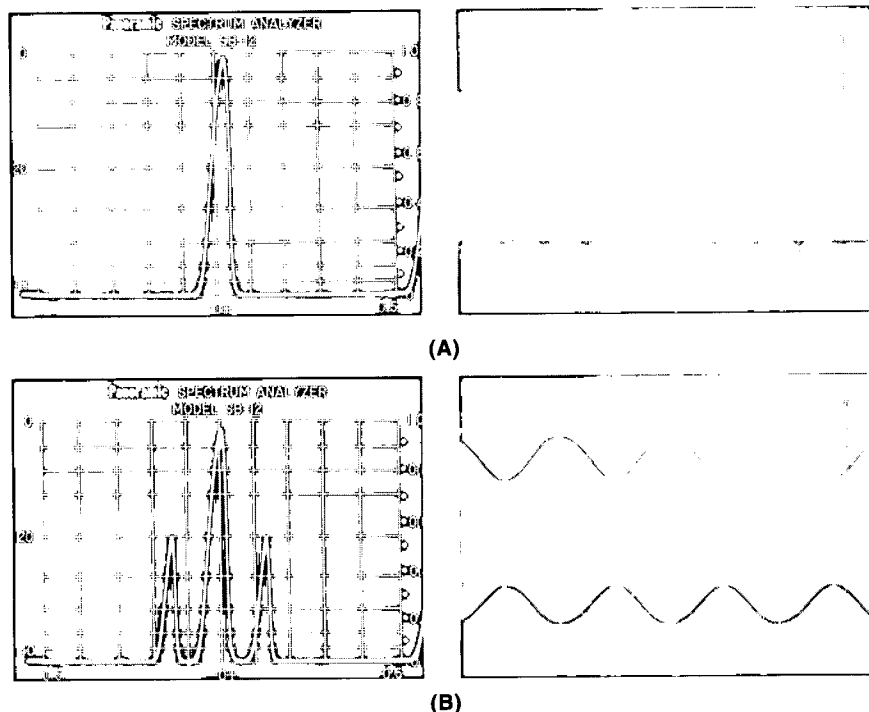

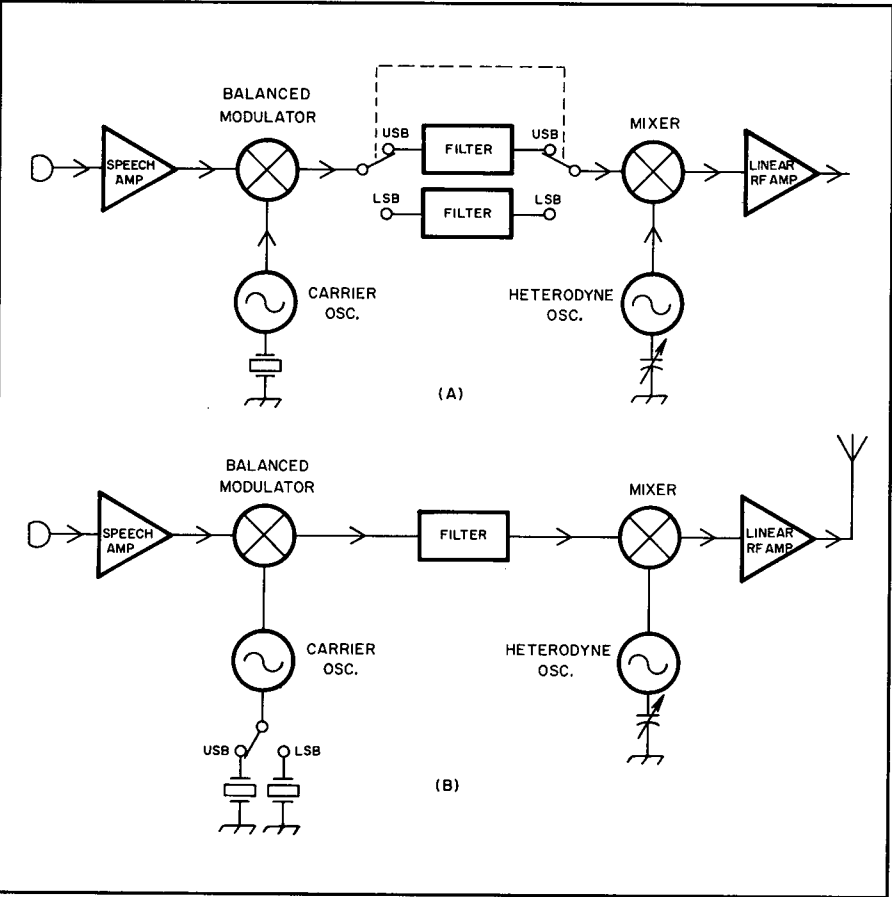

Fig 12.1—Electronic displays of AM signals in the frequency and time domains. A shows an unmodulated carrier or single-tone SSB signal. B shows a full-carrier AM signal modulated 20% with a sine wave.

**Table 12.1**  
**Guidelines for Amateur SSB Signal Quality**

Parameter	Suggested Standard
Carrier suppression	At least 40-dB below PEP
Opposite-sideband suppression	At least 40-dB below PEP
Hum and noise	At least 40-dB below PEP
Third-order intermodulation distortion	At least 30-dB below PEP
Higher-order intermodulation distortion	At least 35-dB below PEP
Long-term frequency stability	At most 100-Hz drift per hour
Short-term frequency stability	At most 10-Hz P-P deviation in a 2-kHz bandwidth

**Fig 12.2—Block diagrams of filter-method SSB generators. They differ in the manner that the upper and lower sideband are selected.**

The basic principle of any balanced modulator is to introduce the carrier in such a way that only the sidebands will appear in the output. The balanced-modulator circuit chosen by a builder depends on constructional considerations, cost and the active devices to be employed.

In any balanced-modulator circuit, there is (theoretically) no output when no audio signal is applied. When audio is applied, the balance is upset, and one branch conducts more than the other. Since any modulation process is the same as “mixing,” sum and difference frequencies (sidebands) are generated. The modu-

lator is not balanced for the sidebands, and they appear in the output.

### SINGLE-SIDE-BAND (SSB)

A further improvement in communications effectiveness can be obtained by transmitting only one of the sidebands. When the proper receiver bandwidth is used, a single-sideband (SSB) signal will show an effective gain of up to 9 dB over an AM signal of the same peak power. Because the redundant information is eliminated, the required bandwidth of an SSB signal is half that of a comparable AM or DSB emission. Unlike DSB, the

phase of the local carrier generated in the receiver is unimportant. **Table 12.1** shows the qualities of a good SSB signal.

### SSB Generation: The Filter Method

If the DSB signal from the balanced modulator is applied to a narrow band-pass filter, one of the sidebands can be greatly attenuated. Because a filter cannot have infinitely steep skirts, the response of the filter must begin to roll off within about 300 Hz of the phantom carrier to obtain adequate suppression of the unwanted sideband. This effect limits the ability to transmit bass frequencies, but those frequencies have little value in voice communications. The filter rolloff can be used to obtain an additional 20 dB of carrier suppression. The bandwidth of an SSB filter is selected for the specific application. For voice communications, typical values are 1.8 to 3.0 kHz.

**Fig 12.2** illustrates two variations of the filter method of SSB generation. In A, the heterodyne oscillator is represented as a simple VFO, but may be a premixing system or synthesizer. The scheme at B is perhaps less expensive than that of A, but the heterodyne-oscillator frequency must be shifted when changing sidebands in order to maintain dial calibration.

The ultimate sense (erect or inverted) of the final output signal is influenced as much by the relationship of the heterodyne oscillator frequency to the fixed SSB frequency as by the filter or carrier frequency selection. The heterodyne-oscillator frequency must be chosen to allow the best image rejection. This consideration requires that the heterodyne-oscillator frequency be above the fixed SSB frequency on some bands and below it on others. To reduce circuit complexity, early amateur filter-method SSB transmitters used a 9-MHz IF and did not include a sideband switch. The result was that the output was LSB on 160, 75 and 40 m, and USB on the higher bands. This convention persists today, despite the flexibility of most modern amateur SSB equipment. Appropriate filtering methods and filters for SSB generation are discussed in the **Filters** chapter.

### SSB Generation: The Phasing Method

**Fig 12.3** shows another method to obtain an SSB signal. The audio and carrier signals are each split into equal components with a 90° phase difference (called *quadrature*) and applied to balanced modulators. When the DSB outputs of the modulators are combined, one sideband is reinforced and the other is canceled. The figure shows sideband selection by means of transposing the audio leads, but the

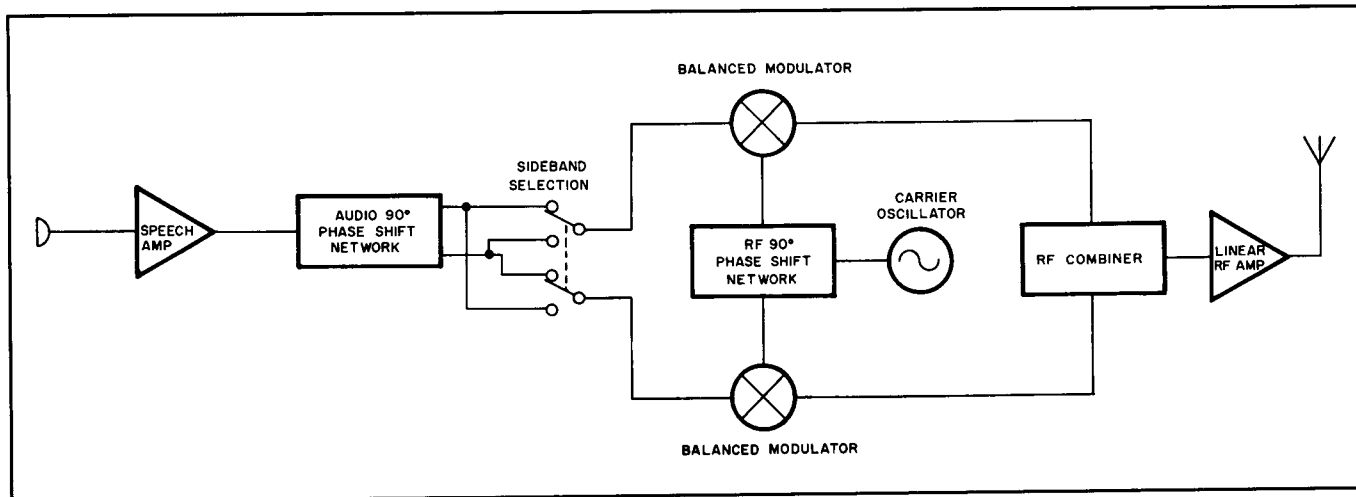

Fig 12.3—Block diagram of a phasing SSB generator.

same result can be achieved by switching the carrier leads.

The phase shift and amplitude balance of the two channels must be very accurate if the unwanted sideband is to be adequately attenuated. Table 12.2 shows the required phase accuracy of one channel (AF or RF) for various levels of opposite sideband suppression. The numbers given assume perfect amplitude balance and phase accuracy in the other channel.

**Table 12.2**  
**Unwanted Sideband Suppression**  
**as a Function of Phase Error**

Phase Error (deg.)	Suppression (dB)
0.125	59.25
0.25	53.24
0.5	47.16
1.0	41.11

15.0	16.69
20.0	13.93
30.0	9.98
45.0	6.0

Fig 12.4—A simple RF phase shifter. Make one of the capacitors adjustable for precise alignment.

The table shows that a phase accuracy of  $\pm 1^\circ$  is required to satisfy the criteria tabulated at the beginning of this chapter. It is difficult to achieve this level of accuracy over the entire speech band. Note, however, that speech has a complex spectrum with a large gap in the octave from 700 to 1400 Hz. The phase-accuracy tolerance can be loosened to  $\pm 2^\circ$  if the peak deviations can be made to occur within that spectral gap.

The major advantage of the phasing system is that the SSB signal can be generated at the operating frequency without the need for heterodyning. Phasing can be used to good advantage even in fixed-frequency systems. A loose-tolerance ( $\pm 4^\circ$ )

phasing exciter followed by a simple two-pole crystal filter can generate a high-quality signal at very low cost.

### Audio Phasing Networks

It would be difficult to design a two-port network having a quadrature ( $90^\circ$ ) phase relationship between input and output with constant-amplitude response over a decade of bandwidth. A practical approach, pioneered by Robert Dome, W2WAM, is to use two networks having a differential phase shift of  $90^\circ$ . This differential can be closely maintained in a simple circuit if precision components are used.

Numerous circuits have been developed to synthesize the required  $90^\circ$  phase shift

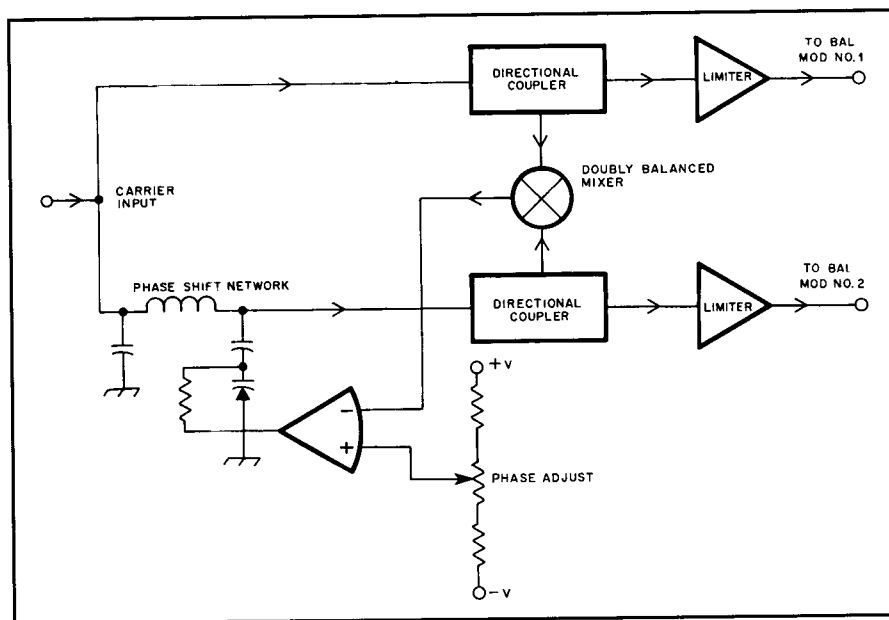

Fig 12.5—A block diagram of a PLL phase-shifting system that can maintain quadrature ( $90^\circ$  phase difference) over a wide frequency range. The doubly balanced mixer is used as a phase detector.

Fig 12.6—Digital RF phase-shift networks. Circuit A uses JK flip-flops; B uses D flip-flops. The carrier frequency must be quadrupled before processing.

electronically. Active-filter techniques are used in many of these systems; use precision components for good results.

### RF Phasing Networks

If the SSB signal is to be generated at a fixed frequency, the RF phasing problem is trivial; any method that produces the proper phase shift can be used. If the signal is produced at the operating frequency, problems similar to those in the audio networks must be overcome.

A differential RF phase shifter is shown in Fig 12.4. The amplitudes of the quadrature signals won't be equal over an entire phone band, but this is of little consequence as long as the signals are strong enough to saturate the modulators.

Where percentage bandwidths are small, such as in the 144.1- to 145-MHz range, the RF phase shift can be obtained conveniently with transmission-line methods. If one balanced-modulator feed line is made an electrical quarter wavelength longer than the other, the two signals will be  $90^\circ$  out of phase. (It is important that the cables be properly terminated.)

One method for obtaining a  $90^\circ$  phase shift over a wide bandwidth is to generate

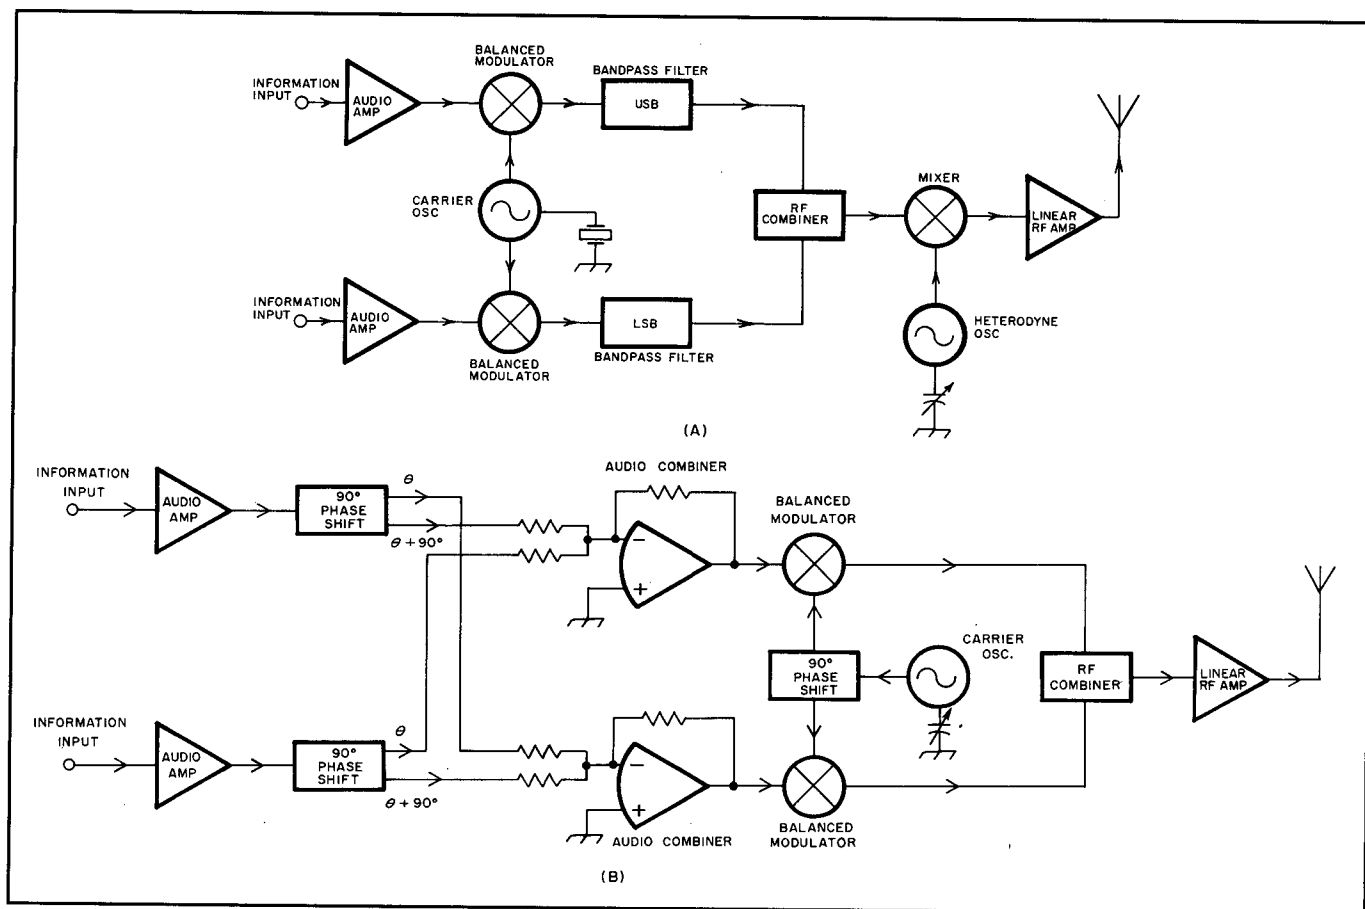

Fig 12.7—Independent-sideband generators. A shows a filter system, B a phasing system. The "RF combiner" may be either a hybrid combiner or a summing amplifier.

the quadrature signals at a fixed frequency and heterodyne them individually to any desired operating frequency. Quadrature hybrids having multioctave bandwidths are manufactured commercially, by Mini-Circuits Labs and others.

Another practical approach uses two VFOs in a master-slave PLL system. Many phase detectors lock the two signals in phase quadrature. A doubly balanced mixer also has this property. One usually thinks of a PLL as having a VCO locked to a reference signal, but a phase differential can be controlled independently of the oscillator. The circuit in **Fig 12.5** illustrates this principle. Two digital phase shifters are sketched in **Fig 12.6**. If ECL ICs are used, this system can work over the entire HF spectrum.

### Independent-Sideband (ISB)

If two SSB exciters, one USB and the other LSB, share a common carrier oscillator, two channels of information can be simultaneously transmitted from one antenna. Methods for ISB generation in filter and phasing transmitters are shown in **Fig 12.7**.

The most obvious amateur application for ISB is the transmission of SSTV with simultaneous audio commentary. On the VHF bands, other combinations are possible, such as voice and code or SSTV and RTTY.

### Amplitude Companded Single Sideband (ACSSB)

When SSB was tried in the Land Mobile Service, several problems arose. One was that users (who are not trained operators) couldn't master the control known as CLARIFIER to land-mobile users or receiver incremental tuning, RIT, to amateurs. In addition, users were annoyed by SSB's fading and noise performance, compared to that of FM.

So, to get the spectrum savings of SSB over FM, Land-Mobile Service engineers came up with a form of SSB that satisfied the users accustomed to FM.

### Pilot Tone

To overcome problems, manufacturers added a pilot tone to the audio. The tone is usually located at 3.1 kHz and filtered so it does not interfere with the audio. The pilot-tone power level is constant at about 10 dB below the voice peak power. (Thus, the transmitter output power is approximately 1/10th of maximum even when there is no voice modulation.)

At the receiver, the pilot tone is compared with an internal reference oscillator in a PLL circuit. So, the receiver automatically tunes in the incoming signal. The

pilot tone is also used to control squelch and AGC circuits. It can be modulated for signaling or telemetry transmission—a useful feature in logic-controlled systems.

### Amplitude Compandoring

Compression of voice signals is common in Amateur Radio SSB. Amateurs, however, rarely employ an expander at the receiving end. The term “compandor” is a fusion of the terms “compressor” and “expander.”

When signal levels are high, ACSSB and NBFM produce similar results. As distance between stations increases, however, both modes suffer, but in different ways: In the near fringe area, NBFM degrades quickly, followed by a complete loss of audio. ACSSB audio tends to degrade gradually over much greater distances, and fading results in transitory distortion.

### ACSSB Potential

Although ACSSB has some potential in earth/space communications, its land-based potential is limited by several factors: Cochannel interference is significantly higher with ACSSB, and unlike NBFM, ACSSB equipment is not interoperable with existing FM equipment. For more information about ACSSB see “On SSB Radio Communications,” by J. S. Belrose, VE2CV, in July 1982 *QEX*, pp 3-4.

## FREQUENCY MODULATION (FM)

When the frequency of the carrier is varied in accordance with the variations in a modulating signal, the result is frequency modulation (FM). Varying the phase of the carrier current is called phase modulation (PM). Frequency and phase modulation are not independent, since the frequency cannot be varied without also varying the phase, and vice versa. This section was written by Dean Straw, N6BV.

The primary advantage of FM is its ability to produce a high signal-to-noise ratio when receiving a signal of only moderate strength. This has made FM popular for mobile communications services and high-quality broadcasting. However, because of the wide bandwidth required and the distortion suffered in skywave propagation, the use of FM has generally been limited to frequencies higher than 29 MHz.

When compared to AM or SSB, FM has some impressive advantages for VHF operation. In an FM transmitter, modulation takes place in a low-level stage. Amplifiers following the modulator can be oper-

ated Class C for best efficiency, since operation need not be linear. The frequency tolerances needed for channelized FM operation are much less severe than for SSB, helping to keep cost down.

The effectiveness of FM and PM for communication purposes depends almost entirely on the methods used for receiving. If the FM receiver responds to frequency and phase changes but is insensitive to amplitude changes, it can discriminate against many forms of noise.

**Fig 12.8** is a representation of frequency modulation. When an audio modulating signal is applied, the carrier frequency is increased during one half cycle of the modulating signal and decreased during the half cycle of opposite polarity. In this figure RF cycles occupy less time (higher frequency) when the modulating signal is positive, and more time (lower frequency) when the modulating signal is negative. The change in the carrier frequency is called *frequency deviation* and is proportional to the instantaneous amplitude of the modulating signal. The deviation is small when the instantaneous amplitude of the modulating signal is small and is greatest when the modulating signal reaches its peak, either positive or negative.

### Phase Modulation (PM)

If the phase of the current in a circuit shifts there is an instantaneous frequency

**Fig 12.8—Graphical representation of frequency modulation. In the unmodulated carrier (A) each RF cycle occupies the same amount of time. When the modulating signal (B) is applied, the radio frequency is increased and decreased according to the amplitude and polarity of the modulating signal (C).**

change during the time the phase is shifting. The amount of frequency change is directly proportional to how rapidly the phase is shifting and to the total amount of the phase shift. The rapidity of the phase shift is directly proportional to the frequency of the modulating signal. In a properly operating PM system, the amount of phase shift is proportional to the instantaneous amplitude of the modulating signal. Phase modulators have a built-in *pre-emphasis*, where deviation increases with modulating frequency.

## FM AND PM SIDEBANDS

The sidebands generated by FM and PM occur at integral multiples of the modulating frequency on either side of the carrier. This is in contrast to AM, where a modulating frequency will produce a single set of sidebands on either side of the carrier frequency. An FM or PM signal therefore inherently occupies a wider channel than AM. The number of additional sidebands that occur in FM and PM depend on the relationship between the modulating frequency and the frequency deviation. The ratio between the frequency deviation, in hertz, and the modulating frequency, also in hertz, is called the *modulation index*.

$$\chi = \frac{D}{m} = \phi \quad (1)$$

where

$\chi$  = modulation index

$D$  = peak deviation ( $1/2$  difference between maximum and minimum frequency)

$m$  = modulation frequency in hertz

$\phi$  = phase deviation in radians (a radian =  $180^\circ/\pi$  or approximately  $57.3^\circ$ ).

For example, the maximum frequency deviation in an FM transmitter is 3000 Hz either side of the carrier frequency. The modulation index when the modulation frequency is 1000 Hz is  $3000/1000 = 3.0$ . At the same deviation with 3000 Hz modulation, the index would be 1; at 100 Hz it would be 30 and so on.

Given a constant input level to the modulator, in PM the modulation index is constant regardless of the modulating frequency. In FM it varies with the modulating frequency, as shown above. In an FM system the ratio of the maximum carrier-frequency deviation to the highest modulating frequency used is called the *deviation ratio*. Thus

$$\text{deviation ratio} = \frac{D}{M} \quad (2)$$

where

$D$  = peak deviation

$M$  = maximum modulation frequency in hertz.

The deviation ratio used above 29 MHz

for narrow-band FM is 5000 Hz (maximum deviation) divided by 3000 Hz (maximum modulating frequency) or 1.67.

Fig 12.9 shows how the amplitudes of the carrier and the various sidebands vary with the modulation index for single-tone modulation. The first pair of sidebands are displaced from the carrier by an amount equal to the modulating frequency, the second by twice the modulating frequency, and so on. For example, if the modulating frequency is 2000 Hz and the carrier frequency is 29,500 kHz, the first sideband pair is at 29,498 and 29,502 kHz, the second pair is at 29,496 and 29,504 kHz, the third at 29,494 and 29,506 kHz, and so on. The amplitudes of these sidebands depend on the modulation index, not on the frequency deviation.

The carrier strength varies with the modulation index—at a modulation index of 2.405, the carrier disappears entirely. As the index is raised further, the carrier level becomes negative, since its phase is reversed compared to the phase without modulation. In FM and PM the energy going into the sidebands is taken from the

carrier—the total power remains the same regardless of the modulation index. Since there is no change in amplitude with modulation, an FM or PM signal can be amplified without distortion by an ordinary Class-C amplifier, either as a straight-through amplifier or frequency-multiplier stage.

If the modulated signal is passed through one or more frequency multipliers, the modulation index is multiplied by the same factor as the carrier frequency. For example, if modulation is applied on 3.5 MHz and the final output is on 28 MHz, the total frequency multiplication is eight times. If the frequency deviation is 500 Hz at 3.5 MHz, it will be 4000 Hz at 28 MHz. Frequency multiplication offers a means for obtaining practically any desired amount of frequency deviation, whether or not the modulator itself is capable of giving that much deviation without distortion.

If the modulation index (with single-tone modulation) does not exceed 0.6 or 0.7, the most important extra sideband, the second, will be at least 20 dB below the unmodulated carrier level. This represents

Fig 12.9—Amplitude variation of the carrier and sideband pairs with modulation index. This is a graphical representation of mathematical functions developed by F. W. Bessel. Note that the carrier completely disappears at modulation indexes of 2.405, 5.52 and 8.654.

an effective channel width about equal to an AM signal. The energy in speech is distributed among many audio frequencies. On average, the modulation index for any one frequency component is smaller than that for a single audio tone having the same peak amplitude. Thus, the effective modulation index for speech can be somewhat higher while retaining the same average bandwidth. The rule-of-thumb for determination of bandwidth requirements for an FM system using *narrow-band* (5 kHz deviation) modulation is

$$B_n = 2(M+D) \quad (3)$$

where

$B_n$  = necessary bandwidth in hertz

$M$  = maximum modulation frequency in hertz

$D$  = peak deviation in hertz.

For narrow-band FM, the bandwidth equals  $2 \times (3000 + 5000) = 16000$  Hz. Additional bandwidth may be needed to compensate for cumulative errors in the transmitter and receiver frequencies.

### FM vs Phase Modulation (PM)

FM cannot be applied to an amplifier stage, but phase modulation (PM) can. PM is therefore readily adaptable to transmitters employing oscillators of high stability, such as the crystal-controlled oscillators. The amount of phase shift that can be obtained with good linearity yields a maximum practicable modulation index of about 0.5. Because phase shift is proportional to the modulating frequency, this index can be used only at the highest frequency present in the modulating signal, assuming that all frequencies will at one time or another have equal amplitudes.

The frequency response of the speech-amplifier system above 3000 Hz must be sharply attenuated to prevent splatter on adjacent channels. Due to its inherent preemphasis, PM received on an FM receiver sounds "tinny." The audio must be processed for PM to have the same modulation-index characteristic as an FM signal. The speech-amplifier frequency-response curve is thus shaped so the output voltage is inversely proportional to frequency over most of the voice range. When this is done the maximum modulation index can only be used below a relatively low audio frequency, perhaps 300 to 400 Hz in voice transmission, and must decrease in proportion to an increase in frequency. The net result is that the maximum linear frequency deviation is only one or two hundred hertz. In order to increase the deviation up to narrowband level, we must typically multiply the frequency by eight or more.

## GENERATING FM

### Direct FM

A simple circuit for producing *direct FM* in amateur transmitters is the *reactance modulator*. An active device is connected to the RF tank circuit of an oscillator to act as a variable inductance or capacitance. Fig 12.10A is a representative circuit using a MOSFET. This modulator acts as though an inductance were connected across the tank. The frequency increases in proportion to the amplitude of the current in this modulator. If the modulated oscillator is free running, it must usually be operated on a relatively low frequency to maintain good carrier stability. Fig 12.10B shows how a varactor may be used to FM a crystal oscillator directly. The supply voltage for either modulator and oscillator should be regulated to reduce residual FM. The oscillator frequency is multiplied up to the final output frequency.

In many modern frequency-synthesized transceivers, a VCO used in one of the phase-locked loops (PLL) is often frequency modulated directly. A PLL consists of a phase detector, a filter, a dc amplifier and a voltage-controlled oscillator (VCO). See Fig 12.11. The VCO runs at a frequency close to that desired when the loop is in lock. The phase detector produces an error voltage if any frequency difference exists between the VCO divided by the variable divider  $N$  and the reference signal. The error voltage is applied to the VCO to keep it locked on the carrier frequency when there is no modulation present. The loop bandwidth of the PLL is made narrow enough so that the audio can change the VCO frequency, while the PLL still keeps the unmodulated carrier frequency on-channel.

### Indirect FM

The same type of reactance-modulator circuit used to vary the tuning of an oscil-

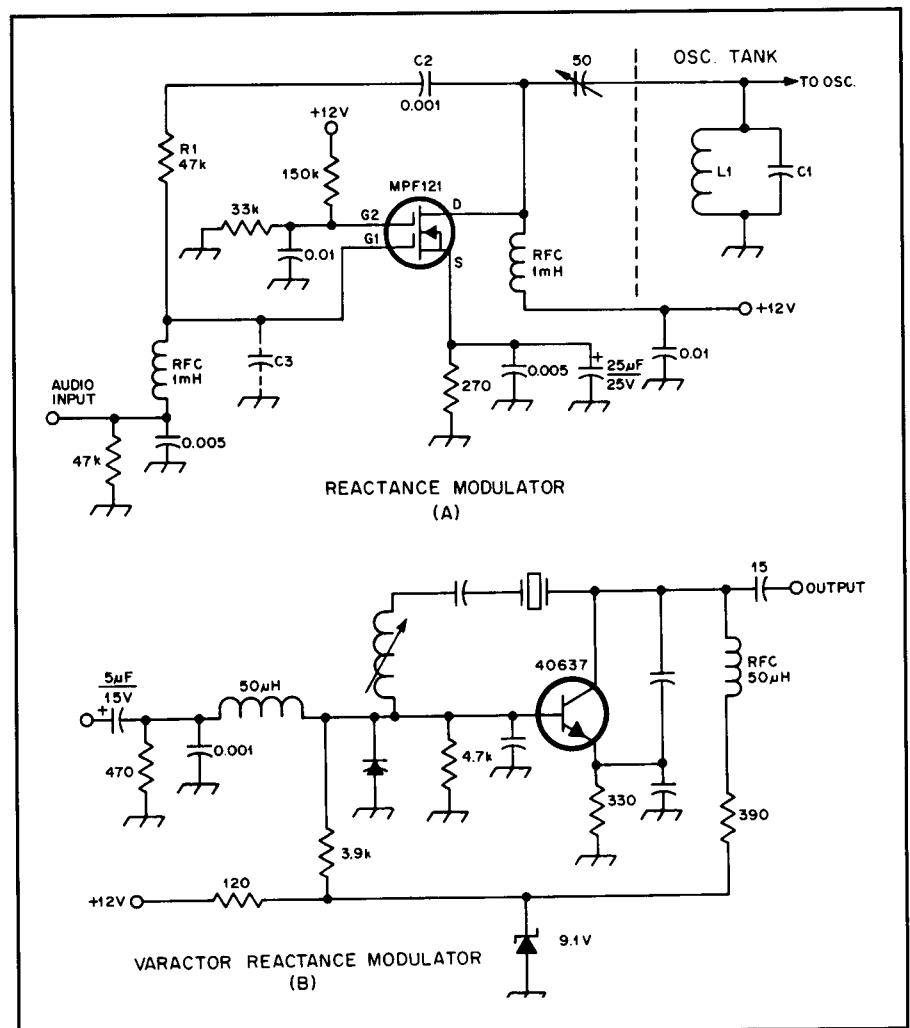

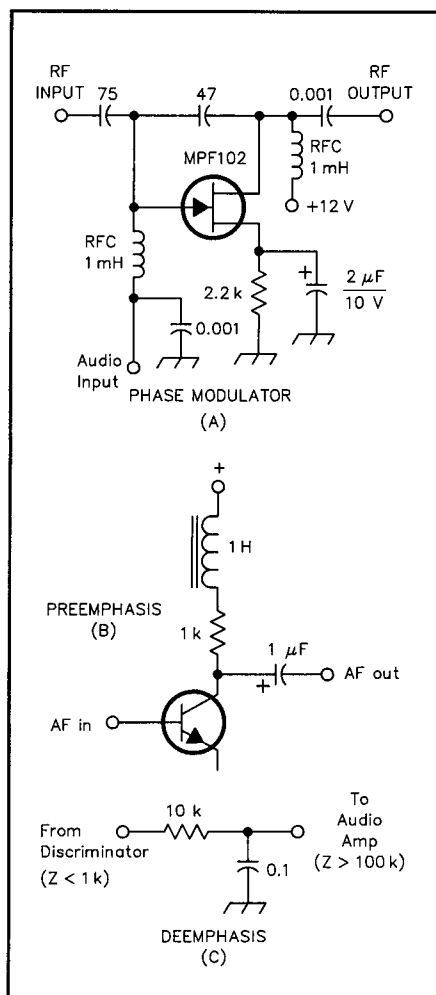

Fig 12.10—At A, reactance modulator using a high-transconductance MOSFET. At B, reactance modulator using a varactor diode.

**Fig 12.11—Simple phase-locked loop (PLL) where VCO is FMed directly. The loop filter is designed to be narrow enough so that the loop will lock onto the desired channel frequency, while audio frequencies will modulate the VCO outside the loop bandwidth.**

**Fig 12.12— At A, a phase-shifter type of phase modulator. At B, preemphasis and at C, deemphasis circuits.**

lator tank in direct FM can be used to vary the tuning of an amplifier tank. See **Fig 12.12A**. This varies the phase of the tank current to create phase modulation. When audio shaping is used in the speech amplifier, an FM-compatible signal will be generated by the phase modulator. The phase shift that occurs when a circuit is detuned from resonance depends on the amount of detuning and the Q of the circuit. The higher the Q, the smaller the amount of detuning needed to secure a given number of degrees of phase shift. Since reactance modulation of an amplifier stage results in simultaneous amplitude modulation, this must be eliminated using succeeding Class-C limiting stages.

### Speech Processing for FM

Several forms of speech processing produce worthwhile improvements in FM system performance. The peak amplitude of the audio signal applied to an FM or PM modulator should be limited so that transmitter cannot be driven into overdeviation. Peak limiting is often maintained using a simple audio clipper between the speech amplifier and modulator. An audio low-pass filter with a cut-off frequency between 2.5 and 3 kHz eliminates harmonics produced by the clipper. Since excessive clipping can cause severe distortion of a voice signal, a more effective audio processor consists of a compressor followed by a clipper and low-pass filter.

An audio shaping network called *preemphasis* is added to an FM transmit-

ter to attenuate the lower audio frequencies, spreading out the energy evenly in the audio band. Preemphasis applied to an FM transmitter gives the deviation characteristic of PM. The reverse process, called *deemphasis*, is used at the receiver to restore the audio to its original relative proportions. See **Fig 12.12B** and **C**.

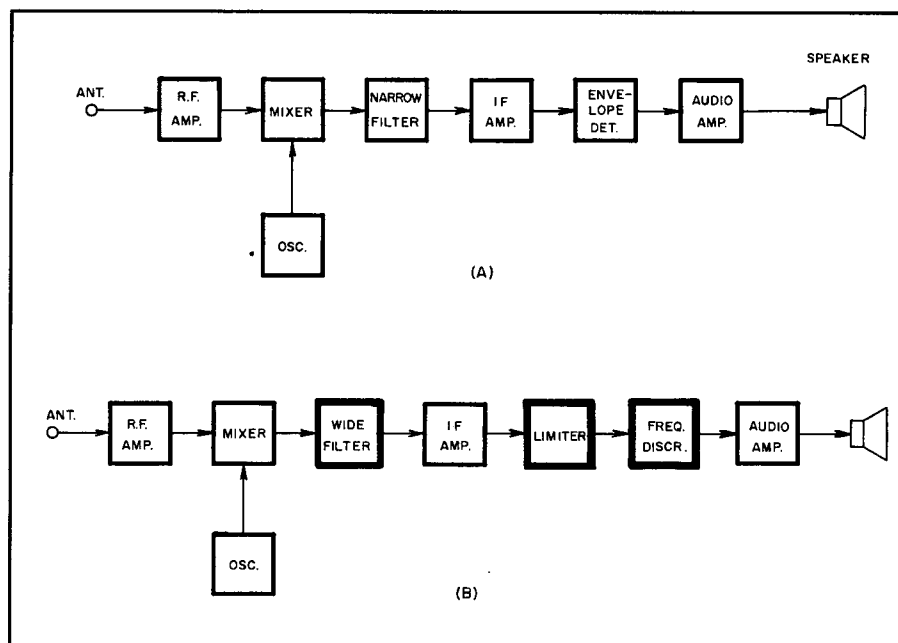

### RECEPTION OF FM SIGNALS

A block diagram of an FM receiver is shown in **Fig 12.13B**. The FM receiver employs a wide-bandwidth filter and an FM detector, and has one or more limiter stages between the IF amplifier and the FM detector. The limiter and discriminator stages in an FM set can eliminate a good deal of impulse noise, except noise that manages to acquire a frequency-modulation characteristic.

FM receivers exhibit a characteristic known as the *capture effect* when QRM is present. The loudest signal received, even if it is only two or three times stronger than other stations on the same frequency, will be the only transmission demodulated.

### Limiters

The circuit in the FM receiver that has the task of chopping noise and amplitude modulation from an incoming signal is the *limiter*. Most types of FM detectors respond to both frequency and amplitude variations of the signal. Thus, the limiter stages preceding the detector are included so only the desired frequency modulation

**Fig 12.13—At A, block diagram of an AM receiver. At B, an FM receiver. Dark borders outline the sections that are different in the FM set.**

(A)

(B)

Fig 12.14—At A, input wave form to a limiter stage shows AM and noise. At B, the same signal, after passing through two limiter stages, is devoid of AM components.

will be demodulated. This action can be seen in Fig 12.14.

For an amplifier to act as a limiter, the applied voltages are chosen so that the stage overloads predictably, even with a small amount of signal input. Limiting action in an FM receiver should start with an RF input of  $0.2 \mu\text{V}$  or less, so a large amount of gain is required between the antenna terminal and the limiter stages. ICs offer simplification of the IF system, as they pack a lot of gain into a single package.

When sufficient signal arrives at the receiver to start limiting action, the set *quiets*—that is, the background noise disappears. The sensitivity of an FM receiver is rated in terms of the amount of input signal required to produce a given amount of quieting, usually 20 dB. Modern receivers achieve 20 dB quieting with  $0.15$  to  $0.5 \mu\text{V}$  of input signal.

Fig 12.15A shows a two-stage limiter using discrete transistors. The base bias on either transistor may be varied to provide limiting at a desired level. The input-signal voltage required to start limiting

action is called the *limiting knee*. This refers to the point at which collector current ceases to rise with increased input signal. Modern ICs have limiting knees of 100 mV for the circuit shown in Fig 12.15B, using the RCA CA3028A or Motorola MC1590G, or 200 mV for the MC1590G

Fig 12.16—The characteristic of an FM discriminator.

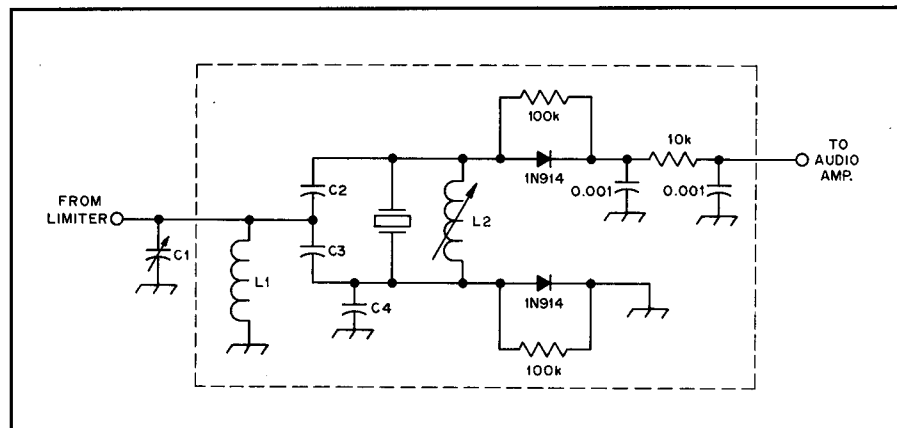

Fig 12.18—A crystal discriminator, C1 and L1 are resonant at the IF. C2 is equal in value to C3. C4 corrects any circuit imbalance so equal amounts of signal are fed to the detector diodes.

of Fig 12.15C. Because high-gain ICs contain many active stages a single IC can provide superior limiting performance compared to most discrete designs.

### Detectors

The first FM detector to gain popularity was the *frequency discriminator*. The characteristic of such a detector is shown in Fig 12.16. When the FM signal has no modulation, and the carrier is at point 0, the

detector has no output. When audio input to the FM transmitter swings the signal higher in frequency, the rectified output increases in the positive direction. When the frequency swings lower, the output amplitude increases in the negative direction. Over a range where the discriminator is linear (shown as the straight portion of the line), the conversion of FM to AM will also be linear. A practical discriminator circuit is shown in Fig 12.17.

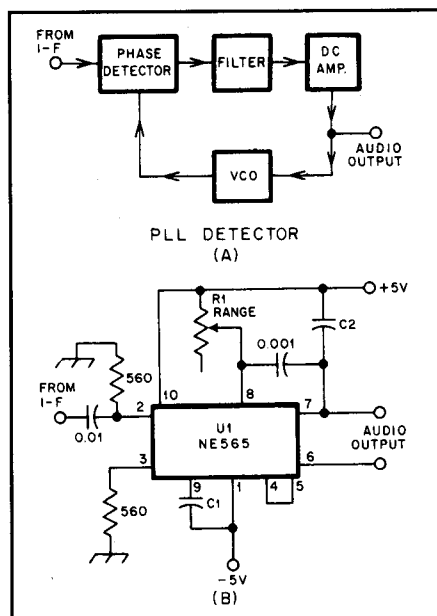

Fig 12.19—At A, block diagram of a PLL demodulator. At B, complete PLL circuit.

### Other Detector Designs

The difficulties often encountered in building and aligning LC discriminators have inspired research that has resulted in a number of adjustment-free FM detector designs. The crystal discriminator utilizes a quartz resonator, shunted by an inductor, in place of the tuned-circuit secondary used in a discriminator transformer. A typical circuit is shown in Fig 12.18.

### The PLL

The *phase-locked loop* (PLL) has made a significant impact on transmitter and receiver design, both for frequency generation and for modulation/demodulation. It can act as an FM detector in a process similar to that used for direct-frequency modulation in a transmitter PLL. As the VCO tracks the frequency of an incoming signal, the voltage at the phase detector output becomes demodulated audio. See Fig 12.19.

# Text (Digital) Modes

## MORSE TELEGRAPHY (CW)

Telegraphy by on-off keying (OOK, or amplitude-shift keying ASK) of a carrier is the oldest radio modulation system. It is also known as CW (for continuous wave). While CW is used by amateurs and other communicators to mean OOK telegraphy by Morse code, parts of the electronics industry use CW to signify an unmodulated carrier.

This discussion centers on aural reception of CW, but computers are used to send and receive CW as well. A table of characters and their Morse equivalents appears in the **References** chapter.

## TRANSMITTING

### WPM vs Bauds

The speed of Morse telegraphy is usually expressed in WPM, rather than bauds, which are the common measure in other digital modes. The following formulas relate WPM to bauds:

$$\text{WPM} = 2.4 \times \text{dot/s} \quad (4)$$

$$\text{WPM} = 1.2 \times B \quad (5)$$

where

WPM = telegraph speed in words per minute

2.4 = a constant calculated by comparing dots per second with plain language Morse code sending the word "PARIS"

1.2 = a constant calculated by comparing the signaling rate in bauds with plain-language Morse code sending the word "PARIS"

B = telegraph speed in bauds.

Thus a keying speed of 25 dot/s or 50 bauds is equal to 60 WPM.

### Rise Time vs Bandwidth

Keying a carrier on and off produces double (upper and lower) sidebands corresponding to the period of the keying pulse. A string of dits at 50 baud will have sidebands at multiples of 50 Hz above and below the carrier. The rise time of the pulses affects the distribution of power among the sidebands. As rise time increases or pulse rate decreases, the bandwidth of the signal decreases. In addition, the rise time affects how our ears hear the signal.

League publications have long promoted 5-ms rise and fall times for CW keying envelopes (see Fig 12.20). This shape is based on an assumed necessary bandwidth of 150 Hz for a 60-WPM (50-

Fig 12.20—Optimum CW keying waveforms.

Fig 12.21—Keying speed vs rise and fall times vs bandwidth for fading and nonfading communications circuits. For example, to optimize transmitter timing for 25 WPM on a nonfading circuit, draw a vertical line from the WPM axis to the K = 3 line. From there draw a horizontal line to the rise/fall time axis (approximately 15 ms). Draw a vertical line from where the horizontal line crosses the bandwidth line and see that the bandwidth will be about 140 Hz.

Table 12.3

## Baudot Signaling Rates and Speeds

Signaling Rate (bauds)	Data Pulse (ms)	Stop Pulse (ms)	Speed (WPM)	Common Name
45.45	22.0	22.0	65.00	Western Union
	22.0	31.0	61.33	"60 speed"
	22.0	33.0	60.61	45 bauds
50.00	20.0	30.0	66.67	European; 50 bauds
56.92	17.57	25.00	76.68	"75 speed"
	17.57	26.36	75.89	57 bauds
74.20	13.47	19.18	100.00	"100 speed"
	13.47	20.21	98.98	74 bauds
100.0	10.00	15.00	133.33	100 bauds

baud) pulse train and an equation relating necessary CW bandwidth to keying speed in Appendix 6 of the CCIR Radio Regulations and §2.202 of the FCC rules. The relationship is shown in Fig 12.21.

K is part of the bandwidth equation. Low K values produce softer keying, while high values sound harder. The CCIR and FCC recommend  $K = 3$  for nonfading circuits and  $K = 5$  for fading circuits with aural reception.  $K = 3$ , is the minimum used for comfortable aural reception, but  $K = 1$  is useful for machine recognition.

Given a 150-Hz bandwidth, how fast can we communicate over a fading path? With an occupied bandwidth of 150 Hz and  $K = 5$ , Fig 12.21 yields 36 WPM. Therefore, 5-ms rise and fall times are suitable for up to 36 WPM on fading circuits and 60 WPM on nonfading circuits.

## RECEIVING

For aural reception, a Morse-code OOK RF signal is not completely demodulated to its original dc pulse, because only thumping would be heard. Instead, the signal is moved (by mixing) down to AF, usually near 700 Hz.

Proper reception of a Morse-code transmission requires that the receiver bandwidth be at least that of the necessary bandwidth plus any frequency error. Thus, if you have 150-Hz receiver bandwidth, it would be necessary for you to carefully tune your receiver to receive a 150-Hz-bandwidth transmission. In practice, it is common to use 500 or 250-Hz IF filters.

Many operators find that it is easier to distinguish between multiple signals as the frequency of the desired signal is lowered to 500 Hz or less. Some modern transceivers provide a CW OFFSET adjustment to accommodate this preference. The same result can be achieved by adjusting the RIT control, although the audio from incoming signals will no longer match the sidetone with this technique.

Those who desire a narrower bandwidth often use audio filters, either an op-amp audio-peak filter or a low-pass switched-capacitor. Such filters may be part of the radio or added as accessories. Look in the **Filters** chapter for projects.

BAUDOT (ITA2)  
RADIOTELETYPE

## The Baudot Code: ITA2

One of the first data communications codes to receive widespread use had five bits (traditionally called "levels") to present the alphabet, numerals, symbols and machine functions. In the US, we use International Telegraph Alphabet No. 2 (ITA2), commonly called *Baudot*, as specified in FCC §97.309(a)(1). The code is defined in the ITA2 Codes table in the **References** chapter. In Great Britain, the almost-identical code is called *Murray* code. There are many variations in five-bit coded character sets, principally to accommodate foreign-language alphabets.

Five-bit codes can directly encode only

$2^5 = 32$  different symbols. This is insufficient to encode 26 letters, 10 numerals and punctuation. This problem can be solved by using one or more of the codes to select from multiple code-translation tables. ITA2 uses a LTRS code to select a table of upper-case letters and a FIGS code to select a table of numbers, punctuation and special symbols. Certain symbols, such as carriage return, occur in both tables. Unassigned ITA2 FIGS codes may be used for the remote control of receiving printers. This scheme can be expanded, as shown by the ASCII-over-AMTOR discussion latter in this chapter.

FCC rules provide that ITA2 transmissions must be sent using start-stop pulses as illustrated in Fig 12.22. The bits in the figure are arranged as they would appear on an oscilloscope.

## Speeds and Signaling Rates

The signaling speeds for all forms of RTTY are those used by the old TTYs: 60, 67, 75 or 100 WPM. Table 12.3 relates speeds, signaling rates and pulse times. In practice, the real speeds do not exactly match their names. The names have been rounded through years of common usage. The Signaling Rates table in the **References** chapter lists names, signaling rates and data patterns for common RTTY speeds.

There's a problem specifying signaling speed of RTTY because the length of the start and stop pulses vary from that of the data bits. The answer is to base the signaling speed on the shortest pulses used. The *baud* is a unit of signaling speed equal to one pulse (event) per second. The signaling rate, in bauds, is the reciprocal of the shortest pulse length. For example, the "Western Union," "60 speed" and "45 bauds" speeds all signal at  $1/0.022 = 45.45$  bauds.

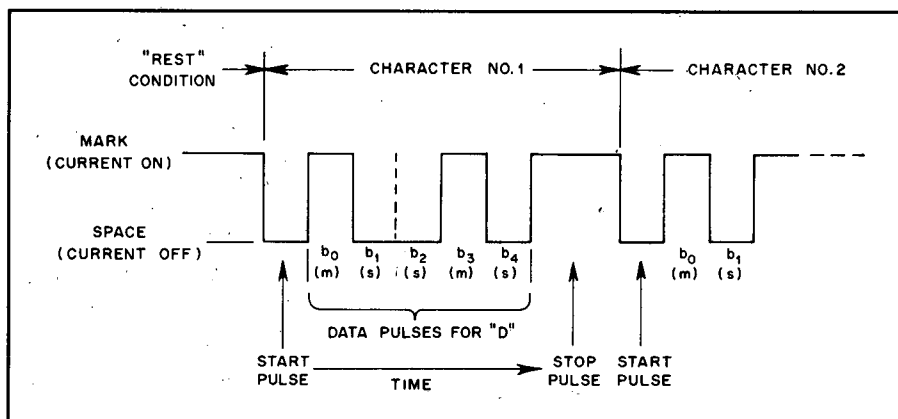

Fig 12.22—A typical Baudot timing sequence for the letter "D."

## Transmitter Keying

When TTYs and TUs (terminal units) roamed the airwaves, frequency-shift keying (FSK) was the order of the day. DC signals from the TU controlled some form of reactance (usually a capacitor or varactor) in a transmitter oscillator stage that shifted the transmitter frequency. Such direct FSK is still an option with some new radios.

## AFSK

Multimode communications processors (MCPs), however, generally connect to the radio AF input and output, often through the speaker and microphone connectors, sometimes through auxiliary connectors. They simply feed AF tones to the microphone input of an SSB transmitter or transceiver. This is called AFSK for "audio frequency-shift keying." When it is properly designed and adjusted, this method of modulation cannot be distinguished from FSK on the air.

When using AFSK, make certain that audio distortion, carrier and unwanted sidebands do not cause interference. Particularly when using the low tones discussed later, the harmonic distortion of the tones should be kept to a few percent. Most modern AFSK generators are of the continuous-phase (CPFSK) type. Older types of noncoherent-FSK (NCFSK) generators had no provisions for phase continuity and produced sharp switching transients. The noise from phase discontinuity caused interference several kilohertz around the RTTY signal.

Also remember that equipment is withstanding a 100% duty cycle for the duration of a transmission. For safe operation, it is often necessary to reduce the transmitter power output (25 to 50% of normal) from that safe for CW operation.

## What are Low Tones?

US amateurs customarily use the same modems (2125 Hz mark, 2295 Hz space) for both VHF AFSK and HF via an SSB transmitter. Because of past problems (when 850-Hz shift was used), some amateurs use "low tones" (1275 Hz mark, 1445 Hz space). Both high and low tones can be used interchangeably on the HF bands because only the *amount* of shift is important. The frequency difference is unnoticed on the air because each operator tunes for best results. On VHF AFSK, however, the high and low tone pairs are not compatible.

## Transmit Frequency

It is normal to use the lower sideband mode for RTTY on SSB radio equipment.

In order to tune to an exact RTTY frequency, remember that most SSB radio equipment displays the frequency of its (suppressed) carrier, not the frequency of the mark signal. Review your MCP's manual to determine the tones used and calculate an appropriate display frequency. For example, to operate on 14,083 kHz with a 2125-Hz AFSK mark frequency, the SSB radio display (suppressed-carrier) frequency should be  $14,083 \text{ kHz} + 2.125 \text{ kHz} = 14,085.125 \text{ kHz}$ .

## Receiving Baudot

Surplus Baudot-encoded teletypewriters (TTY, sometimes called the "green keys") were the mainstay of amateur RTTY from 1946 through around 1977. There are still some mechanical-TTY aficionados, but most operators use computer-based terminals.

Some of the first popular home computers (VIC-20, Commodore 64, Apple II) were adapted to read signals from "terminal units" or "TUs" required by TTYs. TUs translated receiver AF output into 20-mA current-loop signals to drive a polar relay in a TTY. An interface would translate the current-loop signals (or sometimes the receiver AF) to levels appropriate for the computer. Software, unique to each computer, would then decode the stream of marks and spaces into text. This technology was convoluted in that it required many different interfaces and software packages to suit the computers in use. Thankfully, it was soon replaced by multimode communications processors.

MCPs accept AF signals from a radio and translate them into common ASCII text or graphics file formats (see Fig 12.23). Because the basic interface is via ASCII,

MCPs are compatible with virtually any PC running a simple terminal program. There may be compatibility problems with graphics formats, but those are fairly well standardized. Many MCPs handle CW, RTTY, ASCII, AMTOR, packet, fax and SSTV—multimode indeed!

## AFSK Demodulators

An AFSK demodulator takes the shifting tones from the audio output of a receiver and produces TTY keying pulses. FM is a common AFSK demodulation method. The signal is first band pass filtered to remove out-of-band interference and noise. It is then limited to remove amplitude variations. The signal is demodulated in a discriminator or a PLL. The detector output low pass filtered to remove noise at frequencies above the keying rate. The result is fed to a circuit that determines whether it is a mark or a space.

AM (limiterless) detectors, when properly designed, permit continuous copy even when the mark or space frequency fades out completely. At 170-Hz shift, however, the mark and space frequencies tend to fade at the same time. For this reason, FM and AM demodulators are comparable at 170-Hz shift.

At wider shifts (say 425 Hz and above), the independently fading mark and space can be used to achieve an in-band frequency-diversity effect if the demodulator is capable of processing it. To conserve spectrum, it is generally desirable to stay with 170-Hz shift for 45-baud Baudot and forego the possible in-band frequency-diversity gain. Keep the in-band frequency-diversity gain in mind, however, for higher signaling rates that would justify greater shift.

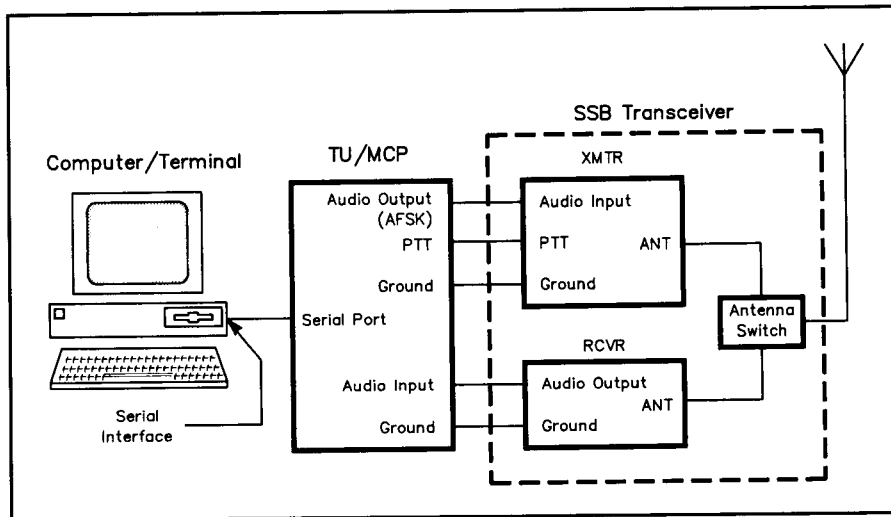

Fig 12.23—A typical MCP station. MCPs can do all available data modes as well as SSTV and fax.

## Diversity Reception

Another type of diversity can be achieved by using two antennas, two receivers and a dual demodulator. This setup is not as far fetched as it may sound; some amateurs are using it with excellent results. One of the antennas would be the normal station antenna for that band. The second antenna could be either another antenna of the same polarization located at least 3/8-wavelength away, or an antenna of the opposite polarization located at the first antenna or anywhere nearby. A problem is to get both receivers on the same frequency without carefully tuning each one. Some RTTY diversity enthusiasts have located slaved receivers on the surplus market. ICOM produced the IC-7072 Transceiver Unit, which slaves an IC-720(A) transceiver to an IC-R70 re-

ceiver. Other methods could include a computer controlling two receivers so that both would track.

Two demodulators are needed for this type of diversity. Also, some type of diversity combiner or selector is needed. Many commercial or military RTTY demodulators are equipped for diversity reception.

The payoff for using diversity is a worthwhile improvement in copy. Depending on fading conditions, adding diversity may be equivalent to raising transmitter power sevenfold (8 dB).

## GLOSSARY OF DIGITAL COMMUNICATIONS TERMINOLOGY

**ACK**—Acknowledgment, the control signal sent to indicate the correct receipt of a transmission block.

**Address**—A character or group of characters that identifies a source or destination.

**AFSK**—Audio frequency-shift keying.

**ALOHA**—A channel-access technique wherein each packet-radio station transmits without first checking to see if the channel is free; named after early packet-radio experiments at the University of Hawaii.

**AMICON**—AMSAT International Computer Network—Packet-radio operation on SSC L1 of AMSAT-OSCAR 10 to provide networking of ground stations acting as gateways to terrestrial packet-radio networks.

**AMRAD**—Amateur Radio Research and Development Corporation, a nonprofit organization involved in packet-radio development.

**AMTOR**—Amateur teleprinting over radio, an amateur radioteletype transmission technique employing error correction as specified in several CCIR documents 476-2 through 476-4 and 625. CCIR Rec. 476-3 is reprinted in the *Proceedings of the Third ARRL Amateur Radio Computer Networking Conference*, available from ARRL Hq.

**ANSI**—American National Standards Institute

**Answer**—The station intended to receive a call. In modem usage, the called station or modem tones associated therewith.

**ARQ**—Automatic repeat request, an error-sending station, after transmitting a data block, awaits a reply (ACK or NAK) to determine whether to repeat the last block or proceed to the next.

**ASCII**—American National Standard Code for Information Interchange, a code consisting of seven information bits.

**AX.25**—Amateur packet-radio link-layer protocol. Copies of protocol specification are available from ARRL Hq.

**Backwave**—An unwanted signal emitted between the pulses of an on/off-keyed signal.

**Balanced**—A relationship in which two stations communicate with one another as equals; that is, neither is a primary (master) or secondary (slave).

**Baud**—A unit of signaling speed equal to the number of discrete conditions or events per second. (If the duration of a pulse is 20 ms, the signaling rate is 50 bauds or the reciprocal of 0.02, abbreviated Bd).

**Baudot code**—A coded character set in which five bits represent one character. Used in the US to refer to ITA2.

**Bell 103**—A 300-baud full-duplex modem using 200-Hz-shift FSK of tones centered at 1170 and 2125 Hz.

**Bell 202**—A 1200-baud modem standard with 1200-Hz mark, 2200-Hz space, used for VHF FM packet radio.

**BER**—Bit error rate.

**BERT**—Bit-error-rate test.

**Bit stuffing**—Insertion and deletion of 0s in a frame to preclude accidental occur-

rences of flags other than at the beginning and end of frames.

**Bit**—Binary digit, a single symbol, in binary terms either a one or zero.

**BLER**—Block error rate.

**BLERT**—Block-error-rate test.

**Break-in**—The ability to hear between elements or words of a keyed signal.

**Byte**—A group of bits, usually eight.

**Carrier detect (CD)**—Formally, received line signal detector, a physical-level interface signal that indicates that the receiver section of the modem is receiving tones from the distant modem.

**CCIR Rec 476-4**—The CCIR Recommendation used as the basis of AMTOR and incorporated by reference into the FCC Rules.

**CCIR**—International Radio Consultative Committee, an International Telecommunication Union (ITU) agency.

**CCITT**—International Telegraph and Telephone Consultative Committee, an ITU agency. CCIR and CCITT recommendations are available from the UN Bookstore.

**Chirp**—Incidental frequency modulation of a carrier as a result of oscillator instability during keying.

**Collision**—A condition that occurs when two or more transmissions occur at the same time and cause interference to the intended receivers.

**Connection**—A logical communication channel established between peer levels of two packet-radio stations.

**Contention**—A condition on a communications channel that occurs when two or

- more stations try to transmit at the same time.
- Control field**—An 8-bit pattern in an HDLC frame containing commands or responses, and sequence numbers.
- CRC**—Cyclic redundancy check, a mathematical operation. The result of the CRC is sent with a transmission block. The receiving station uses the received CRC to check transmitted data integrity.
- CSMA**—Carrier sense multiple access, a channel access arbitration scheme in which packet-radio stations listen on a channel for the presence of a carrier before transmitting a frame.
- CTS**—clear to send, a physical-level interface circuit generated by the DCE that, when on, indicates the DCE is ready to receive transmitted data (abbreviated CTS).
- Cut numbers**—In Morse code, shortening of codes sent for numerals.
- DARPA**—Defense Advanced Research Projects Agency; formerly ARPA, sponsors of ARPANET.
- Data set**—Modem.
- Datagram**—A mode of packet networking in which each packet contains complete addressing and control information. (compare virtual circuit).
- DCE**—Data circuit-terminating equipment, the equipment (for example, a modem) that provides communication between the DTE and the line radio equipment.
- Destination**—In packet radio, the station that is the intended receiver of the frame sent over a radio link either directly or via a repeater.
- Digipeater**—A link-level gateway station capable of repeating frames. The term “bridge” is used in industry.
- Domain**—In packet radio, the combination of a frequency and a geographical service area.
- DTE**—Data terminal equipment, for example a VDU or teleprinter.
- DXE**—In AX.25, Data switching equipment, a peer (neither master nor slave) station in balanced mode at the link layer.
- EASTNET**—A series of digipeaters along the US East Coast.
- EIA**—Electronic Industries Association.
- EIA-232-C**—An EIA standard physical-level interface between DTE (terminal) and DCE (modem), using 25-pin connectors.
- Envelope-delay distortion**—In a complex waveform, unequal propagation delay for different frequency components.
- Equalization**—Correction for amplitude-frequency and/or phase-frequency distortion.
- Eye pattern**—An oscilloscope display in the shape of one or more eyes for observing the shape of a serial digital stream and any impairments.
- FADCA**—Florida Amateur Digital Communications Association.
- FCS**—Frame check sequence. (See CRC.)
- FEC**—Forward error correction, an error-control technique in which the transmitted data is sufficiently redundant to permit the receiving station to correct some errors.
- Field**—In packet radio, at the link layer, a subdivision of a frame, consisting of one or more octets.
- Flag**—In packet switching, a link-level octet (01111110) used to initiate and terminate a frame.
- Frame**—In packet radio, a transmission block consisting of opening flag, address, control, information, frame-check-sequence and ending flag fields.
- FSK**—Frequency-shift keying.
- Gateway**—In packet radio, an interchange point.
- HDLC**—High-level data link control procedures as specified in ISO 3309.
- Host**—As used in packet radio, a computer with applications programs accessible by remote stations.
- IA5**—International Alphabet No. 5, a 7-bit coded character set, CCITT version of ASCII.
- Information field**—Any sequence of bits containing the intelligence to be conveyed.
- ISI**—Intersymbol interference; slurring of one symbol into the next as a result of multipath propagation.
- ISO**—International Organization for Standardization.
- ITA2**—International Telegraph Alphabet No. 2, a CCITT 5-bit coded character set commonly called the Baudot or Murray code.
- Jitter**—Unwanted variations in amplitude or phase in a digital signal.
- Key clicks**—Unwanted transients beyond the necessary bandwidth of a keyed radio signal.
- LAP**—Link access procedure, CCITT X.25 unbalanced-mode communications.
- LAPB**—Link access procedure, balanced, CCITT X.25 balanced-mode communications.
- Layer**—In communications protocols, one of the strata or levels in a reference model.
- Level 1**—Physical layer of the OSI reference model.
- Level 2**—Link layer of the OSI reference model.
- Level 3**—Network layer of the OSI reference model.
- Level 4**—Transport layer of the OSI reference model.
- Level 5**—Session layer of the OSI reference model.
- Level 6**—Presentation layer of the OSI reference model.
- Level 7**—Application layer of the OSI reference model.
- Loopback**—A test performed by connecting the output of a modulator to the input of a demodulator.
- LSB**—Least-significant bit.
- Mode A**—In AMTOR, an automatic repeat request (ARQ) transmission method.
- Mode B**—In AMTOR, a forward error correction (FEC) transmission method.
- Modem**—Modulator-demodulator, a device that connects between a data terminal and communication line (or radio). Also called data set.
- MSB**—Most-significant bit.
- MSK**—Frequency-shift keying where the shift in Hz is equal to half the signaling rate in bits per second.
- NAK**—Negative acknowledge (opposite of ACK).
- NAPLPS**—ANSI X3.110-1983 Videotex/Teletext Presentation Level protocol syntax.
- NBDP**—Narrow-band direct-printing telegraphy.
- NEPRA**—New England Packet Radio Association.
- Node**—A point within a network, usually where two or more links come together, performing switching, routine and concentrating functions.
- NRZI**—Nonreturn to zero. A binary baseband code in which output transitions result from data 0s but not from 1s. Formal designation is NRZ-S (non-return-to-zero—space).
- Null modem**—A device to interconnect two devices both wired as DCEs or DTEs; in EIA RS-232-C interfacing, back-to-back DB25 connectors with pin-for-pin connections except that Received Data (pin 3) on one connector is wired to Transmitted Data (pin 3) on the other.
- Octet**—A group of eight bits.
- OOK**—On-off keying.
- Originate**—The station initiating a call. In modem usage, the calling station or modem tones associated therewith.
- OSI-RM**—Open Systems Interconnection Reference Model specified in ISO 7498 and CCITT Rec X.200.
- Packet radio**—A digital communications technique involving radio transmission of short bursts (frames) of data containing addressing, control and error-checking information in each transmission.
- PACSAT**—AMSAT packet-radio satellite with store-and-forward capability.
- PAD**—Packet assembler/disassembler, a

device that assembles and disassembles packets (frames). It is connected between a data terminal (or computer) and a modem in a packet-radio station (see also TNC).

**Parity check**—Addition of noninformation bits to data, making the number of ones in a group of bits always either even or odd.

**PID**—Protocol identifier. Used in AX.25 to specify the network-layer protocol used.

**PPRS**—Pacific Packet Radio Society.

**Primary**—The master station in a master-slave relationship; the master maintains control and is able to perform actions that the slave cannot. (Compare secondary.)

**Protocol**—A formal set of rules and procedures for the exchange of information within a network.

**PSK**—Phase-shift keying.

**RAM**—Random access memory.

**Router**—A network packet switch. In packet radio, a network-level relay station capable of routing packets.

**RS-232-C**—See EIA-232-C.

**RTS**—Request to send, physical-level signal used to control the direction of data transmission of the local DCE.

**RTTY**—Radioteletype.

**RxD**—Received data, physical-level signals generated by the DCE are sent to

the DTE on this circuit.

**Secondary**—The slave in a master-slave relationship. Compare primary.

**SOFTNET**—An experimental packet-radio network at the University of Linköping, Sweden.

**Source**—In packet radio, the station transmitting the frame over a direct radio link or via a repeater.

**SOUTHNET**—A series of digipeaters along the US Southeast Coast.

**SSID**—Secondary station identifier. In AX.25 link-layer protocol, a multi-purpose octet to identify several packet-radio stations operating under the same call sign.

**TAPR**—Tucson Amateur Packet Radio Corporation, a nonprofit organization involved in packet-radio development.

**Teleport**—A radio station that acts as a relay between terrestrial radio stations and a communications satellite.

**TNC**—Terminal node controller, a device that assembles and disassembles packets (frames); sometimes called a PAD.

**TR switch**—Transmit-receive switch to allow automatic selection between receive and transmitter for one antenna.

**TTY**—Teletypewriter.

**TU**—Terminal unit, a radioteletype modem or demodulator.

**Turnaround time**—The time required to reverse the direction of a half-duplex circuit, required by propagation, modem

reversal and transmit-receive switching time of transceiver.

**TxD**—Transmitted data, physical-level data signals transferred on a circuit from the DTE to the DCE.

**UI**—Unnumbered information frame.

**V.24**—A CCITT standard defining physical-level interface circuits between a DTE (terminal) and DCE (modem), equivalent to EIA RS-232-C.

**V.28**—A CCITT standard defining electrical characteristics for V.24 interface.

**VADCG**—Vancouver Amateur Digital Communications Group.

**VDI**—Video-display terminal.

**VDU**—Video display unit, a device used to display data, usually provided with a keyboard for data entry.

**Videotex**—A presentation-layer protocol for two-way transmission of graphics.

**Virtual circuit**—A mode of packet networking in which a logical connection that emulates a point-to-point circuit is established (compare Datagram).

**WESTNET**—A series of digipeaters along the US West Coast.

**Window**—In packet radio at the link layer, the range of frame numbers within the control field used to set the maximum number of frames that the sender may transmit before it receives an acknowledgment from the receiver.

**X.25**—CCITT packet-switching protocol.

## ASCII

The American National Standard Code for Information Interchange (ASCII) is a coded character set used for information-processing systems, communications systems and related equipment. Current FCC regulations provide that amateur use of ASCII shall conform to ASCII as defined in ANSI Standard X3.4-1977. Its international counterparts are ISO 646-1983 and International Alphabet No. 5 (IA5) as specified in CCITT Rec V.3.

ASCII uses 7 bits to represent letters, figures, symbols and control characters. Unlike ITA2 (Baudot), ASCII has both upper- and lower-case letters. A table of ASCII characters is presented as "ASCII Character Set" in the **References** chapter.

In the international counterpart code, £ replaces #, and the international currency sign ¢ may replace \$ by agreement of the sender and recipient. Without such agree-

ment, neither £, ¢ nor \$ represent the currency of any particular country.

### Parity

While not strictly a part of the ASCII standard, an eighth bit (P) may be added for parity checking. FCC rules permit optional use of the parity bit. The applicable US and international standards (ANSI X3.16-1976; CCITT Rec V.4) recommend an even parity sense for asynchronous and odd parity sense for synchronous data communications. The standards, however, generally are not observed by hams.

### Code Extensions

By sacrificing parity, the eighth bit can be used to extend the ASCII 128-character code to 256 characters. Work is underway to produce an international standard that includes characters for all written languages.

## ASCII Serial Transmission

Serial transmission standards for ASCII (ANSI X3.15 and X3.16; CCITT Rec V.4 and X.4) specify that the bit sequence shall be least-significant bit (LSB) first to most-significant bit (MSB), that is b0 through b6 (plus the parity bit, P, if used).

Serial transmission may be either synchronous or asynchronous. In synchronous transmissions, only the information bits (and optional parity bit) are sent, as shown in **Fig 12.24A**.

Asynchronous serial transmission adds a start pulse and a stop pulse to each character. The start pulse length equals that of an information pulse. The stop pulse may be one or two bits long. There is some variation, but one stop bit is the convention, except for 110-baud transmissions with mechanical teletypewriters.

## ASCII-over-AMTOR

The superior weak signal performance of AMTOR, compared to RTTY and HF packet radio, has made it a popular mode for HF data networks. AMTOR BBS systems are popular for passing long-haul traffic. Traffic from VHF and UHF packet networks is converted into AMTOR (and more recently PACTOR and CLOVER) by specially equipped HF BBS stations. This system combines the best attributes of several different data transfer modes: The convenience and short-range high data rate of VHF/UHF packet is combined with the high reliability of AMTOR/PACTOR/CLOVER for long-range HF data transfer.

There was a problem with AMTOR relays, however. The CCIR-476 and CCIR-625 AMTOR symbol set has no lower-case letters and lacks many punctuation symbols common in VHF/UHF packet radio. Therefore, messages routed via AMTOR can differ from the original in format and appearance. Differences in the header text of AMTOR vs packet messages can be particularly troublesome to automated data-transfer systems.

In late 1991, G3PLX (Peter Martinez) and W5SMM (Vic Poor) devised an extended AMTOR character set that contains all of the printable ASCII symbols (ASCII control characters are not supported). Using this scheme, AMTOR-delivered messages are indistinguishable from those delivered via ASCII-based modes (such as packet radio). This "ASCII-over-AMTOR" system uses the generally unused "blank" character code ("00000" in Baudot, "1101010" in AMTOR) to toggle between the standard AMTOR character set and the new "Blank Code Extension" character set, which includes lower-case letters and ASCII punctuation symbols.

When two ASCII-over-AMTOR equipped stations first link, both controllers are set to the standard CCIR-476/

625 character set; upper-case letters are sent and the FIGS code (AMTOR "0110110") switches between letters and numbers. When the first "blank" character is sent, both stations switch to the new character set. Any following AMTOR letter codes are assumed to be lower-case letters and FIGS codes are translated into the new punctuation symbol set. A second instance of the "blank" code switches both stations back to the standard AMTOR character set. The expanded ASCII-over-AMTOR character set is shown in the Table.

The ASCII-over-AMTOR extended symbol set is supported by most commercially available AMTOR controllers and popular BBS software, such as APLINK and AMTOR MBO. The symbol set is backward compatible with stations that do not have the extended capability. A station that is not equipped with ASCII-over-AMTOR will notice very few differences when receiving these signals except that all letters will appear to be upper-case and the standard punctuation symbols will be printed.

The ASCII-over-AMTOR extension is remarkably efficient. If no nonBaudot characters are sent, there is no additional overhead to the transmission. Even if the extended set is sent, far fewer bits are transmitted than if ASCII were transmitted.

This technique, however, requires an error-correcting code such as AMTOR. The concept would not work with standard Baudot RTTY because a noise "hit" on a Blank character would result in printing from the wrong symbol set. The AMTOR error-correcting code is not infallible, but on-the-air use of ASCII-over-AMTOR has demonstrated that case-errors are very rare occurrences. The system works well and is in daily use by AMTOR BBS stations throughout the world.

Fig 12.24—Typical serial synchronous and asynchronous timing for the ASCII character S.

## ASCII Data Rates

Data-communication signaling rates depend largely on the medium and the state of the art when the equipment was selected. Numerous national and international standards that recommend different

data rates, are listed in Table 12.4. The most-used rates tend to progress in 2:1 steps from 300 to 9600 bits/s and in 8 kbits/s increments from 16 kbits/s upward (see Table 12.5). For Amateur Radio, serial ASCII transmissions data rates of 75, 110, 150, 300, 600, 1200, 2400, 4800, 9600,

16000, 19200 and 56000 bits/s are suggested.

## Bauds vs Bits Per Second

The "baud" is a unit of signaling speed equal to one discrete condition or event per second. In single-channel transmis-

## ASCII-over-AMTOR Blank-Code Extension Symbol Set

Bit Code	Standard CCIR-476		Blank Code Extension	
	Ltrs	Figs	Ltrs	Figs

1011100	SP	SP	SP	SP
1101010	BLNK	BLNK	BLNK	BLNK

CR = carriage return

LF = line feed

LTRS = shift to letter characters

FIGS = shift to figure characters

SP = space

BLNK = toggle between CCIR-476 and Blank Code Extension sets.

### Notes:

1. The logic state "1" represents the Mark or "Z" condition, the higher radiated radio frequency.
2. Certain FIGS-case symbols follow CCIR-476 and common European usage, differing from the "US TTY" symbols shown in the ITA2 Codes table in the **References** chapter. These differences are necessary to assure international compatibility.
3. The signal "BELL" is not supported because it is generally a nuisance to operation of otherwise silent automated message relay stations. If BELL is required, use FIGS-J in the Blank Extension set.

sion, such as the FCC prescribes for Baudot transmissions, the signaling rate in bauds equals the data rate in bits per second. However, the FCC does not limit ASCII to single-channel transmission. Some digital modulation systems have more than two (mark and space) states. In *dibit* (pronounced die-bit) modulation, two ASCII bits are sampled at a time. The four possible states for a dibit are 00, 01, 10 and 11. In four-phase modulation, each state is assigned an individual phase of 0°, 90°, 180° and 270° respectively. For dibit

phase modulation, the signaling speed in bauds is half the information-transfer rate in bits/s. As the FCC specifies the digital sending speed in bauds, amateurs may transmit ASCII at higher information rates by using digital modulation systems that encode more bits per signaling element. This technology is open for exploration by Amateur Radio experimenter. One such example is Clover II.

### Amateur ASCII RTTY Operations

On April 17, 1980 the FCC first permit-

ted ASCII in the Amateur Radio Service. US amateurs have been slow to abandon Baudot in favor of asynchronous serial ASCII.

One cause for resistance is the reasoning that asynchronous ASCII has two (or three with a parity bit added) more bits than asynchronous Baudot and is usually sent at higher speeds. Thus, it is felt that the greater data rates and increased bandwidth needed for ASCII would make its reliability less than that of Baudot. This is true as far as it goes, but does not exhaust the theoretical possibilities, which will be discussed below.

On the practical side, some amateurs tried ASCII on the air and experienced poor results. In some cases, this can be traced to the use of modems that were optimized for 45-baud operation. At 110 or 300 bauds, the 45-baud mark and space filters are too narrow.

On the HF bands, speeds above 50 or 75 bauds are subject to intersymbol interference (ISI, slurring one pulse into the next) from multipath propagation. Multiple paths can be avoided by operating at the maximum usable frequency (MUF), where there is only one ray path. The amount of multipath delay varies according to operating frequency with respect to the MUF and path distance. Paths in the 600- to 5000-mile range are generally less subject to multipath than shorter or longer ones. Paths of 250 miles or less are difficult from a multipath standpoint. As a result, successful operation at the higher ASCII speeds depends on using the highest frequency possible as well as having suitable modems at both ends of the circuit.

Returning to the theoretical comparison of Baudot and ASCII, recall that the FCC requires asynchronous (start-stop) transmission of Baudot. This means that the five information pulses must be sent with a start pulse and a stop pulse, usually of 1.42 times the length of the information pulse. Thus, an asynchronous Baudot transmitted character requires 7.42 units. In contrast, 7 bits of ASCII plus a parity bit, a start and a two-unit stop pulse has 11 units.

However, it is possible to send only the 7 ASCII information bits synchronously (without start and stop pulses), making the number of units that must be transmitted (7 vs 7.42) slightly smaller for ASCII than for Baudot. Or, it is possible to synchronously transmit 8 bits (7 ASCII bits plus a parity bit) and take advantage of the error-detection capability of parity. Also, there is nothing to prevent ASCII from being sent at a lower speed such as 50 or 75 bauds, to make it as immune to multipath as is 45- or 50-baud Baudot RTTY. So it is

**Table 12.4**  
**Data Transmission Signaling-Rate Standards**

Standard	Signaling Rates (bit/s)	Tolerance
<b>CCITT</b>		
V.5	600, 1200, 2400, 4800	± 0.01%

## AMTOR

RTTY circuits are plagued with problems of fading and noise unless something is done to mitigate these effects. Frequency, polarization and space diversity are methods of providing two or more simultaneous versions of the transmission to compare at the receiving station. Another method of getting more than one opportunity to see a given transmission is time diversity. The same signal sent at different times will experience different fading and noise conditions. Time diversity is the basis of AMTOR or Amateur Teleprinting Over Radio.

AMTOR always uses two forms of time diversity in either Mode A (ARQ, automatic repeat request) or Mode B (FEC, forward error correction). In Mode A, a repeat is sent only when requested by the receiving station. In Mode B, each character is sent twice. In both Mode A or Mode B, the second type of time diversity is supplied by the redundancy of the code itself.

Since 1983, AMTOR has been part of the US Amateur Radio rules. The rules recognize several documents that define AMTOR, from 476-2 (1978) to CCIR Rec 476-4 and Rec 625 (1986). Anyone interested in the design aspects of AMTOR should refer to these recommendations. You may obtain a complete reprint of Rec

**Table 12.5**  
**ASCII Asynchronous Signaling Rates**

Bits per Second	Data Pulse (ms)	Stop Pulse (ms)	CPS	WPM
110	9.091	18.182	10.0	100
150	6.667	6.667	15.0	150
300	3.333	3.333	30.0	300
600	1.667	1.667	60.0	600
1200	0.8333	0.8333	120	1200
2400	0.4167	0.4167	240	2400
4800	0.2083	0.2083	480	4800
9600	0.1041	0.1041	960	9600
19200	0.0520	0.0520	1920	19200

CPS = characters per second

$$= \frac{1}{\text{START} + 7(\text{DATA}) + \text{PARITY} + \text{STOP}}$$

$$\text{WPM} = \text{words per minute} = \frac{\text{CPS}}{6} \times 60$$

= number of 5-letter-plus-space groups per minute

easy to see that ASCII can be as reliable as Baudot RTTY, if care is used in system design.

While 45- or 50-baud RTTY circuits can provide reliable communications, this range of signaling speeds does not make full use of the HF medium. Speeds ranging from 75 to 1200 bauds can be achieved on HF with error-detection and error-correction techniques similar to those used in AMTOR. Reliable transmission at higher speeds can be accomplished by means of more sophisticated modes, which are described later in this chapter.

### Overview

AMTOR is based on SITOP, a system devised in the Maritime Mobile Service as a means of improving communications between RTTYs using the ITA2 (Baudot) code. The system converts the 5-bit code to a 7-bit code for transmission such that there are 4 mark and 3 space bits in every character (see the ITA2 and AMTOR Codes table in the **References** chapter).

The constant mark/space ratio limits the number of usable combinations to 35. ITA2 takes up 32 of the combinations; the 3 remaining are service information signals— $\alpha$ ,  $\beta$  and RQ in **Table 12.6**. The table also shows several other service signals that are borrowed from the 32 combinations that equate to ITA2. They are not confused with the message characters because they are sent only by the receiving station.

### Mode B (FEC)

When transmitting to no particular station (for example calling CQ, net operation or bulletin transmissions) there is no (one) receiving station to request repeats. Even if one station were selected, its ability to receive properly may not be representative of others desiring to copy the signal.

Mode B uses a simple forward-error-control (FEC) technique: it sends each character twice. Burst errors are virtually eliminated by delaying the repetition for a period thought to exceed the duration of most noise bursts. In AMTOR, groups of five characters are sent (DX) and then repeated (RX). At 70 ms per character, there is 280 ms between the first and second transmissions of a character.

The receiving station tests for the constant 4/3 mark/space ratio and prints only unmutated DX or RX characters. If both are mutilated, an error symbol or space prints.

The Information Sending Station (ISS) transmitter must be capable of 100% duty-cycle operation for Mode B. Thus, it may be necessary to reduce power level to 25% to 50% of full rating.

### Mode A (ARQ)

This synchronous system, transmits blocks of three characters from the Information Sending Station (ISS) to the Information Receiving Station (IRS). After each block, the IRS either acknowledges correct receipt (based on the 4/3 mark/space ratio), or requests a repeat. This cycle repeats as shown in **Fig 12.25**.

The station that initiates the ARQ protocol is known as the Master Station (MS).

The MS first sends the selective call of the called station in blocks of three characters, listening between blocks. Four-letter AMTOR calls are normally derived from the first character and the last three letters of the station call sign. For example, W1AW's AMTOR call would be WWAW. The Slave Station (SS) recognizes its selective call and answers that it is ready. The MS now becomes the ISS and will send traffic as soon as the IRS says it is ready.

When an ISS is done sending, it can enable the other station to become the ISS by sending the three-character sequence FIGS ZB. A station ends the contact by sending an "end of communication signal," three Idle Signal Alphas.

On the air, AMTOR Mode A signals have a characteristic "chirp-chirp" sound. Because of the 210/240-ms on/off timing, Mode A can be used with some transmitters at full power levels.

W1AW AMTOR Mode B transmissions following the Baudot and ASCII bulletins. A W1AW schedule appears in the **References** chapter.

## PACKET RADIO

*Data communications* is telecommunications between computers. *Packet switching* is a form of data communications that transfers data by subdividing it into "packets," and *packet radio* is packet switching using the medium of radio. This description was written by Steve Ford, WB8IMY.

Packet radio has its roots in the Hawaiian Islands, where the University of Hawaii began using the mode in 1970 to transfer data to its remote sites dispersed throughout the islands. Amateur packet radio began in Canada after the Canadian Department of Communications permitted amateurs to use the mode in 1978. (The FCC permitted amateur packet radio in the US in 1980.)

In the first half of the 1980s, packet radio was the habitat of experimenters and those few communicators who did not mind communicating with a limited number of potential fellow packet communicators. In the second half of the decade, packet radio "took off" as the experimenters built a network that increased the potential number of packet stations that could intercommunicate and thus attracted tens of thousands of communicators who wanted to take advantage of this potential. Today, packet radio is one of the most popular modes of Amateur Radio communications, because it is very effective.

It provides error-free data transfer. The receiving station receives information exactly as the transmitting station sends it, so you do not waste time deciphering communication errors caused by interference or changes in propagation.

It uses time efficiently, since packet bulletin-board systems (PBBSs) permit packet operators to store information for later retrieval by other amateurs.

It uses the radio spectrum efficiently, since one radio channel may be used for

multiple communications simultaneously or one radio channel may be used to interconnect a number of packet stations to form a "cluster" that provides for the distribution of information to all of the clustered stations. The popular *DX PacketClusters* are typical examples (see Fig 12.26).

Each local channel may be connected to other local channels to form a network that affords interstate and international data communications. This network can be used by interlinked packet bulletin-board systems to transfer information, messages and third-party traffic via HF, VHF, UHF and satellite links.

It uses other stations efficiently, since any packet-radio station can use one or more other packet-radio stations to relay data to its intended destination.

It uses current station transmitting and receiving equipment efficiently, since the same equipment used for voice communications may be used for packet communications. The outlay for the additional equipment necessary to make your voice station a packet-radio station may be as little as \$100. It also allows you to use that same equipment as an alternative to costly

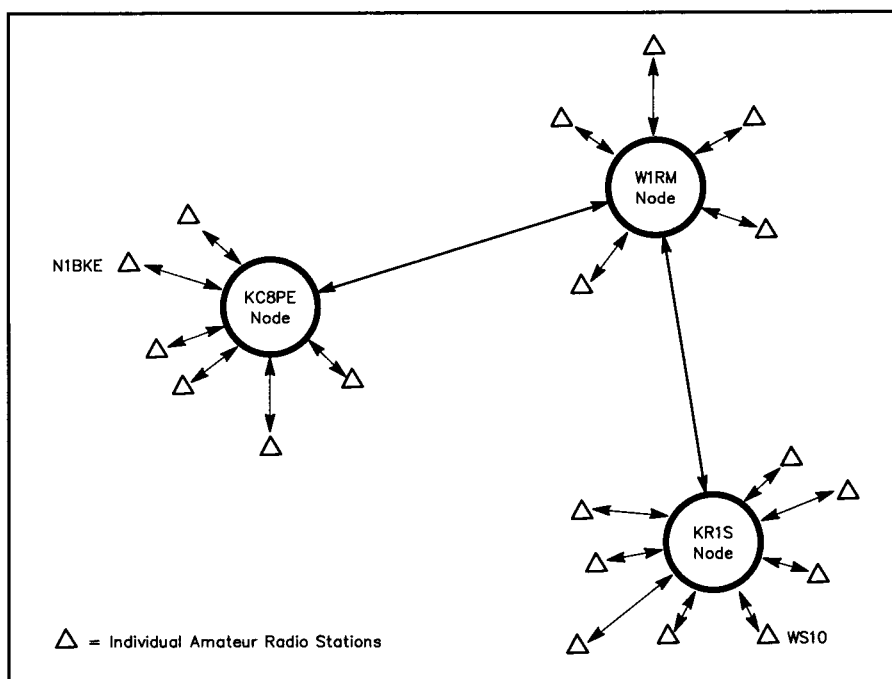

landline data communications links for transferring data between computers.

## The TNC

The terminal node controller—or *TNC*—is at the heart of every packet station. A TNC is actually a computer unto itself. It contains the AX.25 packet protocol firmware along with other enhancements depending on the manufacturer. The TNC communicates with you through your computer or data terminal. It also allows you to communicate with other hams by feeding packet data to your transceiver.

The TNCs accepts data from a computer or data terminal and assembles it into packets (see Fig 12.27). In addition, it translates the digital packet data into audio tones that can be fed to a transceiver. The TNC also functions as a receiving device, translating the audio tones into digital data a computer or terminal can understand. The part of the TNC that performs this tone-translating function is known as a *modem* (see Fig 12.28).

If you're saying to yourself, "These TNCs sound a lot like telephone modems," you're pretty close to the truth! The first

**Fig 12.26—*DX PacketClusters* are networks comprised of individual nodes and stations with an interest in DXing and contesting. In this example, N1BKE is connected to the KC8PE node. If he finds a DX station on the air, he'll post a notice—otherwise known as a *spot*—which the KC8PE node distributes to all its local stations. In addition, KC8PE passes the information along to the W1RM node. W1RM distributes the information and then passes it to the KR1S node, which does the same. Eventually, WS10—who is connected to the KR1S node—sees the spot on his screen. Depending on the size of the network, WS10 will receive the information within minutes after it was posted by N1BKE.**

Fig 12.27—The functional block diagram of a typical TNC.

Fig 12.28—A block diagram of a typical modem.

TNCs were based on telephone modem designs. If you're familiar with so-called *smart* modems, you'd find that TNCs are very similar.

You have plenty of TNCs to choose from. The amount of money you'll spend depends directly on what you want to accomplish. Most TNCs are designed to operate at 300 and 1200 bit/s, or 1200 bit/s exclusively (see Fig 12.29). There are also TNCs dedicated to 1200 and 9600 bit/s operation, or 9600 bit/s exclusively. Many of these TNCs include convenient features such as personal packet mailboxes where friends can leave messages when you're not at home. Some TNCs also include the ability to easily disconnect the existing modem and substitute another. This feature is very important if you wish to experiment at different data rates. For example, a 1200 bit/s TNC with a *modem disconnect header* can be converted to a 9600 bit/s TNC by disconnecting the 1200 bit/s modem and adding a 9600 bit/s modem.

If you're willing to spend more money, you can buy a complete *multimode communications processor*, or MCP. These devices not only offer packet, they also provide the capability to operate RTTY, CW, AMTOR, PACTOR, FAX and other modes. In other words, an MCP gives you just about every digital mode in one box.

#### TNC Emulation and Internal TNCs

In the late 1980s, a software package known as *DIGICOM>64* was developed

by a group of German amateurs. *DIGICOM>64* was designed to run on Commodore computers. It emulated most of the functions of a 1200 bit/s packet TNC and a terminal, requiring only a simple outboard modem to act as the interface to the transceiver. (The modem can be built for less than \$30.) *DIGICOM>64* was a boon to amateurs who were interested in packet, but who couldn't afford a full-featured TNC. Since its introduction, it has become very popular among Commodore users. While *DIGICOM>64* can't compete with TNCs when it comes to features and flexibility, it is more than adequate for general packet operating.

TNC-emulation systems also exist for IBM PCs and compatibles. One is known as *BayCom*. Like *DIGICOM>64*, *BayCom* uses the PC to emulate the functions of a TNC/terminal while a small external modem handles the interfacing. *BayCom* packages are available in kit form for roughly half the price of a basic TNC.

PC owners also have the option of buying full-featured TNCs that mount *inside* their computers. Several of these TNC *cards* are available from various manufacturers. They are complete TNCs that plug into card slots inside the computer cabinet. No TNC-to-computer cables are necessary. Connectors are provided for cables that attach to your transceiver. In many cases, specialized software is also provided for extremely efficient operation.

#### Transceiver Requirements

Packet activity on the HF bands typically takes place at 300 bit/s using common SSB transceivers. The transmit audio is fed from the TNC to the microphone jack or auxiliary audio input. Receive audio is obtained from the external speaker jack or auxiliary audio output. Tuning is critical for proper reception; a visual tuning indicator—available on some TNCs and all MCPs—is recommended.

These simple connections also work for 1200 bit/s packet, which is common on the VHF bands (2 m in particular). Almost any FM transceiver can be made to work with 1200 bit/s packet by connecting the transmit audio to the microphone jack and taking the receive audio from the external speaker (or earphone) jack.

At data rates beyond 1200 bit/s, transceiver requirements become more rigid. At 9600 bit/s (the most popular data rate above 1200 bit/s), the transmit audio must be injected at the modulator stage of the FM transceiver. Receive audio must be

Fig 12.29—Four popular 1200 bit/s packet TNCs: (clockwise, from left to right) the AEA PK-88, MFJ-1270C, DRSI DPK-2 and the Kantronics KPC-3.

tapped at the discriminator. Most 9600 bit/s operators use modified Amateur Radio transceivers or commercial radios. The Motorola *Mitrek* transceiver is a popular choice.

In the mid '90s amateur transceiver manufacturers began incorporating data ports on some FM voice rigs. The new "data-ready" radios are not without problems, however. Their IF filter and discriminator characteristics leave little room for error. If you're off frequency by a small amount, you may not be able to pass data. In addition, the ceramic discriminator coils used in some transceivers have poor group delay, making it impossible to tune them for wider bandwidths. With this in mind, some amateurs prefer to make the leap to 9600 bit/s and beyond using *dedicated* amateur data radios such as those manufactured by Tekk and Kantronics (see Address List in **References** chapter), among others.

Regardless of the transceiver used, setting the proper deviation level is extremely critical. At 9600 bit/s, for example, optimum performance occurs when the maximum deviation is maintained at 3 kHz. Deviation adjustments involve monitoring the transmitted signal with a deviation meter or service monitor. The output level of the TNC is adjusted until the proper deviation is achieved.

## Packet Networking

### Digipeaters

A digipeater is a packet-radio station

capable of recognizing and selectively repeating packet frames. An equivalent term used in industry is *bridge*. Virtually any TNC can be used as a single-port digipeater, because the digipeater function is included in the AX.25 Level 2 protocol firmware. Although the use of digipeaters is waning today as network nodes take their place, the digipeater function is handy when you need a relay and no node is available, or for on-the-air testing.

### NET/ROM

Ron Raikes, WA8DED, and Mike Busch, W6IXU, developed new firmware for the TNC 2 (and TNC-2 clones) that supports Levels 3 and 4, the Network and Transport layers of the packet-radio network. NET/ROM replaces the TNC-2 EPROM (that contains the TAPR TNC-2 firmware) and converts the TNC into a *network node controller (NNC)* for use at wide- and medium-coverage digipeater sites. Since it is so easy to convert an off-the-shelf TNC into an NNC via the NET/ROM route, NET/ROM has become the most popular network implementation in the packet-radio world and has been installed at most dedicated digipeater stations, thus propelling the standard AX.25 digipeater into packet-radio history.

The NET/ROM network user no longer has to be concerned with the digipeater path required to get from one point to another. All you need to know is the local node of the station you wish to contact. NET/ROM knows what path is required, and if one path

is not working or breaks down for some reason, NET/ROM will switch to an alternative path, if one exists. You can be assured that NET/ROM is on top of things, because each NET/ROM node automatically updates its node list periodically, and whenever a new node comes on the air, the other NET/ROM nodes become aware of the new node's existence. In addition to automatic route updating, routing information may also be updated manually by means of a terminal keyboard or remotely using a packet-radio connection.

Once you are connected to another station via the NET/ROM network, most of your packets get through because node-to-node packet acknowledgment is used rather than end-to-end acknowledgment. Besides offering node-to-node acknowledgment, NET/ROM also allows you to build cross-frequency or cross-band multiport nodes. This is done by installing NET/ROM in two TNCs and connecting their serial ports together. In addition to providing these sophisticated NNC functions, NET/ROM also provides the standard AX.25 digipeater function.

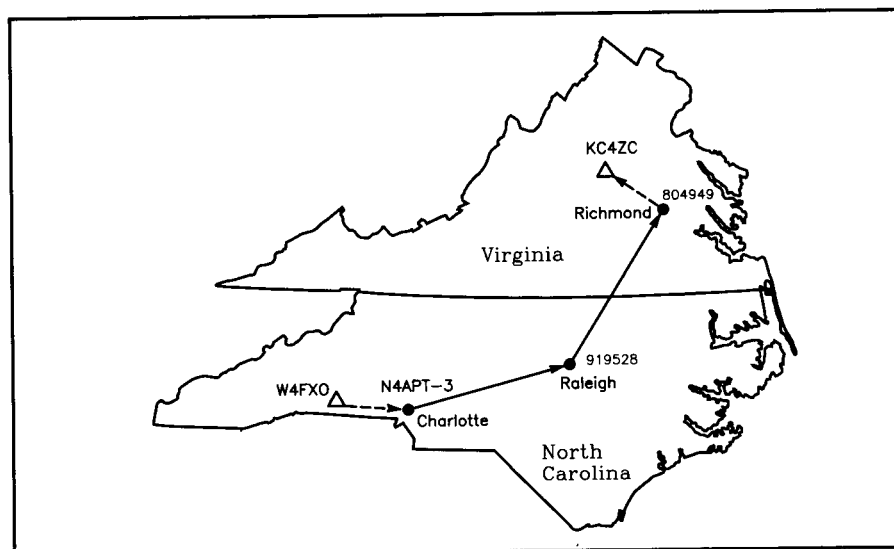

### ROSE

Several years ago, the Radio Amateur Telecommunications Society (RATS) developed a networking protocol known as *RATS Open System Environment*, or *ROSE*. Like networks based on NET/ROM nodes, the objective of ROSE is to let the network do the work when you're trying to connect to another station.

Using a ROSE network is similar to using the telephone. ROSE nodes are frequently referred to as *switches*, and each switch has its own address based on the telephone area code and the first 3 digits of the local exchange. A ROSE switch in one area of Connecticut, for example, may have an address of 203555. 203 is the area code and 555 is the local telephone exchange. The ROSE network uses this addressing system to create reliable routes for packets (see **Fig 12.30**).

Unless you wish to set up a ROSE switch of your own, you won't need special equipment or software to use the network. You can access a ROSE network today if a switch is available in your area. All you need to know is the call sign of your local switch and the ROSE address of the switch nearest to any stations to want to contact.

ROSE networks are appearing in many areas of the country. They are especially popular in the southeast and midAtlantic states. ROSE addresses and system maps are available from RATS (see **References** chapter Address List). Send a business-sized SASE with your request.

**Fig 12.30**—In this hypothetical example, W4FXO, near Charlotte, North Carolina, uses the ROSE network to establish a connection to KC4ZC northwest of Richmond, Virginia. All that W4FXO has to do is issue a connect request that includes his local ROSE switch (N4APT-3) and the ROSE address of the switch nearest KC4ZC (804949). When the request is sent, the network takes over. In this example, the connection to KC4ZC is established by using a ROSE switch in Raleigh.

## TexNet

TexNet is a high speed, centralized packet networking system developed by the Texas Packet Radio Society (TPRS). Designed for local and regional use, TexNet provides AX.25-compatible access on the 2-m band at 1200 bit/s. This allows packeteers to use TexNet without investing in additional equipment or software. The node-to-node backbones operate in the 70-cm band with data moving through the network at 9600 bit/s. Telephone links are also used to bridge some gaps in the system.

The network offers a number of services to its users. Two conference levels are available by simply connecting to the proper node according to its SSID. By connecting to W5YR-2, for example, you'll join the first conference level. Connecting to W5YR-3 places you in the second level. When you connect to a conference, you can chat with anyone else on the network in roundtable fashion.

Every TexNet network is served by a single PBBS. By using only one PBBS, the network isn't bogged down with constant mail forwarding. Even if you're some distance from the PBBS, with the speed and efficiency of TexNet you'll hardly notice the delay.

## TCP/IP

If you're an active packeteer, sooner or later someone will bring up the subject of TCP/IP—Transmission Control Protocol/Internet Protocol. Of all the packet networking alternatives discussed so far, TCP/IP is the most popular. In fact, many packeteers believe that TCP/IP may someday become the standard for amateur packet radio.

Despite its name, TCP/IP is more than two protocols; it's actually a set of several protocols. Together they provide a high level of flexible, "intelligent" packet networking. At the time of this writing, TCP/IP networks are local and regional in nature. For long-distance mail handling, TCP/IP still relies on traditional AX.25 *NET/ROM* networks. Even so, TCP/IP enthusiasts see a future when the entire nation, and perhaps the world, will be linked by high-speed TCP/IP systems using terrestrial microwave and satellites.

Maintaining a packet connection on a *NET/ROM* network can be a difficult proposition—especially if the station is distant. You can only hope that all the nodes in the path are able to relay the packets back and forth. If the one of the nodes becomes unusually busy, your link to the other station could collapse. Even when the path is maintained, your packets are in direct competition with all the other pack-

ets on the network. With randomly calculated transmission delays, collisions are inevitable. As a result, the network bogs down, slowing data throughput for everyone.

TCP/IP has a unique solution for busy networks. Rather than transmitting packets at randomly determined intervals, TCP/IP stations automatically *adapt* to network delays as they occur. As network throughput slows down, active TCP/IP stations sense the change and lengthen their transmission delays accordingly. As the network speeds up, the TCP/IP stations shorten their delays to match the pace. This kind of intelligent network sharing virtually guarantees that all packets will reach their destinations with the greatest efficiency the network can provide.

With TCP/IP's adaptive networking scheme, you can chat using the *telnet* protocol with a ham in a distant city and rest assured that you're not overburdening the system. Your packets simply join the constantly moving "freeway" of data. They might slow down in heavy traffic, but they *will* reach their destination eventually. (This adaptive system is used for *all* TCP/IP packets, no matter what they contain.)

TCP/IP excels when it comes to transferring files from one station to another. By using the TCP/IP *file transfer protocol* (ftp), you can connect to another station and transfer computer files—including software. As you can probably guess, transferring large files can take time. With TCP/IP, however, you can still send and receive mail (using the *SMTP* protocol) or talk to another ham *while* the transfer is taking place.

When you attempt to contact another station using TCP/IP, all network routing is performed automatically according to the TCP/IP address of the station you're trying to reach. In fact, TCP/IP networks are transparent to the average user.

On conventional *NET/ROM* networks, access to backbone links is restricted. This isn't true on TCP/IP. Not only are you allowed to use the backbones, you're actually *encouraged* to do so. If you have the necessary equipment to communicate at the proper frequencies and data rates, you can tap into the high-speed TCP/IP backbones directly. By doing so, you'll be able to handle data at much higher rates. This benefits you and everyone else on the network.

To operate TCP/IP, all you need is a computer (it must be a computer, not a terminal), a 2-m FM transceiver and a TNC with *KISS* capability. As you might guess, the heart of your TCP/IP setup is software. The TCP/IP software set was written by Phil Karn, KA9Q, and is called *NOSNET* or just *NOS*.

There are dozens of *NOS* derivatives available today. All are based on the original *NOSNET*. The programs are available primarily for IBM-PCs and compatibles and Macintoshes. You can obtain *NOS* software from on-line sources such as the CompuServe *HAMNET* forum libraries, Internet ftp sites, Amateur Radio-oriented BBSs and elsewhere. *NOS* takes care of all TCP/IP functions, using your "KISSable" TNC to communicate with the outside world. The only other item you need is your own IP address. Individual IP Address Coordinators assign addresses to new TCP/IP users.

## PACTOR

PACTOR (PT) is an HF radio transmission system developed by German amateurs Hans-Peter Helfert, DL6MAA, and Ulrich Strate, DF4KV. It combines the best of AMTOR and packet to make a system that is superior to both. This description was adapted from PACTOR specifications by the *Handbook* Editor. PACTOR is much faster than AMTOR, yet improves on AMTOR's error-correction scheme. It performs well under both weak-signal and high-noise conditions. PACTOR/AMTOR BBS stations operating in the US and other countries are used by amateurs all over the world. The BBSs respond automatically to both PACTOR and AMTOR calls. PACTOR carries binary data, so it can transfer binary files, ASCII and other symbol sets.

Packet-radio style CRCs (two per packet, 16 bits each) and "ARQ Memory" enable the PT system to reconstruct defective packets by overlaying good and damaged data from different transmissions, which reduces repeats and transmission time. PT's overhead is much less than that of AMTOR. PACTOR uses complete call signs for addressing. The mark/space convention is unnecessary and frequency-shift independent.

## Transmission Formats Information Blocks

All packets have the basic structure shown in **Fig 12.31**, and their timing is as shown in **Table 12.7**:

**Header:** contains a fixed bit pattern to simplify repeat requests, synchronization and monitoring. The header is also important for the Memory ARQ function. In each packet carrying new information the bit pattern is inverted.

**Data:** any binary information. The format is specified in the status word. Current choices are 8-bit ASCII or 7-bit ASCII (with Huffman encoding). Characters are

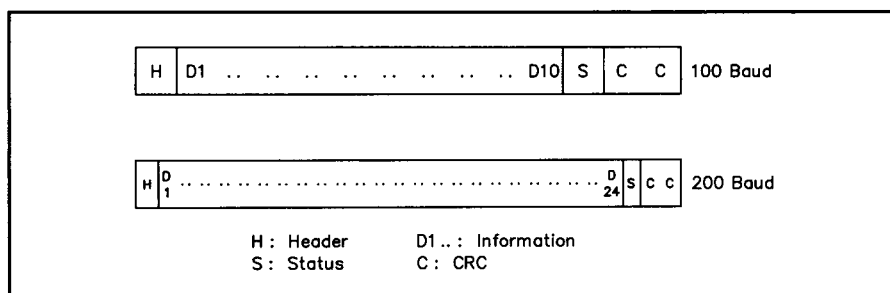

Fig 12.31—PACTOR data packet format.

Table 12.7

**PACTOR Timing**

Object	Length (seconds)
Packet	0.96 (200 bd: 192 bits; 100 bd: 96 bits)
CS receive time	0.29
Control signals	0.12 (12 bits at 10 ms each)
Propagation delay	0.17
Cycle	1.25

Table 12.8

**PACTOR Status Word**

Bit	Meaning
0	Packet count (LSB)
1	Packet count (MSB)
2	Data format (LSB)
3	Data format (MSB)
4	Not defined
5	Not defined
6	Break-in request
7	QRT request

**Data Format Bits**

Format	bit 3	bit 2
ASCII 8 bit	0	0
Huffman code	0	1
Not defined	1	0
Not defined	1	1

Bits 0 and 1 are used as a packet count; successive packets with the same value are identified by the receiver as repeat packets. A modulus-4 count helps with unrecognized control signals, which are unlikely in practice.

not broken across packets. ASCII RS (hex 1E) is used as an IDLE character in both formats.

*Status word:* see **Table 12.8**

*CRC:* The CRC is calculated according to the CCITT standard, for the data, status and CRC.

**Acknowledgment Signals**

The PACTOR acknowledgment signals are similar to those used in AMTOR, except for CS4 (see **Table 12.9**). Each of the signals is 12 bits long. The characters differ in pairs in 8 bits (Hamming offset) so that the chance of confusion is reduced. (One of the most common causes of errors in AMTOR is the small CS Hamming offset of 4 bits.)

If the CS is not correctly received, the TX reacts by repeating the last packet. The request status can be uniquely recognized by the 2-bit packet number so that wasteful transmissions of pure RQ blocks are unnecessary.

Table 12.10

**PACTOR Initial Contact**

**Master Initiating Contact**

Size (bytes)	1	8	8
Content	/Header/SLAVECAL/SLAVECAL/		
Speed (bauds)	100	100	200

**Slave Response**

The receiving station detects a call, determines mark/space polarity, decodes 100-bd and 200-bd call signs. It uses the two call signs to determine if it is being called and the quality of the communication path. The possible responses are:

First call sign does not match slave's (Master not calling this slave)	none
Only first call sign matches slave's (Master calling this slave, poor communications)	CS1
First and second call signs both match the slaves (good circuit, request speed change to 200 bd)	CS4

**Timing**

The receiver pause between two blocks is 0.29 s. After deducting the CS lengths, 0.17 s remain (just as in AMTOR) for switching and propagation delays so that there is adequate reserve for DX operation.

**Contact Flow**

**Listening**

In the listen mode, the receiver scans any received packets for a CRC match. This method uses a lot of computer processing resources, but it's flexible.

**CQ**

A station seeking contacts transmits CQ packets in a FEC mode, without pauses for acknowledgment between packets. The transmit time length number of repetitions and speed are the transmit operator's choice. (This mode is also suitable for bulletins and other group traffic.) Once a listening station has copied the call, the listener assumes the TX station role and initiates a contact. Thus, the station sending CQ initially takes the RX station role. The contact begins as shown in **Table 12.10**

**Speed Changes**

With good conditions, PT's normal signaling rate is 200 baud (for a 600-Hz bandwidth), but the system automatically changes from 200 to 100 baud and back, as conditions demand. In addition, Huffman coding can further increase the throughput by a factor of 1.7. There is no loss of synchronization speed changes; only one

Table 12.9

**PACTOR Control Signals**

Code	Chars (hex)	Function
CS1	4D5	Normal acknowledge
CS2	AB2	Normal acknowledge
CS3	34B	Break-in (forms header of first packet from RX to TX)
CS4	D2C	Speed change request

All control signals are sent only from RX to TX.

packet is repeated.

When the RX receives a bad 200-baud packet, it can acknowledge with CS4. TX immediately assembles the previous packet in 100-baud format and sends it. Thus, one packet is repeated in a change from 200 to 100 baud.

The RX can acknowledge a good 100-baud packet with CS4. TX immediately switches to 200 baud and sends the

next packet. There is no packet repeat in an upward speed change.

### *Change of Direction*

The RX station can become the TX station by sending a special change-over packet in response to a valid packet. RX sends CS3 as the first section of the changeover packet. This immediately changes the TX station to RX mode to read

the data in that packet and responds with CS1 and CS3 (acknowledge) or CS2 (reject).

### *End of Contact*

PACTOR provides a sure end-of-contact procedure. TX initiates the end of contact by sending a special packet with the QRT bit set in the status word and the call of the RX station in byte-reverse order at 100 baud. The RX station responds with a final CS.

## **PACTOR II**

This new protocol is a significant improvement over PACTOR; yet it is fully compatible with the older mode. Invented in Germany, PACTOR uses 16PSK to transfer up to 800 bits/s at a 100-baud rate. This keeps the bandwidth less than 500 Hz. Users believe that PACTOR II is faster and more robust than CLOVER.

PACTOR II uses a DSP with Nyquist waveforms, Huffman and Markov compression, and powerful Viterbi decoding to increase transfer rate and sensitivity into the noise level. The effective transfer rate of text is over 1200 bits/s. Features of PACTOR II include:

- Frequency agility—It can automatically adjust or lock two signals together over a  $\pm 100$ -Hz window.

- Powerful data reconstruction based upon computer power—with over 2 MB of available memory.
- Cross correlation—applies analog Memory ARQ to acknowledgment frames and headers.
- Soft decision making—Uses artificial intelligence (AI) as well as digital information received to determine frame validity.
- Extended data block length—When transferring large files under good conditions, the data length is doubled to increase the transfer rate.
- Automatic recognition of PACTOR I, PACTOR II and so on, with automatic mode switching.

- Intermodulation products are canceled by the coding system.
- Two long-path modes extend frame timing for long-path terrestrial and satellite propagation paths.

This is a fast, robust mode—possibly the most powerful in the ham bands. It has excellent coding gain as well. It can also communicate with all earlier PACTOR I systems. Like packet and AMTOR stations, PACTOR II stations acknowledge each received data block. Unlike those modes, PACTOR II employs computer logic as well as received data to reassemble defective data blocks into good frames. This reduces the number of transmissions and increases the throughput of the data.

## **G-TOR**

This brief description has been adapted from "A Hybrid ARQ Protocol for Narrow Bandwidth HF Data Communication" by Glenn Prescott, WBØSKX, Phil Anderson, WØXI, Mike Huslig, KBØNYK, and Karl Medcalf, WK5M (May 1994 *QEX*, pp 12-19).

G-TOR is short for Golay-TOR, an innovation of Kantronics, Inc. It's a new HF digital-communication mode for the Amateur Service. G-TOR was inspired by HF Automatic Link Establishment (ALE) concepts and is structured to be compatible with ALE systems when they become available.

The purpose of the G-TOR protocol is to provide an improved digital radio communication capability for the HF bands. The key features of G-TOR are:

- Standard FSK tone pairs (mark and space)
- Link-quality-based signaling rate: 300, 200 or 100 baud
- 2.4-s transmission cycle
- Low overhead within data frames
- Huffman data compression—two types, on demand
- Embedded run-length data compression
- Golay forward-error-correction coding

- Full-frame data interleaving
- CRC error detection with hybrid ARQ
- Error-tolerant "Fuzzy" acknowledgments

The primary benefit of these innovations is increased throughput—that is, more bits communicated in less time. This is achieved because the advanced processing features of G-TOR provide increased resistance to interference and noise and greatly reduce multipath-induced data errors.

The G-TOR protocol is straightforward and relatively easy to implement on existing multimode TNCs. (In early 1995, G-TOR is available in the Kantronics KAM Plus only. G-TOR equipped MFJ 1278s should be available later in 1995.)

### **Propagation Problems**

The miserable propagation conditions characteristic of the HF bands make effective data communication a nightmare. Received signals are often weak and subject to multipath fading; ever-present interference can impair reception. With digital communication, the human brain cannot help interpret the signal. Therefore, we need to incorporate great ingenuity into

the receiving system. G-TOR uses modern communication signal processing to help us transmit error-free data via the inherently poor HF communication medium.

Worldwide HF communication may experience interference, multipath fading, random and burst noise. For data communication over the HF bands, three factors dominate: available bandwidth, signaling rate and the dynamic time behavior of the channel.

### **... and Answers**

Transmission bandwidths of 500 Hz or less minimize the effects of multipath propagation and man-made interference. G-TOR transmits at 300 baud or less, with maximum separation of 200 Hz, for a bandwidth just slightly greater than 500 Hz.

The FCC does not currently permit symbol rates greater than 300 symbols per second (baud) on most HF bands. This is a reasonable limit because multipath propagation can become a serious problem with faster rates.

The HF channel has a characteristic dynamic time behavior: Conditions can change significantly in a few seconds. This

indicates an optimum data-transmission length (usually 1 s or less). G-TOR transmissions are nearly 2 s long because the signal-processing techniques can overcome some propagation change.

## The G-TOR Protocol

Since one of the objectives of this protocol is ease of implementation in existing TNCs, the modulation format consists of standard tone pairs (FSK), operating at 300, 200 or 100 baud, depending upon channel conditions. (G-TOR initiates contacts and sends ACKs only at 100 baud.) FSK was chosen for economy and simplicity, but primarily because many hams already have FSK equipment.

The G-TOR waveform consists of two phase-continuous tones (BFSK) spaced 200 Hz apart (mark = 1600 Hz, space = 1800 Hz); however, the system can still operate at the familiar 170-Hz shift (mark = 2125 Hz, space = 2295 Hz), or with any other convenient tone pairs. The optimum spacing for 300-baud transmission is 300 Hz, but we trade some performance for a narrower bandwidth.

Each transmission consists of a synchronous ARQ 1.92-s frame and a 0.48-s interval for propagation and ACK transmissions (2.4 s cycle). All advanced protocol features are implemented in the signal-processing software.

Synchronous operation increases the system throughput during multipath fading and keeps overhead to a minimum. Synchronization is performed using the received data and precise timing.

## Frame Structures

**Data Frames**—The basic G-TOR frame structure (see Fig 12.32) uses multiple 24-bit (triple-byte) words for compatibility with the Golay encoder. Data frames are composed of 72 (300 baud), 48 (200 baud) or 24 (100 baud) data bytes, depending upon channel conditions.

A single byte before the CRC carries command and status information:

- status bits 7 and 6: Command
  - 00 - data
  - 01 - turnaround request
  - 10 - disconnect
  - 11 - connect
- status bits 5 and 4: Unused
  - 00 - reserved
- status bits 3 and 2: Compression
  - 00 - none
  - 01 - Huffman (A)
  - 10 - Huffman (B)
  - 11 - reserved
- status bits 1 and 0: Frame no. ID

The error-detection code transmitted with each frame is a 2-byte cyclic redundancy check (CRC) code—the same used

in AX.25. A CRC calculation determines if error correction is needed, and another tests the result.

The connect and disconnect frames are essentially identical in structure to the data frame and contain the call signs of both stations.

**ACK Frames**—G-TOR ACK frames are not interleaved and do not contain error-correction (parity) bits. There are five different ACK frames:

- Frame received correctly (send next data frame)
- Frame error detected (please repeat)
- Speed-up
- Speed-down
- Changeover

The ACK codes are composed of multiple cyclic shifts of a single 15-bit pseudorandom noise (PN) sequence (plus an extra 0 bit to fill 16 bits). PN sequences have powerful properties that facilitate identification of the appropriate ACK code, even in the presence of noise and interference. We refer to this concept as a “fuzzy” ACK, in that it tolerates 3 bit errors within a received ACK frame.

**Change-over frames** are essentially data frames in which the first 16 bits of data is the ACK changeover PN code.

## Data Compression

Data compression is used to remove redundancy from source data. Therefore, fewer bits are needed to convey any given message. This increases data throughput and decreases transmission time—valuable features for HF. G-TOR uses run-length coding and two types of Huffman coding during normal text transmissions. Run-length coding is used when more than two repetitions of an 8-bit character are sent. It provides an especially large savings in total transmission time when repeated characters are being transferred.

The Huffman code works best when the statistics of the data are known. G-TOR applies Huffman A coding with the upper-

and lower-case character set, and Huffman B coding with upper-case-only text. Either type of Huffman code reduces the average number of bits sent per character. In some situations, however, there is no benefit from Huffman coding. The encoding process is then disabled. This decision is made on a frame-by-frame basis by the information-sending station.

## Golay Coding

The real power of G-TOR resides in the properties of the (24,12) extended Golay error-correcting code, which permits correction of up to three random errors in three received bytes. The (24,12) extended Golay code is a half-rate error-correcting code: Each 12 data bits are translated into an additional 12 parity bits (24 bits total). Further, the code can be implemented to produce separate input-data and parity-bit frames.

The extended Golay code is used for G-TOR because the encoder and decoder are simple to implement in software. Also, Golay code has mathematical properties that make it an ideal choice for short-cycle synchronous communication:

- The rare property of self-duality makes the code “invertible”; that is, the original data can be recovered by simply recoding the parity bits.
- Because of the linear block code structure of the Golay code, the encoder and decoder can be implemented using a simple table look-up procedure. An alternative decoder implementation uses the well-known Kasami decoding algorithm, which requires far less memory than the look-up table.

Error-correction coding inserts some redundancy into each (triple-byte) word so that errors occurring in the receiving process can be corrected. However, most error-correcting codes are effective at correcting only random errors. Burst errors from lightning or interference exceed the capabilities of most error-correcting codes.

**Fig 12.32—G-TOR ARQ system timing and frame structure before interleaving. The data portion may be 69 (300 baud), 45 (200 baud) or 21 (100 baud) bytes depending on the channel quality.**

## Interleaving

The conventional solution is called “interleaving.” Interleaving (the very last operation performed before transmission and first performed upon reception) rearranges the bit order to randomize the effects of long error bursts.

The interleaving process reads 12-bit words into registers by columns and reads 48-bit words out by rows; see Fig 12.33. The deinterleaver simply performs the inverse, reading the received data bits into the registers by row and extracting the original data sequence by reading the columns. If a long burst of errors occurs—say, 12 bits in length—the errors will be distributed into 48 separate 12-bit words before error correction is applied, thus effectively nullifying the long burst. Both data and parity frames are completely interleaved.

## Hybrid ARQ

G-TOR combines error detection and forward error correction with ARQ. Hybrid-ARQ uses a CRC to check for errors in every frame. Only when errors are found; does G-TOR use forward error correction (a relatively slow process) to recover the data.

The half-rate invertible Golay code provides an interesting dimension to the hybrid-ARQ procedure. With separate data and parity frames, both of which can supply the complete data, G-TOR frames al-

ternate between data and parity frames.

When the receiver detects an error and requests a retransmission, the sending station sends the complementary portion of the frame (data or parity).

When the complementary frame arrives, it is processed and checked for errors. If it checks, the data is accepted and a new frame is requested. If it fails the CRC check, the two frames are combined, corrected and checked.

Using this scheme, two transmissions provide three independent chances to correct any errors. If this process still fails, a retransmission is requested.

## G-TOR Performance

Initial testing with G-TOR was conducted during January 1994, between Lawrence, Kansas, and Laguna Niguel, California. During these tests, TRACE was set ON at each station, enabling the raw data display of frames received with and without the aid of forward error correction and interleaving. The results were somewhat surprising. While PACTOR often dropped in transmission speed from 200 to 100 bauds, G-TOR nearly always operated at 300 bauds. Enough frames were corrected to keep the system running at maximum speed, regardless of man-made interference and mild multipath conditions. Transfer duration for the entire test files varied from 12 to 27 minutes for PACTOR, but only 5.5 to 7.5 minutes for

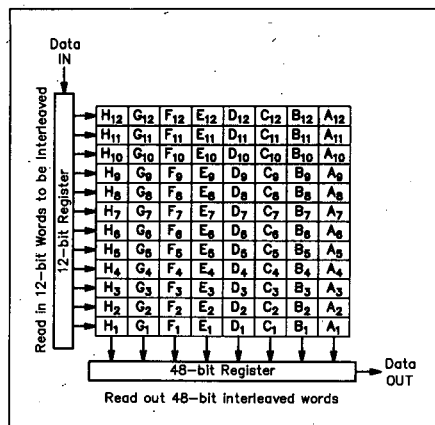

Fig 12.33—Interleaving the bits to be transmitted.

all but one G-TOR transfer. G-TOR simply maintained its highest pace better than PACTOR, resulting in a substantial increase in average throughput.

On-air tests have shown G-TOR to have the ability to “hang in there” when channel conditions get tough. The time required to send a given binary file tends to be much less for G-TOR than for PACTOR.

This protocol should continue to be valuable when DSP-based TNCs become widely available. G-TOR has the essential characteristics to be a useful protocol for years to come.

## CLOVER-II

The desire to send data via HF radio at high data rates and the problems encountered when using AX.25 packet radio on HF radio led Ray Petit, W7GHM, to develop a unique modulation waveform and data transfer protocol that is now called “CLOVER-II.” Bill Henry, K9GWT, supplied this description of the Clover-II system. CLOVER modulation is characterized by the following key parameters:

- Very low base symbol rate: 31.25 symbols/second (all modes).
- Time-sequence of amplitude-shaped pulses to provide a very narrow frequency spectra. Occupied bandwidth = 500 Hz at 50 dB below peak output level.
- Differential modulation between pulses.

## Multilevel modulation.

The low base symbol rate is very resistant to multipath distortion because the time between modulation transitions is much longer than even the worst-case time-smearing caused by summing of multipath signals. By using a time-sequence of tone pulses, Dolph-Chebychev “windowing” of the modulating signal and differential modulation, the total occupied bandwidth of a CLOVER-II signal is held to 500 Hz.

## The CLOVER Waveform

Multilevel tone, phase and amplitude modulation give CLOVER a large selection of data modes that may be used (see Table 12.11). The adaptive ARQ mode of

CLOVER senses current ionosphere conditions and automatically adjusts the modulation mode to produce maximum data throughput. When using the “Fast” bias setting, ARQ throughput automatically varies from 11.6 bytes/s (1.7 times AMTOR) to 70 bytes/s (10.5 times AMTOR).

The CLOVER-II waveform uses four tone pulses that are spaced in frequency by 125 Hz. The time and frequency domain characteristics of CLOVER modulation are shown in Figs 12.34, 12.35 and 12.36. The time-domain shape of each tone pulse is intentionally shaped to produce a very compact frequency spectra. The four tone pulses are spaced in time and then combined to produce the composite output

**Table 12.11**

**CLOVER-II Modulation Modes**

As presently implemented, CLOVER-II supports a total of 7 different modulation formats: 5 using PSM and 2 using a combination of PSM and ASM (Amplitude Shift Modulation).

Name	Description	In-Block Data Rate
16P4A	16 PSM, 4-ASM	750 bps
16PSM	16 PSM	500 bps
8P2A	8 PSM, 2-ASM	500 bps
8PSM	8 PSM	375 bps
QPSM	4 PSM	250 bps
BPSM	Binary PSM	125 bps
2DPSM	2-Channel Diversity BPSM	62.5 bps

**Fig 12.35—A frequency-domain plot of a CLOVER-II waveform.**

**Table 12.12**

**Data Bytes Transmitted Per Block**

Block Size	Reed-Solomon Encoder Efficiency 60%	75%	90%	100%
17	8	10	12	14
51	28	36	42	48
85	48	60	74	82
255	150	188	226	252

**Table 12.13**

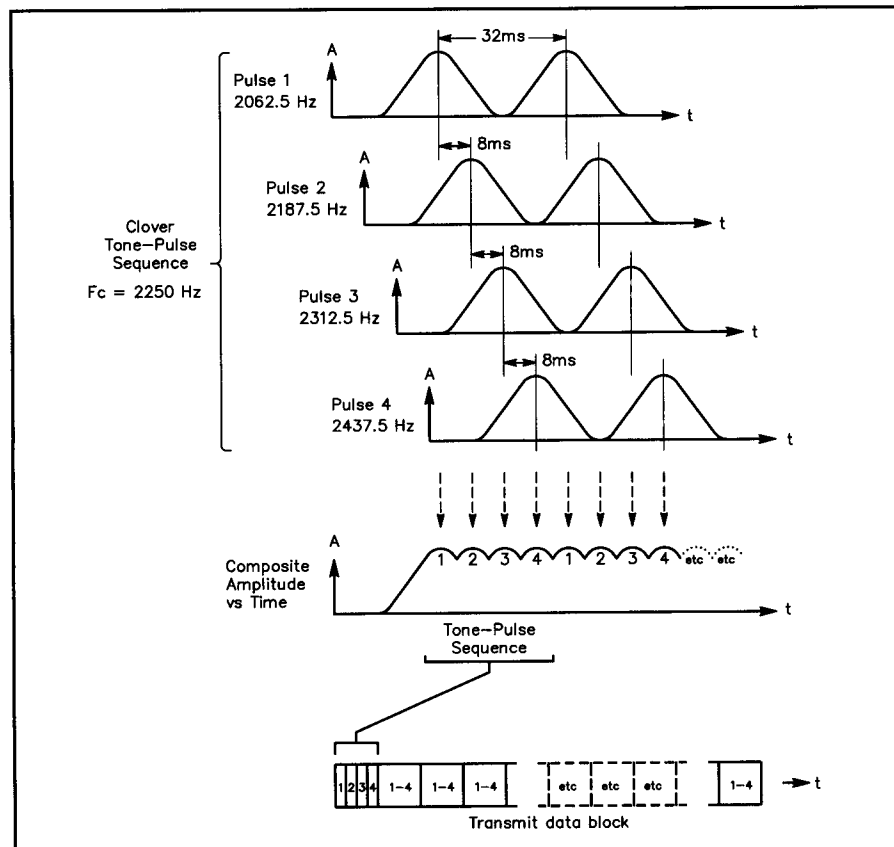

**Correctable Byte Errors Per Block**

Block Size	Reed-Solomon Encoder Efficiency 60%	75%	90%	100%
17	1	1	0	0
51	9	5	2	0
85	16	10	3	0
255	50	31	12	0

the lowest net data throughput. “100% efficiency” turns the encoder off and has the highest throughput but fixes no errors. There is therefore a tradeoff between raw data throughput vs the number of errors that can be corrected without resorting to retransmission of the entire data block.

Note that while the “In Block Data Rate” numbers listed in the table go as high as 750 bps, overhead reduces the net throughput or overall efficiency of a CLOVER transmission. The FEC coder efficiency setting and protocol requirements of FEC and ARQ modes add overhead and reduce the net efficiency.

**Table 12.12** and **Table 12.13** detail the relationships between block size, coder efficiency, data bytes per block and correctable byte errors per block.

**Fig 12.34—Amplitude vs time plots for CLOVER-II's four-tone waveform.**

shown. Unlike other modulation schemes, the CLOVER modulation spectra is the same for all modulation modes.

**Modulation**

Data is modulated on a CLOVER-II signal by varying the phase and/or amplitude of the tone pulses. Further, all data modulation is differential on the same tone pulse; data is represented by the phase (or amplitude) difference from one pulse to the next. For example, when binary phase modulation is used, a data change from “0” to “1” may be represented by a change in the phase of tone pulse 1 by 180° between the first and second occurrence of

that pulse. Further, the phase state is changed only while the pulse amplitude is zero. Therefore, the wide frequency spectra normally associated with PSK of a continuous carrier is avoided. This is true for all CLOVER-II modulation formats. The term “phase-shift modulation” (PSM) is used when describing CLOVER modes to emphasize this distinction.

**Coder Efficiency Choices**

CLOVER-II has four “coder efficiency” options: 60%, 75%, 90% and 100% (“efficiency” being the approximate ratio of real data bytes to total bytes sent). “60% efficiency” corrects the most errors but has

## Multilevel Digital Modulation Waveforms

Digital waveforms discussed so far have all used either on/off keying (OOK, that is Morse code, or CW) or frequency-shift keying (FSK, RTTY, AMTOR, PACTOR and packet radio). Both OOK and FSK are "simple" digital modulation waveforms; they have only two binary states that are represented by two radio-frequency states. In Morse code, the states are key-down = logical "1" and key-up = logical "0." In RTTY, AMTOR, PACTOR and packet radio, one frequency is "1" state, another is the "0" state.

More efficient use may be made of the spectrum by using multilevel modulation, in which one change in the transmitted signal may represent two or more bits of data. A simple example of multilevel modulation is quadrature phase-shift keying, known as QPSK. The simplest QPSK signal transmits a continuous carrier at a single frequency. Digital information is modulated on this carrier by changing the phase shift in 90° increments. Since there are four possible 90°-increment states (0°, 90°, 180° and 270°), four different modulation states may be signaled. Put another way, each phase state may be used to represent two bits of binary data. Examples of four common PSK modes are shown in Fig A.

Note that the phase of the transmitter carrier may be changed from any given state to any other state. Thus when using QPSK, if two bits of data change from "00" to "11," only one change to the transmitter carrier phase is required—from 0° to 270°. This observation illustrates the very important difference between modulation symbol rate (bauds) and data throughput rate (in bits-per-second, bits/s). In QPSK, bauds = 0.5 × bits/s (100 baud = 200 bits/s). This concept can be extended to 8PSK which has 8 phase states that represent 3 bits of data (bits/s = 3 × bauds). Carried further, each phase state in 16PSK modulation represents 4 bits of binary data and the throughput is 4 times the base symbol rate (bit/s = 4 × bauds).

Higher-level phase shift modulation schemes have been used (32PSK and 64PSK for example), but these systems require much more complex demodulator design. In particular, demodulator sensitivity to noise and distortion increases greatly as the number of possible phase states is increased. Consider the relatively simple QPSK example. The design-center phase states of 0°, 90°, 180°, and 270° represent the four possible modulation conditions. Ionosphere propagation, multipath signal reflections, and transmission distortion all conspire to insert phase "jitter" or uncertainty in the received signal. In QPSK, signals with a phase shift between 45° and 135° can be assumed to represent the 90° state, 135° to 225° for the 180° state and so on. The margin for error or "phase margin" for QPSK is  $\pm 45^\circ$ . A similar calculation for 16PSK shows that its phase margin is just  $\pm 12.25^\circ$ . If we consider use of a 10.000 MHz carrier with 16PSK, the period of the carrier sine wave is 0.100 microsecond and the allowable phase jitter corresponds to a time uncertainty of only  $\pm 0.003403$  ms, or  $\pm 3.403$  ns. Obviously, very stable phase references must be used in a 16PSK system and it does not take very much distortion or noise to make correct data detection impossible. However, such systems are commonly used in telephone-line modems.

Telephone modems carry the multilevel concept one step further and use amplitude-level modulation (amplitude-shift keying, ASK) in addition to PSK modulation. If two-level ASK is used with 16PSK, a total of 32 states may be sent. Similarly, use of 4ASK and 16PSK gives 64 unique states for each modulation change. This is commonly called "QAM" for Quadrature Amplitude Modulation and is the modulation used by most 9600-baud telephone modems. Each modulation change can represent the state of 6 bits of binary data; the data

Fig A

throughput is 6 times the base modulation symbol rate (bits/s = 6 × bauds). As noted above, complex multilevel modulation schemes require very complex and expensive demodulators that are very susceptible to noise and distortion. Fortunately, modern telephone lines are relatively noise-free and stable. By use of error correction and line distortion equalization, high "speed" data transmission via telephone line is now in common use.

Unfortunately, these same techniques cannot be directly applied to radio data transmission, particularly to HF signals. Long-range HF signals are propagated via the ionosphere, which is not stable or well defined from instant to instant. Ionosphere reflection height and signal attenuation varies widely with time of day, geographic location, and solar activity. Moreover, noise levels on HF vary considerably with location as well as time of day.

With multipath propagation, multiple copies of an original signal are summed at the receiving antenna. Since each signal travels via a different path, the propagation delays are different. Multiple signals therefore arrive at the receiver at slightly different times and the "mark-to-space" transition time is different for each signal. This causes "smearing" of the exact transition times. Multipath distortion occurs commonly on HF when both single-hop and multiple-hop signals arrive at the receiving antenna with similar strengths. Multipath distortion is also common on VHF and UHF signals in highly populated areas where large buildings provide reflecting surfaces.

The HF environment is therefore complicated and hostile to data transmission. Modulation techniques that work well on stable and predictable telephone lines may also be usable for VHF and UHF radio systems, but they may seldom be directly applied to HF data radio systems. Further, data format protocols that were devised for the stable phone-line environment are generally not optimum for use on HF data radio. For example, both the FSK modulation and the protocol used for AX.25 packet radio lead to serious problems when used on HF signals.

Fig 12.36—Spectra plots of AMTOR, HF packet-radio and CLOVER-II signals.

Fig 12.37—ARQ-mode data throughput vs receiver S/N ratio for AMTOR and three different CLOVER-II configurations.

### CLOVER FEC

All modes of CLOVER-II use Reed-Solomon forward error correction (FEC) data encoding which allows the receiving station to correct errors without requiring a repeat transmission. This is a very powerful error correction technique that is not available in other common HF data modes such as AX.25 packet radio or AMTOR ARQ mode.

### CLOVER ARQ

Reed-Solomon data coding is the primary means by which errors are corrected in CLOVER "FEC" mode (also called

"broadcast mode"). In ARQ mode, CLOVER-II employs a three-step strategy to combat errors. First, channel parameters are measured and the modulation format is adjusted to minimize errors and maximize data throughput. This is called the "Adaptive ARQ Mode" of CLOVER-II. Second, Reed-Solomon encoding is used to correct a limited number of byte errors per transmitted block. Finally, only those data blocks in which errors exceed the capacity of the Reed-Solomon decoder are repeated (selective block repeat). Unlike AX.25 packet radio, CLOVER-II does not repeat blocks which have been received correctly.

With seven different modulation formats,

four data block lengths (17, 51, 85 or 255 bytes) and four Reed-Solomon coder efficiencies (60%, 75%, 90% and 100%), there are 112 ( $7 \times 4 \times 4$ ) different waveform modes that could be used to send data via CLOVER. Once all of the determining factors are considered, however, there are 8 different waveform combinations which are actually used for FEC and/or ARQ modes.

### CLOVER vs AMTOR vs Packet

Fig 12.36 shows the modulator output spectra of CLOVER-II, AMTOR and HF packet radio. Nearly all of the CLOVER-II signal energy is concentrated within  $\pm 250$  Hz of the center frequency. Therefore, CLOVER-II signals can be spaced as closely as 500 Hz from any data-mode signal with very little cochannel interference. Tests show that "cross-talk" between two 500-Hz spaced CLOVER-II signals is less than 50 dB. This is much better than the common spacing of AMTOR (1000 Hz) or HF packet signals (2000 Hz).

Fig 12.37 shows throughput vs S/N for AMTOR and various modes of CLOVER-II. For all values of S/N and all modes of CLOVER, the data throughput obtainable using CLOVER-II is higher than that achievable when using AMTOR. In addition, CLOVER may be used to send full 8-bit computer data whereas AMTOR is restricted to either the Baudot RTTY characters set (CCIR-476/625) or the printable subset of ASCII (ASCII-over-AMTOR).

Table 12.14 shows a subjective comparison of data modes typically used for HF data communications. Morse code is the simplest to implement—a key and good knowledge of CW are all that are required. However, Morse code does not include error correction, has low data throughput, and is best manually received and decoded. Automatic Morse decoding systems exist, but rarely perform as well as a "good CW operator."

RTTY has better automatic receive decoding performance than Morse code and is relatively inexpensive, but offers no automatic error correction. AMTOR includes error correction, has good performance under weak signal conditions and is relatively inexpensive. However, its maximum data throughput rate is low and it cannot support transmission of 8-bit data files.

AX.25 packet radio is inexpensive but its performance on HF is typically very poor. This is due both to the popular choice of modulation (200 Hz shift, 300 baud FSK) and the AX.25 protocol which was not designed to handle the burst-type errors that are common to HF propagation.

Table 12.14

## HF Data Mode Comparisons

Waveform	Modem Cost	Typical HF Throughput	Data Format	Error Correction	Noise & Interference Tolerance	Occupied BW (Hz)	Cost (\$/baud)	Occupied BW (Hz/baud)
Morse Code (On/Off keying)	\$300- \$1000	5-60 wpm 4-50 bd	character	none	poor (auto RX)	250- 500	6 250	10
Teletype (FSK, 170-Hz shift)	\$500- \$3500	60-100 wpm 45-110 bd	baudot	none	fair	500- 1000	5 35	10
AMTOR/SITOR (FSK, 170-Hz shift)	\$500- \$3500	3.0-6.7 c/s 100 bd	baudot	ARQ repeat	good	1000	5 35	10
HF Packet (FSK, 200-Hz shift)	\$500 \$1000	4-10 b/s 75-300 bd	ASCII	ARQ repeat	very poor	2000	2 15	7 35
MIL188-110A (PSK serial)	\$8000 & Up	75- 2400 bd	binary	FEC broadcast	good	3000	3.33 100	1.25 40
CLOVER-II (FSK/PSK/ASK)	\$1000	2-100 b/s 31-750 bd	binary	simultaneous FEC + ARQ	very good	500	1.33 33	0.67 16.7

WPM = words per minute  
c/s = characters per second  
bd = baud  
b/s = bytes per second

The MIL-188/110A (now proposed Federal Standard pFS-1052) "Serial, Single-Tone" waveform works well on HF and can pass error-corrected 8-bit data with a throughput of up to 2400 baud. However, modems for this mode are presently very expensive, the occupied bandwidth of 3000 Hz is very wide, and ARQ or adaptive ARQ modes are still under development.

In comparison, CLOVER-II modems are moderately expensive but will adaptively match existing signal conditions and provide high data throughput rates when conditions permit. CLOVER-II will pass full 8-bit data and a CLOVER signal is the most bandwidth efficient of all modes considered.

## What About PACTOR and G-TOR?

Data for these modes were not available for this comparison. In the 200-baud mode, the spectra should be somewhere between that of AMTOR and packet. In the 100-baud mode it should be close to 110-baud ASCII. Throughput should be much better than that of AMTOR, but probably not as good as CLOVER-II.

# Image Modes

## FACSIMILE

This section, by Ralph E. Taggart, WB8DQT, covers the facsimile systems in most common Amateur Radio use today. The subject of weather fax is covered in greater detail in *The Weather Satellite Handbook*.<sup>1</sup>

Image transmission using voice bandwidth is a trade-off between resolution and time. In the section on slow-scan television, standards are described that permit 240-line black-and-white images to be transmitted in about 36 seconds while color images of similar resolution require anywhere from 72 to 188 seconds, depending on the color format. In terms of resolution, 240-line SSTV images are roughly equivalent to what you would obtain with a standard broadcast TV signal recorded on a home VCR. This is more than adequate for routine video communication, but there are many situations that demand images of higher resolution.

Facsimile (fax) encompasses a number of standards involving the transmission of images ranging from around 500 to up to several thousand image lines. The trade-off with fax is similar to that involved with SSTV—you are restricted to still images

and image transmission times can range from 2.25 to 15 minutes or more.

## FACSIMILE FORMATS

### Line Rate

The line rate (expressed in lines/minute or lpm) is one of the more significant standards in defining a fax format. If the transmitter and recorder do not operate at the same rate, there is no possibility of reproducing the original image. Fax recorders available on the surplus market were typically designed for one or more modes. Single-mode systems are the most common, although a number of systems are available that, through a combination of electronic switching and/or mechanical changes in the drive system, will operate on more than one mode. The following are some of the more common line rates that will be encountered in surplus fax equipment:

- 60 lpm: A standard speed many years ago for wirephoto and weather chart transmissions. Worked well over voice circuits with limited bandwidth or audio fidelity. Almost no operational fax systems use this rate today.
- 90 or 100 lpm: Used for many years in wirephoto service and surplus machines. No longer in operational service, since image transmissions are too long for practical use on the amateur HF bands.
- 120 lpm: The standard speed for weather charts and many wirephoto services. Can

be used for polar orbit satellite images. Transmission of pictures with a reasonable aspect ratio requires 10-15 minutes, so this standard is incompatible with amateur regulations that require station identification at intervals of no more than 10 minutes.

- 240 lpm: Used for weather satellite image transmission and some wirephoto and chart services. Transmission of an 800-line picture (a square image) typically requires about 3.5 minutes, allowing for additional overhead for start and phasing signals. This is the most practical standard line rate for amateur HF use, although the bandwidth of the baseband signal is a bit wide.
- 480 lpm: Used in advanced wirephoto and other image links using high-grade voice circuits. While the image transmission time is short, the video bandwidth is too wide for use on HF.

## Modulation

All fax modes of interest to radio amateurs convey video data by modulation of an audio tone or subcarrier. Two quite different approaches to modulation of this subcarrier are employed to accommodate the operational problems associated with different fax modes.

### Amplitude Modulation

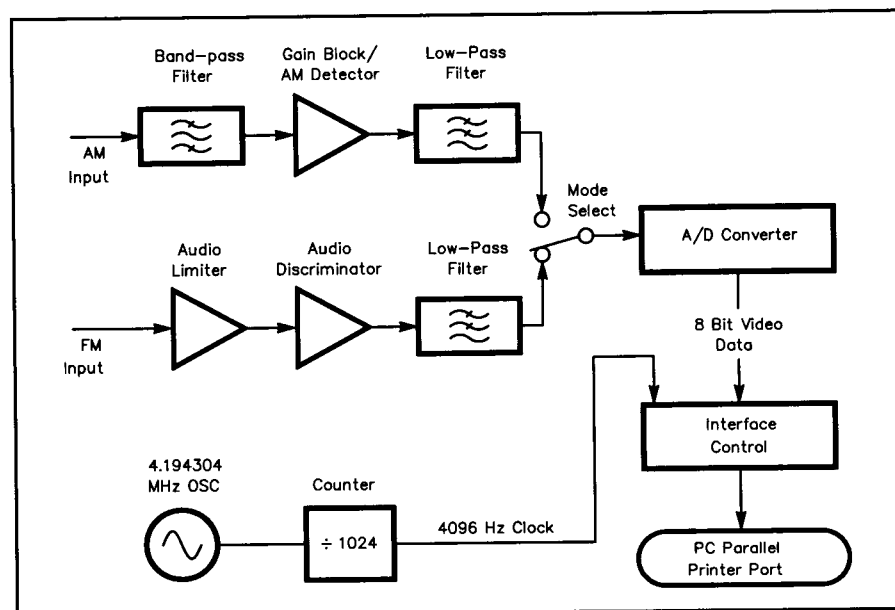

One of the most simplest approaches to fax modulation is to convey luminance (brightness) information by variations in the amplitude of the audio subcarrier. Such AM subcarrier modulation is universally employed in the transmission of weather satellite images using the following standards:

- Subcarrier frequency: 2400 Hz
- White level: 100% amplitude
- Black level: 4% amplitude

Since the image signal is simply an AM tone within the normal audio range, standard AM or FM modulation techniques for the RF signal may be used. In the case of image transmissions from spacecraft, the radio frequency carrier is FM modulated by the audio subcarrier with a deviation of  $\pm 15$  kHz. The downlink signal is demodulated by an FM receiver of standard design, with due allowance for the fact that the deviation is greater than that typically employed in amateur voice work, reproducing the 2400-Hz subcarrier with its AM modulation envelope.

The subcarrier signal is processed for computer display using an external signal demodulator, either a standalone unit or a plug-in interface card. Typical circuits involve bandpass filtering of the subcarrier, gain/level control, full-wave detection, post-detection filtering and an

<sup>1</sup>Taggart, R. E., *The Weather Satellite Handbook*, 5th Ed. (Newington: ARRL, 1994).

**Fig 12.38—A simplified block diagram of the major circuit elements in the weather satellite/HF fax computer interface from the 5th Edition of *The Weather Satellite Handbook*. This is an external unit designed to interface to the computer's parallel printer port. The software supports display of all APT and WEFAX satellite modes as well as HF weather chart and satellite image transmissions.**

analog to digital (A/D) converter to convert the interface output (typically ranging from 0 V for black to +5 V for white) to digital values for computer storage and display (Fig 12.38).

### Subcarrier Frequency Modulation

Amplitude modulation of the subcarrier works well with satellite transmissions since the limiting employed in the FM RF receiver circuits essentially eliminates signal amplitude variations once the received signal has reached "full-quieting." In contrast, fax systems designed for use on HF must use amplitude modulation of the RF carrier (typically single sideband). Signal level variations caused by fading and other path variables are inevitable on HF and cannot be eliminated in the process of RF signal demodulation in the receiver. If amplitude modulation of the subcarrier were used, the result would be variable changes in grayscale display. This can be avoided by using frequency modulation of the subcarrier. Such a fax signal is thus an audio tone that varies in frequency according to the luminance value of the portion of the image being transmitted.

Most HF fax services are standardized to the extent that black is transmitted using a subcarrier frequency of 1500 Hz with 2300 Hz being the white subcarrier limit. Intermediate grayscale values are represented by subcarrier frequencies between the 1500 Hz (black) and 2300 Hz (white) limits. You will note the similarity with the SSTV modulation format discussed in that section. The standards for SSTV modulation were derived from existing HF fax standards. The major difference between most fax formats and SSTV is that there is no provision in fax for line or frame sync pulses (such as the 1200-Hz SSTV luminance sync pulse). Fax systems rely on the extreme accuracy of external time bases at both the transmitting and receiving ends of the circuit to maintain precise synchronization.

Since the FM fax signal is a tone of constant amplitude that varies between 1500 and 2300 Hz, it is completely compatible with HF voice transmitters and can be routed to the audio input with nothing more elaborate than a gain control network to control the peak audio level. Standard HF receiving equipment will recover the fax signal (just as in SSTV) for further processing by an external or internal interface in the computer. SSTV interfaces are entirely suitable for demodulating HF fax signals.

### THE COMPUTER CONNECTION

Fax recorders are fascinating to tinker

with if you enjoy working with mechanical devices, but relatively few people are making the effort these days. The reason is the rapid increase in the graphics capabilities of even the most basic entry-level computers. Today, the computer you purchase for use in the ham shack (on packet, AMTOR, CW, slow scan or even contest logging) will probably have more than adequate graphics capabilities to handle fax.

Computer-based fax systems have many advantages over mechanical recorders. First, the electronic interfaces are quite simple, consisting of AM and/or FM subcarrier demodulator circuits, an A/D converter, and a crystal-locked clock circuit (see Fig 12.38). Most available interfaces are for IBM compatible computers (using VGA graphics) and take the form of internal bus cards or external units that connect computer's serial or parallel port. Second, simple changes in software can add new modes to a computer-based system.

Computer-display systems post the image to the screen, so no supplies are used for routine image evaluation. If hard-copy of a specific image is desired, laser printers can provide one quickly. Mechanical fax systems let you print an image once, as it is being transmitted. You cannot redo an image with different contrast or level settings, and image processing options are very limited. In contrast, computer images can be stored to disk and/or subject to a very wide range of image-enhancement techniques. The most basic VGA display will yield images that were state-of-the-art only a few years ago, and advanced VGA displays have approached or surpassed the theoretical resolution limits of many fax modes.

Finally, if you are interested in transmitting fax, you will find that with just a few bits of additional hardware, a computer-based system can transmit fax as effectively as it can display images. Considering all these factors, it is little wonder that most amateurs are bypassing bulky mechanical fax systems and opting for computer-based operation.

### HF FAX SERVICES

The primary HF fax services of interest to amateurs are wirephotos and weather data. HF wirephoto traffic has declined markedly in recent years as many press services have been moved to digital satellite links. Operating frequencies can be found in some short-wave publications, but the pictures are protected by international copyright laws and other regulations. In general, it would be illegal, barring permission from the news agency in question, to retransmit or otherwise reproduce pictures that are copied.

HF weather services include weather charts and data and transmissions of satellite images (Fig 12.39). *The Weather Satellite Handbook* contains a comprehensive list of worldwide chart and satellite transmission frequencies, organized by region.

Since modulation standards for HF fax are identical to SSTV, any SSTV interface could be used for fax reception or transmission, with suitable software. The FAX480 program (see the next section) for the ViewPort and Pasokon SSTV interfaces supports display of 120-lpm HF weather charts and satellite images. Most of the multi-mode data controllers used for packet, AMTOR, CW and ASCII/RTTY communications will support 120-lpm fax reception and other modes as well. Almost all of these will do a nice job with binary chart display, but the better units vary greatly in their ability to handle grayscale imagery. One of the most comprehensive HF fax systems is marketed by Software Systems Consulting in the form of their PC-Fax hardware and software. This package is very reasonably priced and will handle both reception and transmission of virtually all HF fax formats.

### AMATEUR TWO-WAY FACSIMILE

Two-way amateur fax operation has generally been quite limited. In part this has been due to a lack of a single coherent standard that could serve as a focus for on-the-air activity. Of the various commercial modes, 240 lpm is the only really viable option for amateur HF use. Using this mode, 800-line pictures can be transmitted in slightly under 3.5 minutes. The biggest practical problem with this mode is finding

Fig 12.39—An example of a 120-lpm transmission of a geostationary weather satellite image by the US Navy station NAM on 8080 kHz. The image was displayed using a Pasokon SSTV interface, operating with the FAX480 program.

**Fig 12.40**—Local scenic attractions make excellent subjects for fax transmissions. This Fax-480 picture of the Hank Williams grave site was transmitted by K4ZET (Alabama) on 20 m and received by WB8DQT (Michigan) using the ViewPort SSTV interface and FAX480 software.

other active stations. With the wider use of computer-based systems, there is the potential for increased activity.

Since computers are now almost universally used for most other fax services, it was inevitable that some experimenters would break away from the mechanically based modes and look at options tied to the VGA display capabilities of computers.

#### **Fax-480 Format**

The Fax-480 image standard was proposed by WB8DQT<sup>2</sup> and has rapidly become the most widely used standard for two-way amateur fax. The mode uses the 640×480×16 grayscale display format that is universally available in VGA-equipped personal computers. The Fax-480 image consists of 480 image lines, each comprised of 512 pixels, in a square image format. This allows menu options or other data to be posted on one side of the image when displayed in the 640×480 VGA mode. The images have approximately four times the resolution of standard SSTV pictures and greatly expand the range of pictures suitable for exchange over the air. **Fig 12.40** demonstrates the quality of a fax picture received with Fax-480 software.

#### **WEATHER SATELLITES**

The most consistent and productive involvement of amateurs in facsimile has been in the reception and display of images transmitted by weather satellites.

<sup>2</sup>Taggart, R. E., "A New Standard for Amateur Radio Analog Facsimile," *QST*, February 1993, pp 31-36.

### **NOAA Polar Orbiting Satellites**

### **GOES**

#### **Geostationary Satellites**

**Fig 12.41**—Schematic representation of polar-orbiting and geostationary weather satellite orbital tracks.

This involvement began with Anderson's pioneering presentation in *QST*.<sup>3</sup> Back then, almost every component in the amateur satellite station had to be constructed from scratch. Today, it is a straightforward task to set up a weather satellite ground station using economical components from a wide range of commercial vendors. This state of affairs is almost entirely the result of amateur experimentation and innovation.

ARRL publishes a comprehensive introduction to the subject, *The Weather Satellite Handbook*. This publication covers the various operational satellites, the fundamentals of antennas, receivers and satellite tracking, a simple but effective computer interface for display of both satellite and HF images, and a whole chapter on software development. It also covers reception of weather charts and satellite images on HF, and contains a chapter on high-resolution satellite digital image formats.

There are a number of electronic bulletin-board systems devoted in whole or in part to weather satellites. The WSH BBS is maintained to support projects and related subjects from *The Weather Satellite Handbook* as well as the Fax-480 mode. The most comprehensive BBS devoted to satellites and remote imaging is the DRIG BBS, maintained by the Dallas Remote Imaging Group. This BBS is by far your best choice

for the latest satellite orbital elements, bulletins on the status and schedules of operational satellites, and state-of-the-art projects and experimentation in this area. (See the Address List in the **References** chapter for contact information.)

#### **Operational Weather Satellites**

Operational weather satellites fall into two broad categories—those that operate in near-polar orbits at altitudes around 850 km (530 miles) and those in geostationary orbit over the equator at altitudes of 35,600 km (22,300 mi). The basic geometry of these orbits is shown in **Fig 12.41**.

#### **Polar Orbit Spacecraft**

Spacecraft in near-polar, relatively low orbits, can image almost any part of the earth's surface twice each day, once in daylight and again at night. Representative spacecraft in this category include the TIROS/NOAA satellites operated by the US, several categories of METEOR spacecraft operated by Russia and the Commonwealth of Independent States, and the Feng Yun spacecraft operated by the People's Republic of China. All incorporate a variety of sensors to acquire data on the near-space environment and the earth below, as well as their onboard imaging systems. All of these spacecraft are powered by solar panels with onboard battery systems to continue operations when the spacecraft is on the night side of the planet.

<sup>3</sup>Anderson, W., "Amateur Reception of Weather Satellite Images," *QST*, November 1965, pp 11-17.

Scanning radiometers, consisting of a system of lenses and motor-driven mirrors that provide high-resolution scanning, are *multi-spectral* instruments; image data is obtained from at least one sensor for visible light and several other sensors optimized for different portions of the infrared or IR spectrum. IR radiance ("brightness") is a function of temperature differences, so images may be obtained at IR wavelengths on the night side of the orbit and at both

IR and visible light wavelengths in daylight. The primary imaging system is designed to encode both visible and IR image data into a wide-bandwidth digital data format (known as HRPT) for transmission to ground stations on 1698 or 1707 MHz. Advances in microwave and digital technology and a lot of experimentation by pioneering amateurs now make it practical to construct a station to receive and display HRPT images.<sup>1,4</sup> Fig 12.42 illustrates the

process by which rotating mirrors aboard a satellite produce HRPT-format images. Fig 12.43 shows an example of visible-light HRPT imagery obtained by an amateur station.

Although the primary mission of the TIROS/NOAA is the acquisition of the HRPT imagery, onboard computers sample the high-resolution image data and transmit it to earth in a simple analog image format (known as APT). APT images are sent at a 120-lpm rate using AM fax modulation. If displayed on a 120-lpm display system, visible-light and IR versions of the image will be displayed side by side (Fig 12.44). At night, another IR channel is substituted for the visible light channel. The curving edge of the image in the figure is the result of Doppler shift. The display system uses a fixed-frequency timing reference, while the timing of the spacecraft signals appears slightly high as the spacecraft approaches the ground station and low as it moves away. NOAA images can also be displayed at 240 lpm, with circuits designed to display just the visible light or IR data, if desired (Fig 12.45). APT format signals are transmitted to earth in the 137-MHz range, making them easy to receive.

The Chinese Feng Yun spacecraft is similar to the US TIROS/NOAA series. The Russian METEOR spacecraft, slightly different in terms of orbital parameters, transmit visible light images (120 lpm) during the day (Fig 12.46) and IR images (120 lpm) at night, using AM subcarrier modulation.

Fig 12.42—Meteorological satellites view the Earth through rotating mirrors to produce APT and HRPT images.

**Fig 12.45**—By displaying NOAA image data at 240 lpm and blanking the unwanted data format, either visible light or IR data can be displayed. This is an example of contrast-enhanced IR imagery from NOAA 12.

**Fig 12.46**—Visible light image of Eastern Canada, transmitted by METEOR 2-18 and displayed using the WSH interface and WSHFAX software.

**Fig 12.47**—A sample of the NE quadrant of the earth disc as transmitted from a GOES geostationary spacecraft in the WEFAX mode. This is a sample of visible light GOES imagery, displayed using the WSH interface and WSHFAX software.

**Fig 12.48**—With suitable software, the four WEFAX quadrants that make up the earth disc can be merged to reconstruct the entire hemisphere as viewed (in this case, in visible light) by the GOES spacecraft (WSH interface and WSHFAX software).

### Geostationary Spacecraft

The US GOES series, the European METEOSAT and the Japanese GMS spacecraft are all examples of geostationary satellites. Each of these spacecraft scan the entire earth disc from their permanent stations above the equator. The imaging systems of these spacecraft are also multi-spectral scanning radiometers. The high-resolution image data are computer-processed and then retransmitted, in analog form, in a format known as WEFAX. This is a 240-lpm format using AM subcarrier modulation. WEFAX images are transmitted on a frequency of

1691 MHz for GOES and 1691 and 1694.5 MHz for the European Meteosat and Japanese GMS spacecraft. In the case of GOES WEFAX, the entire earth disc is formatted a four quadrants, one of which is shown in **Fig 12.47**. When a computer is used for display, it is an easy matter to stitch the four quadrants together to create a full-disk image (**Fig 12.48**).

### Receiving Hardware

Polar orbit signals are the easiest to receive, since transmissions are made in the 137-138 MHz frequency range. Antennas should be circularly polarized (RHC) for best results. Gain antennas, operated by

an elevation/azimuth rotor system, are usually crossed-Yagis or helix designs. Given the effectiveness of GaAsFET preamplifiers in this frequency range, many stations utilize simple omnidirectional antennas (turnstile and quadrifilar helix designs are popular), eliminating the need to track the spacecraft. With such an antenna system, a computer-based display can capture and store images during the day when the station operator is at work or otherwise occupied.

The downlink modulation of APT signals from all operational polar orbiters is FM. A basic FM receiver with a low-noise front end (often a preamplifier, remotely located at the antenna) is adequate for reception. Primary operational frequencies include 137.50 and 137.62 MHz (US TIROS/NOAA spacecraft), and 137.30, 137.40 and 137.85 MHz for Russian METEORs. Both crystal-control and synthesized receivers are widely used. Required IF bandwidth is 30-40 kHz to accommodate both signal deviation and Doppler shift. A number of vendors supply moderately-priced receivers designed specifically for satellite service (see Chapter 3 of *The Weather Satellite Handbook*) and modification of scanners or amateur 2-m receivers is feasible if it is possible to widen the IF response. Stock receivers have too narrow a response (typically 15 kHz) for effective use.

Reception of GOES and other WEFAX signals in the 1691 MHz-range requires the use of a suitable microwave antenna. While some stations use loop Yagis, dish antennas in the 1.2-m (4 ft) range will provide a more useful gain margin. GaAsFET preamplifiers at the dish feed are utilized to set the system noise figure.<sup>5</sup> Converters are then used to shift the signal down in frequency (typically to 137.50 MHz), where the polar-orbit FM receiver is used for demodulation. Commercial downconverters are available at reasonable cost from a number of vendors.

*The Weather Satellite Handbook* contains extensive coverage of polar-orbit and geostationary antenna systems, receivers and downconverters, and a sample link analysis for WEFAX reception. WEFAX images are also transmitted several times daily by many HF fax stations (see **Fig 12.39**). Since most modern HF transceivers incorporate general-coverage receivers, reception of satellite images on HF can provide a convenient introduction to satellite imagery.

<sup>5</sup>Shuch, H. P., "A Low-Noise Preamp for Weather Satellite VISSR Reception," *QEX*, February 1989, pp 3-9. Feedback, *QEX*, June 1989, p 11.

## Display Hardware

Most satellite activity is conducted using signal-processing hardware interfaced to personal computers. The widest range of systems is available for use with IBM-compatible computers using VGA graphics adapters.

There are two common approaches. Incorporating the circuits onto a bus-compatible plug-in circuit card is a very popular approach.<sup>6</sup> Some commercial systems even integrate the APT VHF receiver into the card. A second approach is to construct

<sup>6</sup>Shuch, H. P., "A Weather Facsimile Display Board for the IBM PC," *QEX*, September 1988, pp 3-7, 15.

an external interface that connects to the computer through a serial or parallel port. Fig 12.38 is a block diagram of the WSH Satellite Interface, which connects to a PC-compatible parallel port. In addition to both AM (satellite) and FM (HF fax) signal processing, the unit is easily moved between computers and can be used with machines that do not have PC/AT bus slots or where all available slots are occupied with cards for other applications. The parallel port interfacing scheme also provides maximum flexibility for those who might wish to adapt the interface to other computer families.

All the commercially available interface systems (and the WSH unit) have

comprehensive software packages available that handle image display functions in the various modes along with image-processing options. Additional features may include satellite tracking, hard-copy printing, file-management functions, image labeling, image gridding, temperature readout from IR data and conversion of image to various standard graphics formats. *The Weather Satellite Handbook* contains information and advertisements for most popular systems. In addition, an entire chapter is devoted to software manipulation of the WSH Interface for those who would like to experiment with software development.

## SLOW-SCAN TELEVISION (SSTV)

An ancient Chinese proverb states: "A picture is worth a thousand words." It's still true today. Sight is our highest bandwidth sense and the primary source of information about the world around us. What would you think about a TV news program without pictures about the stories? Would you enjoy reading the comics if there were no drawings with the text? Do you close your eyes when talking to someone in person? Many hams feel the same way about conversing with Amateur Radio: sending images is a wonderful way to enhance communication. This material was written by John Langner, WB2OSZ.

For decades only a dedicated few kept SSTV alive. The little commercial equipment was very expensive and home brewing was much too complicated for most people. Early attempts at computer-based systems were rather crude and frustrating to use.

The situation has changed dramatically in recent years. There is now a wide variety of commercial products and homebrew projects to fit every budget, and SSTV activity is experiencing rapid growth. There is even software that uses the popular Sound Blaster computer sound card for SSTV.

The early SSTV 8-second transmission standard is illustrated in Fig 12.49. Audio tones in the 1500 to 2300-Hz range represent black, white, and shades of gray. A short 1200-Hz burst separates the scan lines, and a longer 1200-Hz tone signals the beginning of a new picture.

### Color SSTV Evolution

The early experimenters weren't content with only black and white (B&W) images and soon devised a clever way to send color pictures with B&W equipment. The transmitting station sends the same

image three times, one each with red, green and blue filters in front of the TV camera lens. The receiving operator took three long-exposure photographs of the screen, placing red, green and blue filters in front of the film camera's lens at the appropriate times. This was known as the "frame sequential" method.

In the 1970s, it became feasible to save these three images in solid-state memory and simultaneously display them on an ordinary color TV. But, the frame-sequential method had some drawbacks. As the first frame was received you'd see a red and black image. During the second frame, green and yellow would appear. Blue, white, and other colors wouldn't show up until the final frame. Any noise (QRM or QRN) could ruin the image registration (the overlay of the frames) and spoil the picture.

The next step forward was the "line sequential" method. Each line is scanned 3 times: once each for the red, green, and blue picture components. Pictures could be seen in full color as they were received and registration problems were reduced. The Wraase SC-1 modes are examples of early line-sequential color transmission. They have a horizontal sync pulse for each of the color component scans. The major weakness here is that if the receiving end gets out of step, it won't know which scan represents which color.

Rather than sending color images with the usual RGB (red, green, blue) components, Robot Research used luminance and chrominance signals for their 1200C modes. The first half or two thirds of each scan line contains the luminance information which is a weighted average of the R, G and B components. The remainder of each line contains the chrominance signals with the color information. Existing

B&W equipment could display the B&W-compatible image on the first part of each scan line and the rest would go off the edge of the screen. This compatibility was very beneficial when most people still had only B&W equipment.

The luminance-chrominance encoding made more efficient use of the transmission time. A 120-line color image could be sent in 12 s, rather than the usual 24 s. Our eyes are more sensitive to details in changes of brightness than color, so the time could be used more efficiently by devoting more time to luminance than chrominance. The NTSC and PAL broadcast standards also take advantage of this vision characteristic and use less bandwidth for the color part of the signal.

**Fig 12.49—Early SSTV operators developed a basic 8-second black and white transmission format. The sync pulses are often called "blacker than black." A complete picture would have 120 lines (8 seconds at 15 ms per line). Horizontal sync pulses occur at the beginning of every line; a 30 ms vertical sync pulse precedes each frame.**

The 1200C introduced another innovation: it encodes the transmission mode in the vertical sync signal. By using narrow FSK encoding around the sync frequency, compatibility was maintained. This new signal just looked like an extra-long vertical sync to older equipment. (See the sidebar "Examining Robot's Vertical-Interval-Signaling (VIS) Code" for more details.)

The luminance-chrominance encoding offers some benefits but image quality suffers. It is acceptable for most natural images but looks bad for sharp, high-contrast edges, which are more and more common as images are altered via computer graphics. As a result, all newer modes have returned to RGB encoding.

The Martin and Scottie modes are es-

entially the same except for the timings. They have a single horizontal sync pulse for each set of RGB scans. Therefore, the receiving end can easily get back in step if synchronization is temporarily lost. Although they have horizontal sync, some implementations ignore them on receive. Instead, they rely on very accurate time bases at the transmitting and receiving stations to keep in step. The advantage of this "synchronous" strategy is that missing or corrupted sync pulses won't disturb the received image. The disadvantage is that even slight timing inaccuracies produce slanted pictures.

In the late 1980s, yet another incompatible mode was introduced. The AVT mode is different from all the rest in that it has *no horizontal sync*. It relies on very

accurate oscillators at the sending and receiving stations to maintain synchronization. If the beginning-of-frame sync is missed, it's all over. There is no way to determine where a scan line begins. However, it's much harder to miss the 5-s header than the 300-ms VIS code. Redundant information is encoded 32 times and a more powerful error-detection scheme is used. It's only necessary to receive a small part of the AVT header in order to achieve synchronization. After this, noise can wipe out parts of the image, but image alignment and colors remain correct. **Table 12.15** lists characteristics of common modes.

## Scan Converters

A scan converter is a device that con-

### Examining Robot's Vertical-Interval-Signaling (VIS) Code

The original 8-second black-and-white SSTV-image standard used a 30-millisecond, 1200-Hz pulse to signal the beginning of a new frame. In the Robot 1200C, Robot Research increased the vertical sync period by a factor of 10, encoded 8 bits of digital data into it and called it *vertical-interval signaling* (VIS). VIS is composed of a start bit, 7 data bits, an even parity bit, and a stop bit, each 30 milliseconds long. (See Fig A).

Since then, inventors of new SSTV modes (Martin, Scottie, AVT, etc) have adopted Robot's scheme and assigned codes to their particular mode that are unused by the Robot modes. So, each of the SSTV transmission modes has a unique VIS code. This allows new equipment to automatically select any of the new SSTV modes while maintaining compatibility with the older equipment.—WB2OSZ

**Fig A—Composition of the vertical interval signaling (VIS) code.**

**Table 12.15**

#### Popular SSTV Modes

Family	Name	Type	Time (Sec)	Lines	Notes
Robot	8	B&W	8	120	A,E
	12	B&W	12	120	E
	24	B&W	24	240	E
	36	B&W	36	240	E
	12	Y&C	12	120	
	24	Y&C	24	120	
	36	Y&C	36	240	
	72	Y&C	72	240	
Wraase SC-1	24	RGB	24	128	C
	48	RGB	48	256	B
	96	RGB	96	256	B
Martin	M1	RGB	114	256	B
	M2	RGB	58	256	B
	M3	RGB	57	128	C
	M4	RGB	29	128	C
Scottie	S1	RGB	110	256	B
	S2	RGB	71	256	B
	S3	RGB	55	128	C
	S4	RGB	36	128	C
	DX	RGB	269	256	C
AVT	24	RGB	24	120	D
	90	RGB	90	240	D
	94	RGB	94	200	D
	188	RGB	188	400	D
	125	B&W	125	400	D

**Types:** B&W = Black and white.  
Y&C =Color as luminance and chrominance.  
RGB =Color as red, green and blue components.

#### Notes:

A—Very similar to the original 8-second SSTV standard.

B—The top 16 lines are always sent as gray scale, so 240 lines are usable.

C—The top 8 lines are always sent as gray scale, so 120 lines are usable.

D—AVT modes have a 5-second digital header and don't use horizontal sync.

E—The Robot 1200C doesn't actually have monochrome modes to send the luminance (Y) component of an RGB image in memory. Instead, it sends any one of the R, G, or B components.

Note that the number of pixels per scan line is not listed. That's because the demodulated slow-scan video is a continuously varying signal *that can be sampled at different pixel rates* depending on the implementation. Hardware-based equipment (such as, the Robot 400) used powers of two (such as 256) because they're easy to implement with hard-wired logic. Using software, it's just as easy to use any other number. Pasokon TV uses 320 pixels per line to get the proper aspect ratio with a VGA display.

—WB2OSZ

## SSTV Glossary

**ATV**—Amateur Television. Sending pictures by Amateur Radio. You'd expect this abbreviation to apply equally to fast-scan television (FSTV), slow-scan television (SSTV) and facsimile (fax), but it's generally applied only to FSTV.

**AVT**—Amiga Video Transceiver.

1) Interface and software for use with an Amiga computer, developed by Ben Blish-Williams, AA7AS, and manufactured by Advanced Electronic Applications (AEA);

2) a family of transmission modes first introduced with the AVT product.

**Back porch**—The blank part of a scan line immediately following the horizontal sync pulse.

**Chrominance**—The color component of a video signal. NTSC and PAL transmit color images as a black-and-white compatible luminance signal along with a color subcarrier. The subcarrier phase represents the hue and the subcarrier's amplitude is the saturation. Robot color modes transmit pixel values as luminance (Y) and chrominance (R-Y [red minus luminance] and B-Y [blue minus luminance]) rather than RGB (red, green, blue).

**Demodulator**—For SSTV, a device that extracts image and sync information from an audio signal.

**Field**—Collection of top to bottom scan lines. When interlaced, a field does not contain adjacent scan lines and there is more than one field per frame.

**Frame**—One complete scanned image. The Robot 36-second color mode has 240 lines per frame. NTSC has 525 lines per frame with about 483 usable after subtracting vertical sync and a few lines at the top containing various information.

**Frame Sequential**—A method of color SSTV transmission which sent complete, sequential frames of red, then green and blue. Now obsolete.

**Front porch**—The blank part of a scan line just before the horizontal sync.

**FSTV**—Fast-Scan TV. Same as common, full-color, motion commercial broadcast TV.

**Interlace**—Scan line ordering other than the usual sequential top to bottom. For example, NTSC sends a field with just the even lines in  $\frac{1}{60}$  second, then a field with just the odd lines in  $\frac{1}{60}$  second. This results in a complete frame 30 times a second. AVT "QRM" mode is the only SSTV mode that uses interlacing.

**Line Sequential**—A method of color SSTV transmission that sends red, green, and blue information for *each sequential scan line*. This approach allows full-color images to be viewed during reception.

**Luminance**—The brightness component of a video signal. Usually computed as  $Y$  (the luminance signal) =  $0.59 G$  (green) +  $0.30 R$  (red) +  $0.11 B$  (blue).

**Martin**—A family of amateur SSTV transmission modes developed by Martin Emmerson, G3OQD, in England.

**NTSC**—National Television System Committee. Television standard used in North America and Japan.

**PAL**—Phase alteration line. Television standard used in Germany and many other parts of Europe.

**Pixel**—Picture element. The dots that make up images on a computer's monitor.

**P7 monitor**—SSTV display using a CRT having a very-long-persistence phosphor.

**RGB**—Red, Green, Blue. One of the models used to represent colors. Due to the characteristics of the human eye, most colors can be simulated by various blends of red, green, and blue light.

**Robot**—(1) Abbreviation for Robot 1200C scan converter; (2) a family of SSTV transmission modes introduced with the 1200C.

**Scan converter**—A device that converts one TV standard to another. For example, the Robot 1200C converts SSTV to and from FSTV.

**Scottie**—A family of amateur SSTV transmission modes developed by Eddie Murphy, GM3SBC, in Scotland.

**SECAM**—Sequential color and memory. Television standard used in France and the Commonwealth of Independent States.

**SSTV**—Slow Scan Television. Sending still images by means of audio tones on the MF/HF bands using transmission times of a few seconds to a few minutes.

**Sync**—That part of a TV signal that indicates the beginning of a frame (vertical sync) or the beginning of a scan line (horizontal sync).

**VIS**—Vertical Interval Signaling. Digital encoding of the transmission mode in the vertical sync portion of an SSTV image. This allows the receiver of a picture to automatically select the proper mode. This was introduced as part of the Robot modes and is now used by all SSTV software designers.

**Wraase**—A family of amateur SSTV transmission modes first introduced with the Wraase SC-1 scan converter developed by Volker Wraase, DL2RZ, of Wraase Elektronik, Germany.

verts signals from one TV standard to another. In this particular case we are interested in converting between SSTV, which can be sent through audio channels, and fast scan (broadcast or ATV), so we can use ordinary camcorders and color televisions to generate and display pictures. From about 1985 to 1992, the Robot 1200C was king.

Fig 12.50 shows a typical SSTV station built around a scan converter such as the

Robot 1200C or a SUPERSCAN 2001. The scan converter has circuitry to accept a TV signal from a camera and store it in memory. It also generates a display signal for an ordinary television set. The interface to the radio is simply audio in, audio out and a push-to-talk (PTT) line. In the early days, pictures were stored on audio tape, but now computers store them on disks. Once a picture is in a computer, it can be enhanced with paint programs.

This is the easiest approach. Just plug in the cables, turn on the power and it works. Many people prefer special dedicated hardware, but most of the recent growth of SSTV has been from these lower cost PC-based systems.

### SSTV with a Computer

There were many attempts to use early home computers for SSTV. Those efforts were hampered by very small computer

Fig 12.50—Diagram of an SSTV station based on a scan converter.

Fig 12.51—A modern, PC-based SSTV station.

Fig 12.52—Block diagram of an analog SSTV demodulator.

### Courteous SSTV Operating

- Recommended frequencies: Although 14.230 MHz is the primary recommended 20-m frequency, it is often overcrowded, and 14.233 is often pretty busy too. Some people are also using 14.236 and 14.239 when the others are busy.
- Make contact by voice before sending SSTV.
- Not all systems recognize the VIS code, so it is good manners to announce the mode before transmitting.

memories, poor graphics capabilities and poor software development tools.

The first comprehensive computer-based SSTV system was the AVT Master for the Commodore Amiga computer. At the time, the Amiga had graphics capabilities far beyond those common in the IBM PC community.

The AVT Master used a simple microprocessor based interface to demodulate the received audio. The Amiga's built-in sound generation capability provided tones for transmission. The comprehensive software supported all the transmission modes in use.

Surprisingly, nothing comparable was available for the ubiquitous IBM PC until around 1992, when several systems appeared in quick succession. By this time, all new computers had a VGA display, which is required for this application. Most new SSTV stations look like Fig 12.51. Some sort of interface is used to get audio in and out of the computer. These can be external interfaces connected to a serial or printer port, an internal card specifically for SSTV or even a peripheral audio card. Most of the SSTV work is done in software. System updates are performed by reading a floppy disk instead of changing EPROMs or other components.

None of the current systems have an integral frame grabber to capture a TV-camera signal; this must be purchased separately. Even without a camera and frame grabber, you can still send images that you have created or received and modified with a paint program.

### How It Works

Transmitting SSTV images with a computer is quite simple. All you need to do is generate fairly accurate tones and change them at the proper pixel rate. Tones in the range of 1500 to 2300 Hz correspond to the pixel intensities, and most modes use

1200-Hz sync pulses. A very low-cost system could even use the computer's built-in tone generator for transmitting, but the tones must be pure with little distortion in order to produce an acceptable RF signal via AFSK (see "AFSK" under Baudot section of this chapter).

SSTV reception is a little more difficult. First you must somehow measure the frequency of the incoming tone. You can't simply count the number of cycles in a second, or even 0.01 second, because the frequency is changing thousands of times each second. Fig 12.52 illustrates one way of rapidly measuring the incoming tone's frequency. Two filters are designed to have maximum outputs a little beyond the ends of the frequency range of interest. The output of one filter is rectified to become a positive voltage; the output of the other is rectified to become a negative voltage; then the voltages are summed. A low-pass filter, with a 1-kHz cutoff, removes the audio carrier ripple while passing the slower video signal. With careful design, the result is a voltage that is fairly proportional to the input frequency. Finally, an analog to digital (A/D) converter processes the signal for the computer.

Another frequency-measuring approach uses digital circuitry to measure the period of each audio cycle (see Fig 12.53). When the signal amplitude crosses zero, a counter is reset. It then proceeds to count pulses from a crystal controlled oscillator. At the end of the audio cycle, the counter content is snatched, the counter is reset and the process starts all over again.

The digital approach offers a few advantages over the analog approach. A single chip can contain the counter and handle several other functions as well. The analog approach requires a handful of op amps, resistors, capacitors, diodes and an analog to digital (A/D) converter. The digital approach has crystal controlled accuracy and no adjustments are required. The fre-

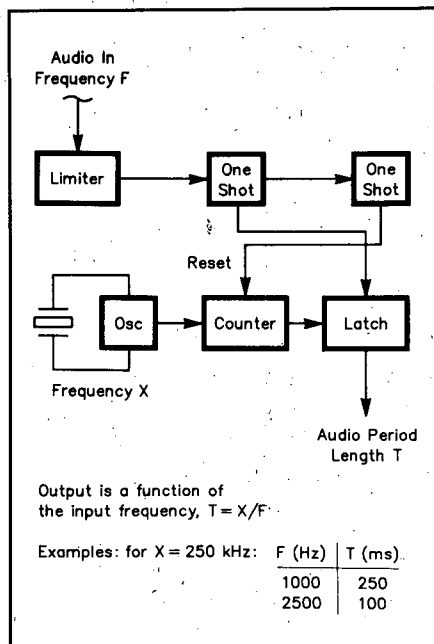

Fig 12.53—Block diagram of a digital SSTV demodulator.

quency-to-voltage transfer function of the analog version isn't exactly linear and can change with temperature, power-supply variations and component aging.

Digital Signal Processing (DSP) is an exciting possibility for SSTV demodulators. With DSP, a high speed A/D converter is used to sample the audio input. After that, it's all software. DSP can be used to construct filters that are more flexible, accurate, stable and reproducible than their analog counterparts.

Once you have the tone-frequency information, the real work begins. The next step is to separate the composite signal into the sync and video components. To reduce the effects of noise, the sync pulses are cleaned up with a low pass filter and Schmitt trigger. Then, sync is used to control the timing of pixel sampling. Fig 12.54 contains a high level outline of a

Set line number, L, to 1

Fig 12.55—An example SSTV image.

program used to receive an 8-s B&W picture. Receiving colors isn't much more difficult. For nonRobot modes, gather the R, G, and B scans for each line, combine them and display a line in color. Robot modes require considerably more calculation to undo their encoding.

## AN INEXPENSIVE SSTV SYSTEM

Here is a color SSTV/FAX480/ weatherfax (Fig 12.55) system for IBM PCs and compatibles that is essentially 99% software! (It originally appeared in Jan 1994 QST, pp 27-29.) And this system transmits, too! The software is on the disk that accompanies this book.

Ben Vester's, K3BC, work is aimed at the experimentally inclined, so if you're not familiar with BASIC programming, be prepared to learn a little about it if you want to maximize the utility of this system.

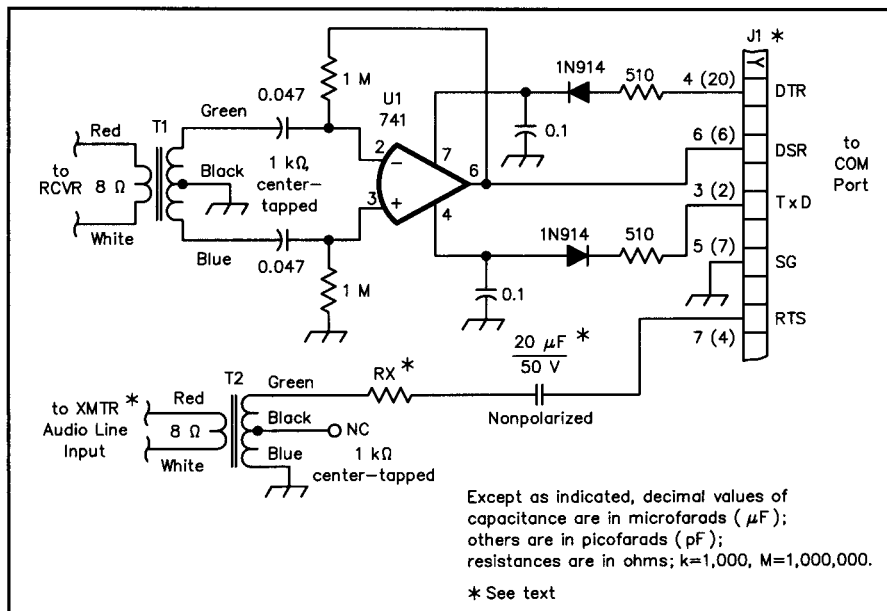

## Hardware

Fig 12.56 shows a simple circuit used for receiving and transmitting. Connect the output of T2 to the phone patch input (often labeled LINE INPUT) of your transceiver. If you already have a phone patch, you can eliminate T2, and connect the line directly to the patch's phone-line terminals. Nearly all patches employ transformer isolation, but a

## Slanted Pictures

As mentioned in the text, the synchronous modes, such as AVT, require very accurate timing to avoid slanted pictures. Let's quickly calculate the accuracy required.

One of the most popular SSTV modes is the AVT 94-second, which has  $320 \times 200$  pixels using three color components per pixel. Multiply all of that together and the result is 192,000 samples. Suppose the maximum acceptable slant was an offset of 4 pixels at the bottom of the screen. This requires an accuracy of  $4 \div 192,000 = 0.002\% = 20 \text{ ppm}$ . Actually, if the transmitting station was off this much in one direction, and the receiving station was off the same amount in the opposite direction, the bottom of the picture would shift 8 pixels. Rather shabby, but it's the worst case. There's no need for a micro-computer time-of-day clock to have this accuracy: so many PCs probably won't. Be suspicious of any SSTV interface that doesn't have its own crystal-controlled oscillator that you can tweak to avoid slanted pictures!—WB2OSZ

**Fig 12.56—Schematic of the simple SSTV receive and transmit circuit. This circuit is based on one that appears in the September 1991 Technical Correspondence column. T1 and T2 are Radio Shack 273-1380 audio-output transformers; the 20-μF, 50-V capacitor is a parallel combination of two Radio Shack 272-999 10-μF, 50-V nonpolarized capacitors; equivalent parts can be substituted. See text for value of RX. Unless otherwise specified, resistors are 1/4-W, 5%-tolerance carbon composition or film units. An optional low-pass filter can be used between the output of the computer and the transmitter's audio-input line (see text). At J1, numbers in parentheses are for 25-pin connectors; other numbers are for 9-pin connectors.**

simple ohmmeter check will verify that is true of *your* patch. (Avoid using the transceiver's mike input because of possible RF feedback problems.) RX is chosen to set the proper level for the audio going to the transmitter. SSTV has a 100% duty cycle signal, so you must set the audio signal to the transceiver at a level it can handle without overheating. Ben wired his transceiver directly to the phone patch with an RX value of 43 kΩ.

There is no low-pass filtering in the audio line between the computer output and transmitter audio input. On-the-air checks with many stations reveal that no additional external filtering is required when using SSB transmitters equipped with mechanical or crystal filters. If you intend to use this circuit with an AM or phasing-type SSB rig (or with VHF/UHF FM transmitters), add audio filtering to provide the required spectral purity. An elliptical low-pass filter such as described by Campbell<sup>1</sup> should be adequate for most cases.

Circuit component values aren't critical nor is the circuit's physical construction. *Do* use a socket for the IC. A PC board

is available from FAR Circuits,<sup>2</sup> but PCB construction employing short leads works fine.

### The Computer

The most important piece of hardware is the computer, which should have an 80286 (or better) microprocessor; a '386 machine running at 16 or 33 MHz definitely gives better results. You need a VGA color monitor that can provide a 640×480, 256-color noninterlaced display and a VGA (usually identified as SVGA) video adapter card that offers a 640×480×256-color mode.<sup>3</sup> The software directly addresses six of the most common SVGA chip types and also includes a VESA standard choice. If your video adapter card doesn't match one of the six, you'll need a VESA driver for your specific card. If you have trouble finding a driver, try some computer BBSs; I'm told that the Steve Rimmer BBS (tel 416-729-4609) has many video drivers.

### Software

GW BASIC is the programming tool. Al-

though the guts of the program are contained in assembly language code (.ASM files), this code is available to the program (and you) through BASIC. All of the modifications to the core programs (.ASM files) that adapt them to the multitude of SSTV/FAX modes are accomplished using BASIC POKEs. This allows experimenters with even a limited knowledge of BASIC programming to make modifications that add other modes, and so on. In deference to a few friends who complained about learning any BASIC, the programs include a system configuration list. The program uses this list to determine which POKEs to make. This system is strictly keyboard controlled. The software uses a unique technique to get wider color definition than is normally available with a 256-color video card.

### Some Program Details

One of the common SSTV practices is to retransmit a picture you just received so other SSTVers not copying the originating station can see the image. This capability is included.

RT.BAS is the receive and retransmit program. On receive, you simply choose the mode from a menu, and wait for the picture transmission to complete. As of this writing, Robot 36 and 72 modes are available in either a synchronous or a line-synced mode. Other modes (all synchronous) are Scottie 1 and 2, Martin 1 and 2, AVT90, AVT94, Wraase 96, FAX480 and weatherfax.

When receiving, if you fail to get the mode selection made in time to catch the frame sync, you can go directly to copying by pressing the keyboard's spacebar. On all but the AVT modes, the next line sync is picked up and starts the picture. The AVT modes copy out of sync. Because the program allows you to scroll horizontally across the RGB color frames, you can resync after the picture has been received. A few images have nonstandard color registration, so the program can adjust color registration after the picture is received. You also can save the picture—usually after you have scrolled the picture so the CRT screen frames just the part you want to keep.

TX.BAS is used for transmitting any picture file. When queried, you provide the mode and the file name, and after a brief pause while the picture loads, press G(o) to transmit. To avoid additional switching complexity, VOX transmitter switching is used.

VU.BAS allows you to view a picture. It has the same adjustments available as RT.BAS. One feature (applicable only to the Robot modes) is the ability to "retune" the picture (in 10-Hz increments) as you view its color balance.

<sup>1</sup> R. Campbell, "High-Performance, Single-Signal Direct-Conversion Receivers," *QST*, Jan 1993, pp 32-40. See also Feedback, *QST*, Apr 1993, p 75.

<sup>2</sup> FAR Circuits (see Address List in References chapter). The PC board is \$4.50, plus \$1.50 shipping.

<sup>3</sup> Picture quality is degraded with an interlaced display. Few, if any, newer displays are interlaced at 640×480.

## Commercial SSTV Products

All software and computer interfaces are for IBM PC with VGA display unless otherwise noted. Contact information for each of these sources appears in the Address List in the **References** chapter.

### Scan Converters

**DFM 1200 USA**—PC Boards and instructions to build a Robot 1200C clone. The builder must collect EPROM and other parts. Muneki also supplies some of the hard-to-find parts.

Donald P. Lucarelli, K8SQL

Felipe Rojas

Muneki Yamafuzi, JF3GOH

**SUPERSCAN 2001**—Similar to 1200C but with many new features such as: four image memories, built-in mouse interface, on-screen help messages, and battery back up of CMOS memory to save system parameters when power is turned off. EPROMs developed by Martin Emmerson. Available assembled and in various semi-kit options.

Jad Bashour

**Replacement EPROMs**—A brand new 1200C was capable of only the "Robot" modes. Martin supplies replacement EPROMs which add the Martin, Scottie, AVT, Wraase, and fax modes and other interesting features such as an "oscilloscope" tuning indicator. Product Reviews: Jul 1991 73 *Amateur Radio Today*, p 46 (version 4.0); *IVCA Newsletter* Fall 1991 (version 4.1); *IVCA Newsletter* Spring 1993 (version 4.2)

### Computer-based SSTV Systems

**BMK-MULTY**—Software for transmitting and receiving AMTOR, RTTY, CW, PACTOR, Audio Spectrum Analyzer, HF WEFA, and SSTV.

Schnedler Systems, AC4IW

**MFJ-1278B**—MCP for packet radio, RTTY, AMTOR, CW and so on. It is also capable of sending and receiving most popular SSTV modes with the MultiCom software.

MFJ Enterprises Inc

**Pasokon TV**—Interface to send and receive SSTV fits inside expansion slot of computer. Software supports all popular modes, automatic receive mode selection from VIS code, up to 32k simultaneous colors on screen, graphical user interface with mouse support. Article: Jan 1993 *QST*, p 20. A free demo version, called EZSSTV, is available in many of the ham radio software depositories.

Absolute Value Systems

**PC SSTV 5**—Compact separate send and receive interfaces plug into a serial port. Software supports the most popular modes, reads/writes popular image file formats, built-in text generating capability.

Software Systems Consulting

**Slow Scan II**—Software to send and receive SSTV using the popular Sound Blaster (or compatible) sound card instead

of interface dedicated to SSTV. Details: May 1993 *QEX*. A free demo version of the software is available on CompuServe: Go HAMNET, Library 6, search for "SSTV", "SLOWSC.ZIP".

Harlan Technologies

**SSTV Explorer**—Low cost, receive-only system for most popular modes. Compact interface plugs into serial port. Has graphical user interface with mouse support, automatic receive mode selection, super VGA support with up to 32768 colors. Product Review: April 1994 *QST*, p 80.

Radioware

**Viewport VGA**—External interface to send and receive plugs into printer port. Software (shareware by KA2PYJ) supports most popular modes. Construction article: 73 Aug 1992.

A&A Engineering

### Accessories and Related Software

**ART (Amiga Robot Terminal)**—Hardware interface and software to control Robot 1200C from Amiga computer. Contains paint program, multifont text, and many image processing functions. Supports Martin and Scottie EPROMs.

Thomas M. Hibben, KB9MC

**Audio Analyzer**—Software for use with the Sound Blaster. Produces frequency vs time plots of audio signals. Useful for studying SSTV signals.

Harlan Technologies

**DFM SSTV Bandpass Filter**—A bandpass filter especially designed for SSTV.

Donald Lucarelli

**GEST**—"all-in-one" SSTV utility package for the Robot 1200C. Includes paint program, text generation, special effects and image processing tools. Graphical user interface supports CGA, EGA, VGA and mouse. Controls the 1200C through parallel port.

Torontel

Royal Electronics (Canada)

**HiRes**—Paint program for use with the Robot 1200C. Has many impressive special effects and character fonts.

Tom Jenkins, N9AMR

**HiRes 32**—New version of HiRes designed specifically for use with PC-based SSTV systems. Requires VGA display adapter capable of 32768 simultaneous colors.

Tom Jenkins, N9AMR

**Robot Helper**—Robot 1200C control program for Microsoft Windows and OS/2 environments. Some features include: thumbnail previews of images on disk, dual image preview windows, fast image load and save to Robot, support for Robot or Martin EPROMs.

William Montgomery, VE3EC

**SCAN**—Software for use with Robot 1200C.

Bert Beyt, W5ZR

SLIDESH0.BAS gives you the vehicle to display a bunch of pictures as a slide show. Place SLIDESH0.BAS in a directory contained in your PATH statement so it can be called up from anywhere.

TIFCONV.BAS converts 640x480, 24-bit color, TIFF pictures into a format that can be transmitted by any of the supported SSTV modes except Robot. TIFF is a common format used to transfer higher-resolution pictures between programs. This program works with the Computer Eyes/RT<sup>4</sup> and Software Systems Consult-

<sup>4</sup> ComputerEyes R/T by Digital Vision (see Address List in **References** chapter).

ing<sup>5</sup> frame grabbers. The picture output from this program can be viewed with VU.BAS and, of course, is bound by 320x240 with 18-bit color.

LABEL.BAS allows you to add call signs and other text to the SSTV pictures. It takes any black-and-white TIFF (that is, 1-bit) file and creates a mask cutout where the black is. You can superimpose the cutout over an SSTV picture either in any color you want, or transfer a cutout of any background file you find interesting. The letters will then look like they were cut out of the background picture.

<sup>5</sup> Software Systems Consulting (see Address List in **References** chapter).

Obviously, you can use squares or circles in addition to fonts to transfer a piece of one file onto another one. Use a cheap hand scanner to capture interesting fonts you find. You can get a three-dimensional effect by painting a color through the mask, then moving the mask a few pixels and rerunning the data through LABEL with a background file or another color. Or, run several different masks through LABEL in sequence to obtain different colors or patterns on different letters.

Work with Ben Vester's system continues. Look at articles by Vester in the SSTV Bibliography and watch *QST* for more discussion.

## SUMMARY

For decades there was a convenient excuse for not trying SSTV: it cost kilobucks to buy a specialized piece of equipment. But you can't use that excuse anymore. There are several free programs that only require trivial interfaces to receive pictures. Once you get hooked, there are plenty of other home-brew projects and commercial products available at affordable prices. You need not be a computer wizard to install and use these systems.

SSTV is a rapidly changing area of Amateur Radio. In the year that this was written, the popular Robot 1200C and AEA AVT Master have been discontinued. Many new products have been introduced. For up-to-date information, look in the ARRL BBS and other Amateur Radio software archives for a file named something like "sstv\_info" or "SSTVINFORM.DOC".

## FAST-SCAN TELEVISION

Fast-scan amateur television (FSTV or just ATV) is a wide-band mode that uses standard broadcast, or NTSC, television scan rates. It is called "fast scan" only to differentiate it from slow-scan TV. In fact, no scan conversions or encoder/decoders are necessary with FSTV. Any standard TV set can display the amateur video and audio. Standard (1 V P-P into 75  $\Omega$ ) composite video from home camcorders, cameras, VCRs or computers is fed directly

into an AM ATV transmitter. The audio has a separate connector and goes through a 4.5 MHz FM subcarrier generator which is mixed with the video. This section was written by Tom O'Hara, W6ORG.

Amateurs regularly show themselves in the shack, zoom in on projects, show home video tapes, computer programs and just about anything that can be shown live or by tape (see **Figs 12.57 and 12.58**). Whatever the camera "sees" and "hears" is faithfully transmitted, including color and sound information. Picture quality is about equivalent

to that of a VCR, depending on video signal level and any interfering carriers. All of the sync and signal-composition information is present in the composite-video output of modern cameras and camcorders. Most camcorders have an accessory cable or jacks that provide separate video and audio outputs. Audio output may vary from one camera to the next, but usually it has been amplified from the built-in microphone to between 0.1 to 1 V P-P (into a 10-k $\Omega$  load).

ATV transmitters have been carried by helium balloons to above 100,000 ft, to the edge of space. The result is fantastic video transmissions, showing the curvature of the Earth, that have been received as far as 500 miles from the balloon. Small cameras have been put into the cockpits of R/C model airplanes to transmit a pilot's-eye view. Many ATV repeaters retransmit Space Shuttle video and audio from NASA during missions. This is especially exciting for schools involved with SAREX. ATV is used for public service events such as parades, races, Civil Air Patrol searches and remote damage assessment.

Emergency service coordinators have found that live video from a site gives a better understanding of a situation than is pos-

**Fig 12.57**—ATV used to communicate between students in science and computer classes peaks their interest in this video age.

**Fig 12.58**—The ATV view shows the aft end of the Space Shuttle cargo bay during mission STS-9.

**Table 12.16**

**Line-of-Sight Snow-Free 70-cm ATV Communication Distances**

This table relates transmit and receive station antenna gains to communication distances in miles for 1/10/100 W PEP at 440 MHz. To find the possible snow-free distance under line-of-sight conditions, select the column that corresponds to transmit antenna gain and the row for the receive antenna gain. Read the distance where the row and column intersect. Multiply the result by 0.5 for 902 MHz and 0.33 for 1240 MHz. The table assumes 2 dB of feed-line loss, a 3 dB system noise figure at both ends and snow-free is greater than 40 dB picture:noise ratio (most home cameras give 40 to 45 dB picture:noise; this is used as the limiting factor to define snow-free ATV pictures). The P unit picture rating system goes down about 6 dB per unit. For instance, P4 pictures would be possible at double the distances in the table.

	TX Antenna			
	0 dBd	4 dBd	9 dBd	15.8 dBd
RX Antenna				
0 dBd	0.8/2.5/8	1/3.5/11	2/7/22	5/15/47
4 dBd	1/3.5/11	2/6/19	3.5/11/34	7.5/23/75
9 dBd	2/7/22	3.5/11/34	6/19/60	13/42/130
15.8 dBd	5/15/47	7.5/23/75	13/42/130	29/91/290

sible from voice descriptions alone. Weather-radar video, WEFAX, or other computer generated video has also been carried by ATV transmitters for RACES groups during significant storms. This use enables better allocation of resources by presenting real-time information about the storm track. Computer graphics and video special effects are often transmitted to dazzle the viewers.

**How Far Does ATV Go?**

The theoretical snow-free line-of-sight distance for 10 W, given 15.8-dBd antennas and 2-dB feed-line loss at both ends, is 91 miles. (See **Table 12.16**.) However, except for temperature-inversion skip conditions, reflections, or through high hilltop repeaters, direct line-of-sight ATV contacts seldom exceed 25 miles. The RF horizon over flat terrain with a 50-ft tower is 10 miles. For best DX use low loss feed line and a broadband high-gain antenna, up as high as possible. The antenna system is the most important part of an ATV system because it affects both receive and transmit signal strength.

A snow-free, or "P5," picture rating (see **Fig 12.59**) requires at least 200  $\mu$ V (−61 dBm) of signal at the input of the ATV receiver, depending on the system noise figure and bandwidth. The noise floor increases with bandwidth. Once the receiver system gain and noise figure reaches this floor, no additional gain will increase sensitivity. At 3-MHz bandwidth the noise floor is 0.8  $\mu$ V (−109 dBm) at standard temperature. If you compare this to an FM voice receiver with 15 kHz bandwidth; there is a 23 dB difference in the noise floor. However the eye, much like the ear of experienced CW operators, can pick out sync bars in the noise below the noise floor. Sync lock and large well contrasted objects or lettering can be seen between 1 and 2  $\mu$ V. Color and subcarrier

sound come out of the noise between 2 and 8  $\mu$ V depending on their injection level at the transmitter and TV-set differences.

Two-meter FM is used to coordinate ATV contacts. Operators must take turns transmitting on the few available channels and the 2-m link allows full-duplex audio from many receiving stations to the ATV transmitting station, who is speaking on the sound subcarrier. This is great for interactive show and tell. Also it is much easier to monitor a squelched 2-m channel using an omni antenna rather than searching out each station with a beam. Depending on the third-harmonic relationship to the video on 70 cm, 144.34 MHz and 146.43 MHz (simplex) are the most popular frequencies; they are often mixed with the subcarrier sound on ATV repeater outputs.

**Getting the Picture**

Since the 70-cm band corresponds to cable channels 57 through 61, seeing your first ATV picture may be as simple as connecting a good outside 70-cm antenna (aligned for the customary local polarization) to a cable-ready TV set's antenna input jack. Cable channel 57 is 421.25 MHz, and each channel is progressively 6 MHz higher. (Note that cable and broadcast UHF channel frequencies are different.) Check the *ARRL Repeater Directory* for a local ATV repeater output that falls on one of these cable channels. Cable-ready TVs may not be as sensitive as a low-noise downconverter designed just for ATV, but this technique is well worth a try.

Most stations use a variable tuned downconverter specifically designed to convert the whole amateur band down to a VHF TV channel. Generally the 400 and 900 MHz bands are converted to TV channel 3 or 4, whichever is not used in the area. For

**P5—Excellent**

**P4—Good**

**P3—Fair**

**P2—Poor**

**P1—Barely perceptible**  
**Fig 12.59—An ATV quality reporting system.**

1200 MHz converters, channels 7 through 10 are used to get more image rejection. The downconverter consists of a low-noise preamp, mixer and tunable or crystal-controlled local oscillator. Any RF at the input comes out at the lower frequencies. All signal processing is done in the TV set. A complete receiver with video and audio output would require all the TV sets circuitry, less the sweep and CRT components. There is no picture-quality gain by going direct from a receiver to a video monitor (as compared with a TV set) because IF and detector bandwidth are still the limiting factors.

A good low-noise amateur downconverter with 15 dB gain ahead of a TV set will give sensitivity close to the noise floor. A preamp located in the shack will not significantly increase sensitivity, but rather will reduce dynamic range and increase the probability of intermod interference. Sensitivity can be increased by increasing antenna-system gain: reducing feed-line loss, increasing antenna gain or adding an antenna mounted preamp (which will eliminate the coax loss plus any loss through transmit linear amplifier TR relays). Remember that each 6 dB increase in combination of transmitted power, reduced coax loss, antenna gain or receiver sensitivity can double the line-of-sight distance.

Foliage greatly attenuates the signal at UHF, so place antennas above the tree tops for the best results. Beams made for 432-MHz weak-signal work or 440-MHz FM may not have enough SWR bandwidth to cover all the ATV frequencies for transmitting, but they are okay for reception. A number of manufacturers now make ATV beam antennas to cover the whole band from 420 to 450 MHz. Use low-loss coax (such as Belden 9913: 2.5 dB/100 ft at 400 MHz) or Hardline for runs over 100 ft. All outside connectors must be weatherproofed with tape or coax sealer; any water that gets inside the coax will greatly increase the attenuation. Almost all ATV antennas use N connectors, which are more resistant to

moisture contamination than other types.

Antenna polarization varies from area to area. Technically, the polarization should be chosen to give additional isolation (up to 20 dB) from other users near the channel. It is more common to find that the polarity was determined by the first local ATV operators (which antennas they had in place for other modes). Generally, those on 432 MHz SSB and weak-signal DX have horizontally polarized antennas, and those into FM, public service or repeaters will have vertical antennas. Check with local ATV operators before permanently locking down the antenna-mast clamps. Circularly polarized antennas let you work all modes, including satellites, with only 3 dB sacrificed when working a fixed polarity.

### ATV Frequencies

Standard broadcast TV channels are 6 MHz wide to accommodate the composite video, 3.58 MHz color and 4.5 MHz sound subcarriers. (See Fig 12.60.) Given the NTSC 525 horizontal line and 30 frames per second scan rates, the resulting horizontal resolution bandwidth is 80 lines per MHz. Therefore, with the typical TV set's 3-dB rolloff at 3 MHz (primarily in the IF filter), up to 240 vertical black lines can be seen. Color bandwidth in a TV set is less than this, resulting in up to 100 color lines. Lines of resolution are often confused with the number of horizontal scan lines per frame. The video quality should be every bit as good as on a home video recorder.

The lowest frequency amateur band wide enough to support a TV channel is 70 cm (420 - 450 MHz), and it is the most popular. With transmit power, antenna gains and coax losses equal, decreasing frequency increases communication range. The 33-cm band goes half the distance that 70 cm does, but this can be made up to some extent with high-gain antennas, which are physically smaller at the higher frequency. A Technician class or higher license is required to transmit ATV on this band, and Novices can transmit ATV only in the 1270 to 1295 MHz segment of the 23-cm band.

Depending on local bandplan options, there is room for no more than two simultaneous ATV channels in the 33- and 70-cm bands without interference. Unlike cable channels, broadcast TV signals must skip a channel to keep a strong adjacent channel signal from interfering with a weaker on-channel signal. Cable companies greatly filter and equalize the signal amplitudes in order to use every channel.

Generally, because only two channels are available in the 70-cm band, an ATV repeater input on 439.25 or 434.0 MHz is shared with simplex. 421.25 MHz is the most popular in-band repeater output frequency.

At least 12 MHz of separation is necessary for in-band repeaters because of filter-slope attenuation characteristics and TV-set adjacent-channel rejection. Some repeaters have their output on the 33-cm or 23-cm (the 923.25 and 1253.25 MHz output frequencies are most popular) bands which frees up a channel on 70 cm for simplex. Such cross-band repeaters also make it easier for the transmitting operator to monitor the repeated video with only proper antenna separation to prevent receiver desensitization. 426.25 MHz is used for simplex, public service and R/C models in areas with cross-band repeaters, or as a alternative to the main ATV activities on 434.0 or 439.25 MHz. Before transmitting, check with local ATV operators, repeater owners and frequency coordinators listed in the *ARRL Repeater Directory* for the coordinated frequencies used in your area.

Since a TV set receives a 6-MHz bandwidth, ATV is more susceptible to interference from many other sources than are narrower modes. Interference 40 dB below the desired signal can be seen in video. Many of our UHF (and above) amateur bands are shared with radar and other government radio positioning services. These show up as horizontal bars in the picture. Interference from amateurs who are unaware of the presence of the ATV signal (or in the absence of a technically sound and publicized local band plan) can wipe out the sound or color or put diagonal lines in the picture.

### DSB and VSB Transmission

While most ATV is double sideband (DSB) with the widest component being the sound subcarrier out plus and minus 4.5 MHz, over 90% of the spectrum power is in the first 1 MHz on both sides of the carrier for DSB or VSB (vestigial sideband). As can be seen in Fig 12.61, the video power density is down more than 30 dB at frequencies greater than 1 MHz from

**Fig 12.60**—A 6-MHz video channel with the video carrier 1.25 MHz up from the lower edge. The color subcarrier is at 3.58 MHz and the sound subcarrier at 4.5 MHz above the video carrier.

**Fig 12.61**—A spectrum-analyzer photo of a color ATV signal. Each vertical division represents 10 dB; horizontal divisions are 1 MHz. Spectrum power density varies with picture content, but typically 90% of the sideband power is within the first 1 MHz.

the carrier. DSB and VSB are both compatible with standard TV receivers, but the lower sound and color subcarriers are rejected in the TV IF filter as unnecessary. In the case of VSB, less than 5% of the lower sideband energy is attenuated. The other significant energy frequencies are the sound (set in the ATV transmitter at 15 dB below the peak sync) and the color at 3.58 MHz (greater than 22 dB down).

Narrow-band modes operating greater than 1 MHz above or below the video carrier are rarely interfered with or know that the ATV transmitter is on unless the narrow-band signal is on one of the subcarrier frequencies or the stations are too near one another. If the band is full and the lower sideband color and sound subcarrier frequencies need to be used by a dedicated link or repeater, a VSB filter in the antenna line can attenuate them another 20 to 30 dB, or the opposite antenna polarization can be used for more efficient packing of the spectrum. Since all amateur linear amplifiers re-insert the lower sideband to within 10 dB of DSB, a VSB filter in the antenna line is the only cost-effective way to reduce the unnecessary lower sideband subcarrier energy if more than 1 W is used. In the more populated areas, 2-m calling or coordination frequencies are often used to work out operating time shifts, and so on, between all users sharing or overlapping the same segment of the band.

### ATV Identification

ATV identification can be on video or the sound subcarrier. A large high-contrast call-letter sign on the wall behind the operating table in view of the camera is the easiest way to fulfill the requirement. Transmitting stations fishing for DX during band openings often make up call-ID signs using fat black letters on a white background to show up

best in the snow. Their city and 2-m monitoring frequency are included at the bottom of the sign to make beam alignment and contact confirmation easier.

Quite often the transmission time exceeds 10 minutes, especially when transmitting demonstrations, public-service events, space-shuttle video, balloon flights or a videotape. A company called High Technology Flight makes the GVID video-overlay board that automatically superimposes white call letters over the camera video every nine

minutes to meet the FCC identification requirement (see Fig 12.62). They even have versions that accept data from GPS receivers, altitude and temperature sensors and other devices that are overlaid on the camera video. The PC Electronics VOR-2 board has an automatic nine-minute timer, but it also has an end-of-transmission hang timer that switches to another video source for ID. While this module is normally used to switch in an Eltronics VDG-1 video ID generator at ATV repeaters, it can also be used at the home station with any other video source, such as a color computer or second camera, for automatic video ID.

### A 10-W ATV Transceiver

Many newcomers to ATV start out by buying an inexpensive downconverter board just to check out the local simplex or repeater activity. Once they see a picture it isn't long before they want to transmit. The downconverter board can be kept separate or put in a larger chassis with

Fig 12.63—A is the front view of a complete ATV transceiver and B is the inside view. This complete 10-W 70-cm ATV transceiver is assembled from readily available built and tested modules and mounted in a Hammond 1590F die-cast aluminum enclosure. On the box floor, left to right: TVC-2G downconverter, FMA5-F 4.5-MHz sound subcarrier generator and TXA5-70 80-mW exciter/video modulator. On the back (top left) is the downconverter-to-TV F connector and a 4-pin mic jack (which serves as the +13.8 V dc input). To the right is the DMTR TR relay board mounted to a flanged N connector. On the inside in front of the heatsink is the PA5 10-W power-amplifier module using a Toshiba SAU4.

Fig 12.62—A photo of an ATV image of the Space Shuttle interior with K6KMN's repeater ID overlaid. Automatic video overlay in the picture easily solves the 10-minute ID requirement for Space Shuttle retransmissions and other long transmissions.

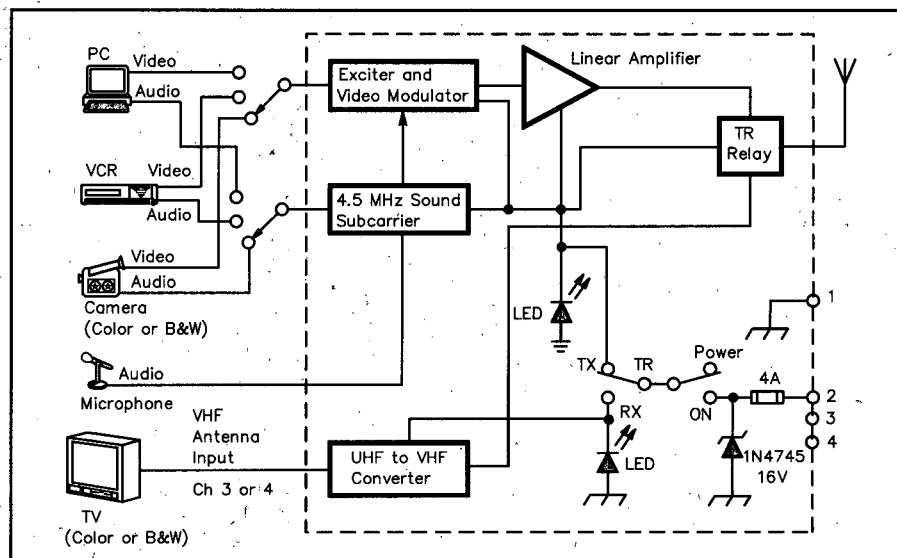

Fig 12.64—Block diagram of a complete ATV station using the 10-W transceiver.

**Fig 12.65—An ATV waveform.** Camera and corresponding transmitter RF output power levels during one horizontal line scan for black-and-white TV. (A color camera would generate a “burst” of 8 cycles at 3.58 MHz on the back porch of the blanking pedestal.) Note that “black” corresponds to a higher transmitter output power than does “white.” For the purposes of blanking pedestal setup with a RF power meter rather than an oscilloscope, the 75% PEV corresponds to slightly less than 60% power.

transmitter boards to make one convenient package, as shown in Fig 12.63. All the modules shown here are available wired and tested from PC Electronics and are also functionally representative of what is available from other suppliers. Fig 12.64 shows a block diagram of this transceiver.

The complete 10-W ATV transceiver consists of the

- TVC-2G downconverter (420 - 450 MHz in, TV channel 2, 3 or 4 out)
- TXA5-70 80 mW exciter/modulator
- FMA5-F 4.5-MHz sound subcarrier generator
- PA5-70 10-W brick linear amplifier
- DMTR video detector, video monitor driver and TR relay modules.

The modules must be mounted in an aluminum enclosure for RF shielding and heat sinking. A 2.5×7×7-inch or larger aluminum chassis and bottom cover will make a nice transceiver. The Hammond 1590F diecast aluminum box makes a more rugged and RF tight enclosure. Lay all the modules in the selected chassis to position for best fit before drilling the mounting holes. Board wiring and mounting layouts come with each module.

Mount the PA5-70 amplifier and DMTR TR relay on the back panel, with the Toshiba SAU4 RF power module as low as possible for best air flow. Unscrew the power module and its board from the heatsink and poke through the four mounting holes and a piece of paper with a pencil. Use this as a template to center punch the

drill locations on the chassis from the outside. Make sure the heatsink will mount at least 1/8" above the bottom edge of the chassis. Drill the 3/16-diam holes and carefully debur each side. The SAU4 must be on a perfectly flat surface or the ceramic substrate could crack when its mounting bolts are tightened. Use a thin layer of heatsink compound under both the SAU4 and the heatsink. Mount the SAU4 and its board inside the chassis, and the heatsink outside by running the four screws from the SAU4 side through the chassis into the heatsink.

The DMTR TR relay board mounts directly on a flange NUG58 chassis connector. Use RG-174 (small 50-Ω coax) for the RF leads to the amplifier and downconverter modules. To minimize RF coupling inside the chassis, carefully dress the coax braid back over its outer insulation (no more than 1/4 inch) and solder the shield directly to the board ground planes. When soldering, make sure there are no bends or stress on the coax. Do not twist the braid into a “pig tail” at UHF.

A four-pin mic jack is used for the +13.8 V dc power connector. It is wired through a 4 A fast-acting fuse to the SPST power switch. The two unused pins can be used to control or power external devices such as a camera. A 1N4745A 16-V, 1-W Zener diode is connected from the transceiver side of the fuse to ground to help protect the circuits in case of accidental or reverse voltage. The downconverter, exciter and subcarrier generator can be mounted inside the chassis with #4-40×1/2 screws with double nuts for spac-

ers (see module board mounting detail). Again, keep the exposed length of the interconnecting RG-174 center conductor less than 1/4 inch. Solder the coax carefully and check with an ohmmeter for shorts. Use #18 wire for the amplifier power leads and #22 solid wire for all of the other wiring. Dress all dc leads away from the RF coaxes and the power module. The video and audio leads, and the panel-pot connections, can be #22 twisted pair (up to 6 inches long). Use RG-174 for longer runs.

You may want to remove and change some of the board mounted trimpots to panel mounted potentiometers to make adjustments easier. (For example, the video gain on the exciter, the mic and line gain on the sound subcarrier board, and the down-converter frequency tuning may be changed.) Remove the trimpots and run three wires from the mounting holes to their respective carbon (no wire wounds as they are inductive at video frequencies) panel potentiometers. 100-Ω carbon panel controls for the video gain are difficult to find, but they are available from PC Electronics.

For RF purposes, bypass each video input connector (100-pF ceramic disc capacitor) and each audio connector (220-pF disc) directly at the connector with short leads.

Most camcorders use phono jacks for the composite-video and line-audio connections. A low-impedance mic with push-to-talk can be used in parallel with the camera or VCR audio, which is mixed in the sound subcarrier board and the transmit receive toggle switch. An F connector on the back panel supplies downconverter output to the TV set antenna input. Use 75-Ω coax for the line to the TV. (300-Ω twin lead picks up too much interference from strong adjacent-channel broadcast TV stations.) Do not put any other boards inside the chassis that might be RF susceptible.

### Transceiver Checkout

Use an ohmmeter to verify that there are no short circuits in the coax or +13.8 V dc leads. (The antenna input will show a short because of the stripline tuned circuit.) Connect a good resonant 70-cm antenna, do not run a piece of wire or other band antenna just to try it out. With the transceiver off, connect the downconverter output coax to the TV set antenna jack. Switch the TV set on and select a channel that is not used in your area, usually 3 or 4. Adjust the fine tuning for minimum adjacent-channel interference. Then turn on the transceiver and adjust the downconverter tuning for a known nearby ATV station that you have contacted on 2 m. Peak the input trimmer cap on the TR relay board for minimum snow.

Next, with no video connected, switch the

transmitter on for no more than 10 seconds at a time while verifying that you have less than 1 W of reflected power (as shown by an RF power meter in the antenna line). Continued transmission into an SWR of more than 2:1 can damage the SAU4 power module. If the SWR is low, peak the trimmer cap on the DMTR board for maximum output, then proceed to set the blanking pedestal pot on the TXA5-70 exciter.

ATV is a complex waveform that requires that the video to sync ratio remains constant throughout all of the linear amplifiers and with camera contrast changes (see Fig 12.65). The modulator contains a blanking clamp circuit that also acts as a sync stretcher to compensate for amplifier gain compression. To set this level, the pedestal control is set to maximum power output and then backed off to 60% of that value. The sync tip, which is the peak power, is constant at the maximum power read and the blanking level is the 60% point. This procedure must be repeated anytime a different power amplifier is added or applied voltage is changed by more than 0.5 V. Any other RF power measurements with an averaging power meter under video modulation are meaningless.

The camera video can now be connected, and the video gain set for best picture as described by the receiving station (or by observing a video monitor connected to the output jack on the DMTR board). Be careful not to overmodulate. Overmodulation is indicated by white smearing in the picture and sync buzz in the audio.

Connect a low-impedance (150  $\Omega$  to 600  $\Omega$ ) dynamic mic (Radio Shack has some tape recorder replacements with a push-to-talk switch) into the mic jack and adjust the audio gain to a comfortable level as described by the receiving station. Electret mics are not good for this application because they are more susceptible to RF pickup (symptom: sync buzz in the audio).

**Fig 12.66—An oscilloscope used to observe a video waveform. The lower trace is the video signal as it comes out of the sync stretcher. The upper trace is the signal from the Mirage D1010-N amplifier.**

RF pickup may also be a problem with inadequately shielded mic cords. For example, it may be necessary to replace a cord having a spiral wrapped shield with one that has a braided shield, in order to improve shielding at UHF. The FMA5-F board has a soft limiter that comes in at the standard 25-kHz deviation.

The line-audio input has an independent volume control for the camcorder amplified mic or VCR audio, which is mixed with the low impedance mic input. This feature is great for voice-over commenting during video tapes.

### Driving Amplifiers with ATV

Wide-band AM video requires some special design considerations for linear amplifiers (as compared to those for FM and SSB amplifiers). Many high-power amateur amplifiers would oscillate (and possibly self destruct) from high gain at low frequencies if they were not protected by feedback networks and power RF chokes. These same stability techniques can affect some of the 5-MHz video bandwidth. Sync, color and sound can be very distorted unless the amplifier has been carefully designed for both stability and AM video modulation.

Mirage, RF Concepts and Down East Microwave either make special ATV amplifiers or offer standard models that were designed for all modes, including ATV. Basically the collector and base bias supplies have a range of capacitors to keep the voltage constant under modulation while at the same time using the minimum-value low-resistance series inductors or chokes to prevent self oscillation.

Almost all amateur linear power amplifiers have gain compression from half to their full rated peak envelope power. To compensate for this, the ATV exciter/modulator has a sync stretcher to maintain the proper transmitted video to sync ratio (see Fig 12.66). With both video and sound subcarrier disconnected, the pedestal control is set for maximum power output. Peak sync should first be set to 90% of the rated peak envelope power. (This is necessary to give some head room for the 4.5 MHz sound that is mixed and adds with the video waveform.) The TXA5-70 exciter/modulator has a RF power control to set this. Once this is done, the blanking pedestal control can be set to 60% of the peak sync value. For example, a 100-W amplifier would first be set for 90 W with the RF power control and then 54 W with the pedestal control. Then the sound subcarrier can be turned back on and the video plugged in and adjusted for best picture. If you could read it on a peak-reading power meter made for video, the power is between 90 and 100 W PEP. On a dc oscilloscope connected to a RF diode detector in

the antenna line, it can be seen that the sync and blanking pedestal power levels remain constant at their set levels regardless of video gain setting or average picture contrast. On an averaging meter like a Bird 43, however, it is normal to read something less than the pedestal set up power.

### ATV Repeaters

Basically there are two kinds of ATV repeaters: in band and cross band. 70-cm in-band repeaters are more difficult to build and use, yet they are more popular because equipment is more available and less expensive. Indeed, cable-ready TV sets tune the 70-cm band with no modifications.

Why are 70-cm repeaters more difficult to build? The wide bandwidth of ATV makes for special filter requirements. Response across the 6-MHz passband must be as flat as possible with minimum insertion loss, but also must sharply roll off to reject other users as little as 12 MHz away. Special multipole interdigital or combline VSB filters are used to meet the requirement. An ATV duplexer can be used to feed one broadband omnidirectional antenna, but an additional VSB filter is needed in the transmitter line for sufficient attenuation of noise and IMD products.

A cross-band repeater, because of the great frequency separation between the input and output, requires less sophisticated filtering to isolate the transmitter and receiver. In addition, a cross-band repeater makes it easier for users to see their own video (no duplexer is needed, only sufficient antenna spacing). Repeater linking is easier too, if the repeater outputs alternate between the 23- and 33-cm bands.

Fig 12.67 shows a block diagram for a simple 70-cm in-band repeater. No duplexer is shown because the antennas and VSB filters provide adequate isolation. The repeater transmitter power supply should be separate from the receiver and exciter supply. ATV is amplitude modulated, therefore the current varies greatly from maximum at the sync tip to minimum during white portions of the picture. Power supplies are not generally made to hold tight regulation with such great current changes at rates up to several megahertz. Even the power supply leads become significant inductors at video frequencies; they will develop a voltage across them that can be transferred to other modules on the same power-supply line.

To prevent unwanted key up from other signal sources, ATV repeaters use a video operated relay (VOR). The VOR senses the horizontal sync at 15,734 Hz in much the same manner that FM repeaters use CTCSS tones. Just as in voice repeaters, an ID timer monitors VOR activity and

starts the repeater video ID generator every nine minutes or a few seconds after a user stops transmitting.

## Frequency Modulated ATV (FMATV)

While AM is the most popular mode because of greater equipment availability, lower cost, less occupied bandwidth and use of a standard TV set, FMATV is gaining interest among experimenters and also repeater owners for links. FM on the 1200-MHz band is the standard in Europe because there is little room for video in their allocated portion of the 70-cm band. FMATV occupies 17 to 21 MHz depend-

ing on deviation and sound subcarrier frequency. The US 70-cm band is wide enough but has great interference potential in all but the less populated areas. Most available FMATV equipment is made for the 1.2, 2.4 and 10.25-GHz bands. Fig 12.68 is a block diagram of an FMATV receiver.

The US standard for FMATV is 4 MHz deviation with the 5.8-MHz sound subcarrier set to 10 dB below the video level. 1252 or 1255 MHz are suggested frequencies in order to stay away from FM voice repeaters and other users higher in the band while keeping sidebands above the 1240-MHz band edge. Using the US

standard with Carsons rule for FM occupied bandwidth, it comes out to just under 20 MHz. So 1250 MHz would be the lowest possible frequency. Almost all modern FMATV equipment is synthesized, but if yours is not, use a frequency counter to monitor the frequency for warm up drift. Check with local frequency coordinators before transmitting because the band plan permits other modes in that segment.

Experimentally, using the US standard, FMATV gives increasingly better picture-to-noise ratios than AMATV at receiver input signals greater than 5  $\mu$ V. Because of the wider noise bandwidth and FM threshold effect, AM video can be seen in

Fig 12.67—A block diagram of a 70-cm in-band ATV repeater. The antennas are Diamond omnidirectional verticals, which require 20 ft (minimum) of separation to prevent receiver desensitization. The filters are made by International Crystal Mfg; they have the proper VSB band-pass characteristics and only 1 dB insertion loss. The receiver, 1-W transmitter and VOR are made by PC Electronics. The Communications Specialists DTD-1 DTMF decoder and ID8 Morse identifier (optional if a video ID is used) are used to remotely turn the repeater transmitter on or off and to create a CW ID, respectively. More elaborate control and ID can be substituted.

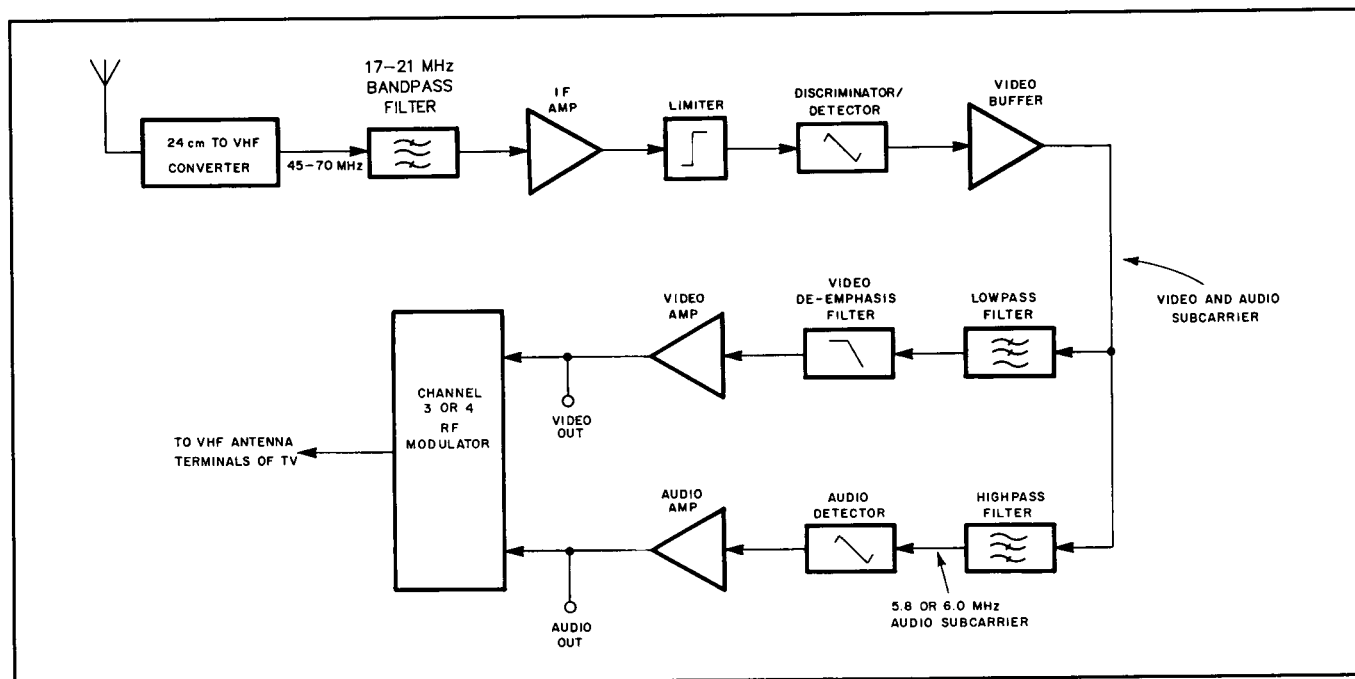

Fig 12.68—Block diagram of an FMATV receiver.

the noise well before FM. For DX work, it has been shown that AM signals are recognizable signals in the snow at four times (12 dB) greater distance than FM signals with all other factors equal. Above the FM threshold, however, FM rapidly overtakes AM; snow-free pictures occur above 50  $\mu\text{V}$ , or 4 times farther away than with AM signals. The crossover point is near the signal level where sound and color begin to appear for both systems. **Fig 12.69** compares AM and FMATV across a wide range of signal strengths.

To receive FMATV, a downconverter is connected to a FM video receiver, which in turn drives a video monitor. There are companies that make FMATV receivers to the amateur 4-MHz deviation and 5.8-MHz sound standards. Many hams have modified surplus satellite receivers by adding video amplifiers, however. The satellite receivers are made for 11-MHz deviation. Some satellite LNBS can tune the 1240-1300 MHz band directly.

**Fig 12.69—Two approaches to ATV receiving.** This chart compares AM (A) and FM (F) ATV as seen on a TV receiver and monitor. Signal levels are into the same downconverter with sufficient gain to be at the noise floor. The FM receiver bandwidth is 17 MHz, using the US standard.

# Radio Control

Amateur Radio gave birth to the radio control (R/C) hobby as we know it today. Part 97 of the FCC regulations (§97.215) specifically permits "remote control of model craft" as a licensed amateur station activity. Station identification is not required for R/C, and the transmitter power is limited to 1 W. Before 1950, development of telecommand radio systems small enough to be used for remote radio control of model aircraft, cars and boats, was primarily an Amateur Radio activity. In the early 1950s, the FCC licensed R/C transmitter operation on nonham frequencies, without an operator license examination. The invention of the transistor and the subsequent increase in R/C development activity lead to the sophisticated electronic control systems in use today. This section was contributed by H. Warren Plohr, W8IAH.

The simplest electronic control systems are currently used in low-cost toy R/C models. These toys often use simple on/off switching control that can be transmitted by on/off RF carrier or tone modulation. More expensive toys and R/C hobby models use more sophisticated control techniques. Several simultaneous proportional and switching controls are available, using either analog or digital coding on a single RF carrier.

R/C hobby sales records show that control of model cars is the most popular segment of the hobby. Battery powered cars like that shown in **Fig 12.70** are the most popular. Other popular types include models powered by small internal combustion "gas" engines.

R/C model aircraft are next in the line of popularity and include a wide range of styles and sizes. Fixed-wing models like those shown in **Fig 12.71** are the most popular. They can be unpowered (gliders) or powered by either electric or "gas" motors. The basic challenge for a new model pilot is to operate the model in flight without crashing. Once this is achieved, the challenge extends to operating detailed scaled models in real-

istic flight, performing precision aerobatics, racing other models or engaging in model-to-model combat. The challenge for the R/C glider pilot is to keep the model aloft in rising air currents. The most popular rotary-wing aircraft models are helicopters. The sophistication of model helicopters and their control systems can only be appreciated when one sees a skilled pilot perform a schedule of precision flight maneuvers. The most exotic maneuver is sustained inverted flight, a maneuver not attainable by a full-scale helicopter

R/C boats are another facet of the hobby. R/C water craft models can imitate full-scale ships and boats. From electric motor powered scale warships that engage in scale battles, to "gas" powered racing hydroplanes, model racing yachts and even submarines.

Most R/C operation is no longer on Amateur Radio frequencies. The FCC currently authorizes 91 R/C frequencies between 27 MHz and 76 MHz. Some frequencies are for all models, some are for aircraft only and others for surface (cars, boats) models only. Some frequencies are used primarily for toys and others for hobbyist models. Amateur Radio R/C operators use the 6-m band almost exclusively. Spot frequencies in the upper part of the band are used in geographical areas where R/C operation is compatible with 6-m repeater operation and TV Channel-2 signals that can interfere with control. Eight spot frequencies, 53.1 to 53.8 MHz, spaced 100 kHz apart, are used. There is also a newer 200 kHz R/C band from 50.8 to 51.0 MHz providing ten channels spaced 20 kHz apart. The close channel spacing in this band requires more selective receivers than do the 53-MHz channels. The *AMA Membership Manual* provides a detailed list of all R/C frequencies in current use.<sup>7</sup>

<sup>7</sup>Academy of Model Aeronautics *Membership Manual* is available from AMA, Muncie, IN 47302.

The *ARRL Repeater Directory* lists current Amateur Radio R/C frequencies.

**Fig 12.72** shows a typical commercial R/C system, consisting of a hand-held aircraft transmitter (A), a multiple-control receiver, four control servos and a battery (B). This particular equipment is available for any of the ten R/C frequencies in the 50.80 to 51.00 MHz band. Other commercially available control devices include

**Fig 12.71**—Photo of two R/C aircraft models.

(A)

(B)

**Fig 12.70**—Photo of three R/C model electric cars.

relays (solid-state and mechanical) and electric motor speed controllers.

Some transmitters are tailored to specific kinds of models. A helicopter, for example, requires simultaneous control of both collective pitch and engine throttle. A model helicopter pilot commands this response with a linear motion of a single transmitter control stick. The linear control stick signal is conditioned within the transmitter to provide the encoder with a desired combination of nonlinear signals. These signals then command the two servos that control the vertical motion of the helicopter.

Transmitter control-signal conditioning is provided by either analog or digital circuitry. The signal conditioning circuitry is often designed to suit a specific type of model, and it is user adjustable to meet an individual model's control need. (Low-cost transmitters use analog circuitry.) They are available for helicopters, sailplanes and pattern (aerobatic) aircraft.

More expensive transmitters use digital microprocessor circuitry for signal conditioning. **Fig 12.73** shows a transmitter that uses a programmable microprocessor. It is available on any 6-m Amateur Radio R/C frequency with switch-selectable PPM or PCM coding. It can be programmed to suit the needs of a helicopter, sailplane or pattern aircraft. Nonvolatile memory retains up to four user-programmed model configurations.

Many R/C operators use the Amateur Radio channels to avoid crowding on the nonham channels. Others do so because they can operate home-built or modified R/C transmitters without obtaining FCC type acceptance. Still others use commercial R/C hardware for remote control purposes around the shack. Low-cost R/C servos are particularly useful for remote actuation of tuners, switches and other devices. Control can be implemented via RF or hard wire, with or without control multiplexing.

## R/C RF MODULATION

The coded PPM or PCM information for R/C can modulate an RF carrier via either amplitude- or frequency-modulation techniques. Commercial R/C systems use both AM and FM modulation for PPM, but use FM exclusively for PCM.

The AM technique used by R/C is 100% "down modulation." This technique switches the RF carrier off for the duration of the PPM pulse, usually 250 to 350  $\mu$ s. A typical transmitter design consists of a third-overtone transistor oscillator, a buffer amplifier and a power amplifier of about  $\frac{1}{2}$  W output. AM is achieved by keying the 9.6-V supply to the buffer and

final amplifier.

The FM technique used by R/C is frequency shift keying (FSK). The modulation is applied to the crystal-oscillator stage, shifting the frequency about 2.5 or 3.0 kHz. The direction of frequency shift, up or down with a PPM pulse or PCM code, can be in either direction, as long as the receiver detector is matched to the transmitter. R/C manufacturers do not standardize, so FM receivers from different manufacturers may not be compatible.

## SIGNALING TECHNIQUES

### Background

Radio control (R/C) of models has used many different control techniques in the past. Experimental techniques have included both frequency- and time-division multiplexing, using both electronic and mechanical devices. Most current systems use time-division multiplexing of pulse-width information. This signaling technique, used by hobbyist R/C systems, sends pulse-width information to a remotely located pulse-feedback servomechanism. Servos were initially developed for R/C in the 1950s and are still used today in all but low-cost R/C toys.

**Fig 12.74** is a block diagram of a pulse-feedback servo. The leading edge of the input pulse triggers a linear one-shot multivibrator. The width of the one-shot output pulse is compared to the input pulse. Any pulse width difference is an error signal that is amplified to drive the motor. The motor drives a feedback potentiometer that controls the one-shot timing. When this feedback loop reduces the error signal to a few microseconds, the drive motor stops. The servo position is a linear function of the input pulse width. The motor-drive electronics are usually timed for pulse repetition rates of 50 Hz or greater and a pulse width range of 1 to 2 ms. A significantly slower repetition rate reduces the servomechanism slew rate but not the position accuracy.

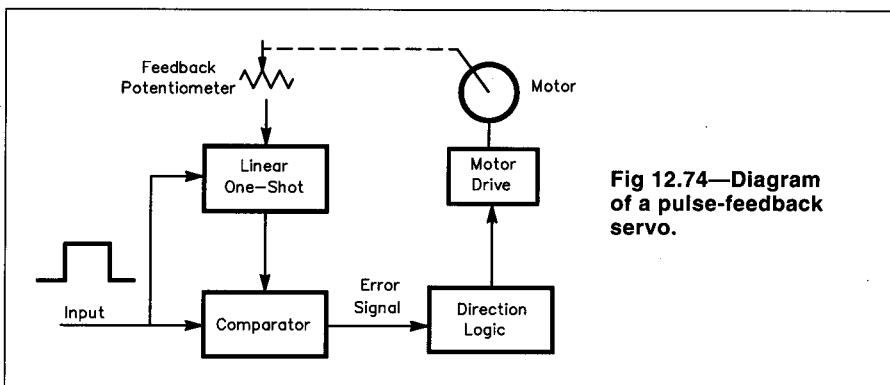

In addition to motor driven servos, the concept of pulse-width comparison can be used to operate solid-state or mechanical relay switches. The same concept is used in solid-state proportional electric motor speed controllers. These speed controllers are used to operate the motors powering model cars, boats and aircraft. Currently available model speed controllers can handle tens of amperes of direct current at voltages up to 40 V dc using MOSFET semiconductor switches.

### Requirements

The signaling technique required by R/C is the transmission of 1- to 2-ms-wide pulses with an accuracy of  $\pm 1 \mu$ s at repetition rates of about 50 Hz. A single positive-going dc pulse of 3 to 5 V amplitude can be hard wire transmitted successfully to operate a single control servomechanism. If such a pulse is sent as modulation of an RF carrier, however, distortion of the pulse width in the modulation/demodulation process is often unacceptable.

**Fig 12.73—Photo of Airtronics Infinity 660 R/C aircraft transmitter.**

**Fig 12.74—Diagram of a pulse-feedback servo.**

Consequently, the pulse-width information is usually coded for RF transmission. In addition, most R/C systems require pulse-width information for more than one control. Time-division multiplexing of each control provides this multichannel capability. Two coding techniques are used to transfer the pulse-width information for multiple control channels, pulse-position modulation (PPM) and pulse-code modulation (PCM).

### Pulse-Position Modulation

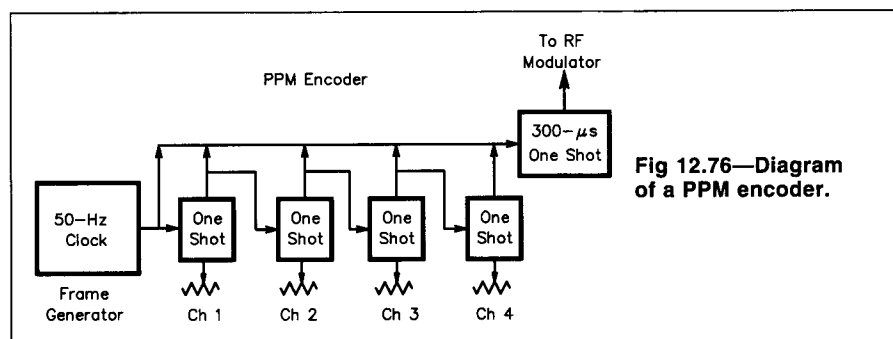

PPM is analog in nature. The timing between transmitted pulses is an analog of

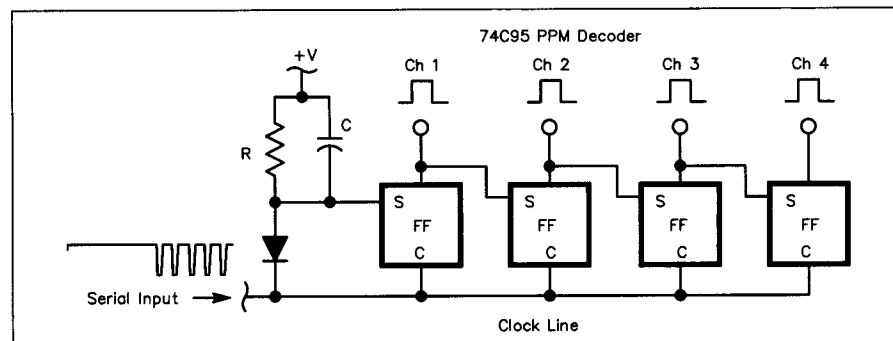

**Fig 12.75—Diagram of a four-channel PPM RF envelope.**

the encoded pulse width. A train of pulses encodes multiple channels of pulse-width information as the relative position or timing between pulses. Therefore the name, pulse-position modulation. The transmitted pulse is about 300  $\mu$ s in width and uses slow rise and fall times to minimize the transmitter RF bandwidth. The shape of the received waveform is unimportant because the desired information is in the timing between pulses. **Fig 12.75** diagrams a frame of five pulses that transmits four control channels of pulse-width information. The frame of modulation pulses is clocked at 50 Hz for a frame duration of 20 ms. Four multiplexed pulse widths are encoded as the times between five 300- $\mu$ s pulses. The long period between the first and the last pulse is used by the decoder for control-channel synchronization.

PPM is often incorrectly called digital control because it can use digital logic circuits to encode and decode the control pulses. A block diagram of a typical encoder is shown in **Fig 12.76**. The 50-Hz clock frame generator produces the first 300- $\mu$ s modulation pulse and simultaneously triggers the first one-shot in a

**Fig 12.76—Diagram of a PPM encoder.**

**Fig 12.77—Diagram of a 74C95 PPM decoder.**

chain of multivibrators. The trailing edge of each one-shot generates a 300- $\mu$ s modulation pulse while simultaneously triggering the succeeding multivibrator one-shot. In a four-channel system the fifth modulation pulse, which indicates control of the fourth channel, is followed by a modulation pause that is dependent on the frame rate. The train of 300- $\mu$ s pulses are used to modulate the RF.

Received pulse decoding can also use digital logic semiconductors. **Fig 12.77** shows a simple four-control-channel decoder circuit using a 74C95 CMOS logic IC. The IC is a 4-bit shift register operated in the right-shift mode. Five data pulses spaced 1 to 2 ms apart, followed by a synchronization pause, contain the encoded pulse-width information in one frame. During the sync pause, the RC circuit discharges and sends a logic-one signal to the 74C95 serial input terminal. Subsequent negative going data pulses remove the logic-one signal from the serial input and sequentially clock the logic one through the four D-flip-flops. The output of each flip-flop is a positive going pulse, with a width corresponding to the time between the clocking pulses. The output of each flip-flop is a demultiplexed signal that is used to control the corresponding servo.

### Pulse Code Modulation

PCM uses true digital code to transfer R/C signals. The pulse width data of each control channel is converted to a binary word. The digital word information of each control channel is coded and multiplexed to permit transmission of multiple channels of control on a single RF carrier. On the receiving end, the process is reversed to yield the servo control signals.

There is no standard for how the digital word is coded for transmission. Therefore PCM R/C transmitters and receivers from different makers are not interchangeable. Some older PCM systems provide only 256 discrete positions for 90° of servo motion, thereby limiting servo resolution. Newer systems use more digital bits for each word and provide smooth servo motion with 512 and 1024 discrete positions. All PCM and PPM systems use the same servo input-signal and supply voltages. Therefore the servos of different manufacture are interchangeable once compatible wiring connectors have been installed.

# Spread Spectrum

This introduction to spread spectrum communications was written by André Kesteloot, N4ICK. *The ARRL Spread Spectrum Sourcebook* contains a more complete treatment of the subject.

## A Little History

Spread spectrum has existed at least since the mid 1930s. Despite the fact that John Costas, W2CRR, published a paper on nonmilitary applications of spread spectrum communications in 1959,<sup>8</sup> spread spectrum was used almost solely for military purposes until the late 1970s. In 1981, the FCC granted the Amateur Radio Research and Development Corporation (AMRAD) a Special Temporary Authorization to conduct Amateur Radio spread spectrum experiments. In June 1986, the FCC authorized all US amateurs to use spread spectrum above 420 MHz.

## Why Spread Spectrum

Faced with increasing noise and interference levels on most RF bands, traditional wisdom still holds that the narrower the RF bandwidth, the better the chances that "the signal will get through." This is not so.

In 1948, Claude Shannon published his famous paper, "A Mathematical Theory of Communication" in the *Bell System Technical Journal*, followed by "Communications in the Presence of Noise" in the *Proceedings of the IRE* for January 1949. A theorem that follows Shannon's, known as the Shannon-Hartley theorem, states that the channel capacity  $C$  of a band-limited gaussian channel is

$$C = W \log_2 (1 + S/N) \text{ bits/s} \quad (6)$$

where

- $W$  is the bandwidth,
- $S$  is the signal power and
- $N$  is the noise within the channel bandwidth.

This theorem states that should the channel be perfectly noiseless, the capacity of the channel is infinite. It should be noted, however, that making the bandwidth  $W$  of the channel infinitely large does *not* make the capacity infinite, because the channel noise increases proportionately to the channel bandwidth.

Within reason, however, one can trade power for bandwidth. In addition, the power density at any point of the occupied bandwidth can be very small, to the point that it may be well *below* the noise floor of the receiver. The US Navy Global Positioning System (GPS) is an excellent ex-

ample of the use of what is called direct-sequence spread spectrum. The average signal at the GPS receiver's antenna terminals is approximately -160 dBW (for the C/A code). Since most sources of interference are relatively narrow-band, spread-spectrum users will also benefit, as narrow-band interfering signals are rejected automatically during the despreading process, as will be explained later in this section.

These benefits are obtained at the cost of fairly intricate circuitry: The transmitter must spread its signal over a wide bandwidth in accordance with a certain prearranged code, while the receiver must somehow synchronize on this code and recombine the received energy to produce a usable signal. To generate the code, use is made of pseudo-noise (PN) generators. The PN generators are selected for their correlation properties. This means that when two similar PN sequences are compared out of phase their correlation is nil (that is, the output is 0), but when they are exactly in phase their correlation produces a huge peak that can be used for synchronization purposes.

This synchronization process has been (and still is) the major complicating factor in any spread spectrum link, for how can one synchronize on a signal that can be well below the receiver's noise floor? Because of the cost associated with the complicated synchronization processes, spread spectrum applications were essentially military-related until the late 1970s. The development of ICs then allowed for the replacement of racks and racks of tube equipment by a few plug-in PC boards, although the complexity level itself did not improve. Amateur Radio operators could not afford such levels of complexity and had to find simpler solutions, at the cost of robustness in the presence of interference.

## Spread-Spectrum Transmissions

A transmission can be called "spread spectrum" if the RF bandwidth used is (1) much larger than that needed for traditional modulation schemes and (2) independent of the modulation content. Although numerous spread spectrum modulation schemes are in existence, only two, frequency-hopping (FH) and direct-sequence spread spectrum (DSSS) are specifically authorized by the FCC for use by the Amateur Radio community.

To understand FH, let us assume a transmitter is able to transmit on any one of 100 discrete frequencies F1 through F100. We now force this equipment to transmit for 1 second on each of the

frequencies, but in an apparently random pattern (for example, F1, F62, F33, F47...; see Fig 12.78). Should some source interfere with the receiver site on three of those discrete frequencies, the system will still have achieved reliable transmission 97% of the time. Because of the built-in redundancy in human speech, as well as the availability of error-correcting codes in data transmissions, this approach is particularly attractive for systems that must operate in heavy interference.

In a DSSS transmitter, an RF carrier and a pseudo-random pulse train are mixed in a doubly balanced mixer (DBM). In the process, the RF carrier disappears and is replaced by a noise-like wide-band transmission, as shown in Fig 12.79. At the receiver, a similar pseudo-random signal is reintroduced and the spread spectrum signal is correlated, or despread, while narrow-band interference is spread simultaneously by the same process.

The technical complexity mentioned above is offset by several important advantages for military and space applications:

- *Interference rejection.* If the interference is not synchronized with the original

Fig 12.78—Power vs frequency for frequency-hopping spread spectrum signals. Emissions jump around to discrete frequencies in pseudo-random fashion.

Fig 12.79—Power vs frequency for a direct-sequence-modulated spread spectrum signal. The envelope assumes the shape of a  $\sin^2(x)$  curve. With proper modulating techniques, the carrier is suppressed.

<sup>8</sup>Poisson, Shannon and the Radio Amateur," *Proceedings of the IRE*, Dec 1959.

spread spectrum signal, it will not appear after despreading at the receiver.

- **Security.** The length and sophistication of the pseudo-random codes used can be such as to make unauthorized recovery difficult if not impossible.
- **Power density.** Low power density makes for easy hiding of the RF signal and a resulting lower probability of detection.

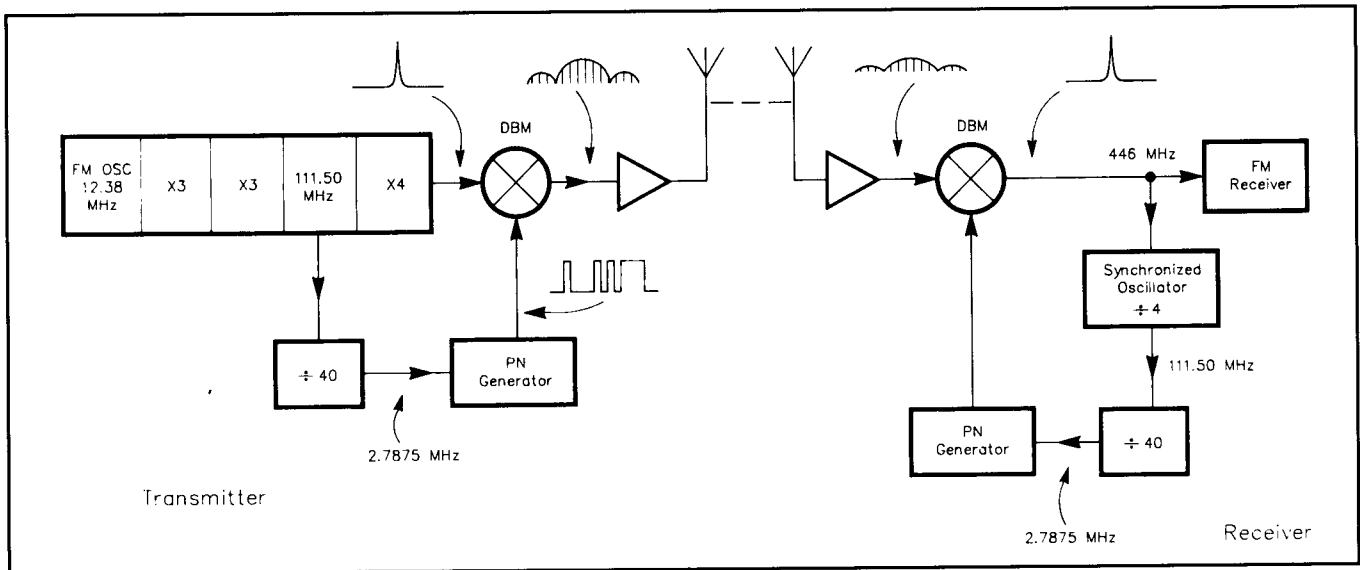

As far as the Amateur Radio community is concerned, particular benefit will be derived from the interference rejection just mentioned, as it offers both robustness and reliability of transmissions, as well as low probability of interference to other users. Additionally, spread spectrum has the potential to allow better utilization

of the RF spectrum allocated to amateurs. There is a limit as to how many conventional signals can be placed in a given band before serious transmission degradation takes place. Additional spread spectrum signals will not cause severe interference, but may instead only raise the background noise level. This becomes particularly important in bands shared with other users and in our VHF and UHF bands increasingly targeted by would-be commercial users. The utilization of a channel by many transmitters is essentially the concept behind CDMA (Code Division Multiple Access), a system in which several DSSS transmissions can share the same RF bandwidth, provided they utilize orthogonal pseudo-random sequences.

## Amateur Spread Spectrum

When radio amateurs (limited in both financial resources and time available for experimentation) decided to try their hand at spread spectrum transmissions, they had to attack the problem by simplifying several assumptions. Security and privacy, the primary goals of the military, were sacrificed in favor of simplicity of design and implementation.

Experimentation sponsored by AMRAD began in 1981 and continues to this day. These experiments have led to the design and construction of a practical DSSS UHF link. This project was described in May 1989 *QST* and was reprinted in *The ARRL Spread Spectrum*

**Fig 12.80—A block diagram of the practical spread spectrum link. The success of this arrangement lies in the use of a synchronized oscillator (right) to recover the transmitter clock signal at the receiving site.**

**Fig 12.81—(A) The envelope of the unfiltered biphas-modulated spread spectrum signals as viewed on a spectrum analyzer. In this practical system, band-pass filtering is used to confine the spread spectrum signal to the amateur band. (B) At the receiver end of the line, the filtered spread spectrum signal is apparent only as a 10-dB hump in the noise floor. (C) The despread signal at the output of the receiver DBM. The original carrier—and any modulation components that accompany it—has been recovered. The peak carrier is about 45 dB above the noise floor—more than 30 dB above the hump shown at B. (These spectrograms were made at a sweep rate of 0.1 s/division and an analyzer bandwidth of 30 kHz; the horizontal scale is 1 MHz/division.)**

*Sourcebook*. In it, N4ICK offered a simple solution to the problem of synchronization. (Because of its simplicity, this solution does not offer all the anti-jamming properties of more sophisticated systems, but this should not be of concern to Amateur Radio operators.) The block diagram is shown in **Fig 12.80**. **Fig 12.81** shows the RF signals at the transmitter output, at the receiver antenna terminals and the recovered signal after correlation. James Vincent, G1PVZ, replaced the original FM scheme with a continuously variable delta modulation system, or CVSD. A description of his work can be found in the September and October 1993 issues of the British magazine *Electronics World & Wireless World*.

In addition to *The ARRL Spread Spectrum Sourcebook*, interested readers may want to pay particular attention to Robert Dixon's text, *Spread Spectrum Systems*. Additional information can be found in the publications and magazines listed below.

# RF Power Amplifiers and Projects

## 13

**T**his chapter describes the design and construction of power RF amplifiers for use in an Amateur Radio station. Dick Ehrhorn, W4ETO, contributed materially to this section.

An amplifier may be required to develop as much as 1500 W of RF output power, the legal maximum in the United States.

The voltages and currents needed to perform this feat are much higher than those found in other amateur equipment—the voltage and current levels are potentially lethal, in fact.

Every component in an RF power amplifier must be carefully selected to endure these high electrical stress levels without

failing. Large amounts of heat are produced in the amplifier and must be dissipated safely. Generation of spurious signals must be minimized, not only for legal reasons, but also to preserve good neighborhood relationships. Every one of these challenges must be overcome to produce a loud, clean signal from a safe and reliable amplifier.

## Types of Power Amplifiers

Power amplifiers are categorized by their power level, intended frequencies of operation, device type, class of operation and circuit configuration. Within each of these categories there almost always are two or more options available. Choosing the most appropriate set of options from all those available is the fundamental concept of design.

### SOLID STATE VERSUS VACUUM TUBES

With the exception of high-power amplifiers, nearly all items of amateur equipment manufactured commercially today use solid-state (semiconductor) devices exclusively. Semiconductor diodes, transistors and integrated circuits (ICs) offer several advantages in designing and fabricating equipment:

- Compact design—Even with their heat sinks, solid-state devices are smaller than functionally equivalent tubes, allowing smaller packages.
- “No-tune-up” operation—By their nature, transistors and ICs lend themselves to low impedance, broadband operation. Fixed-tuned filters made with readily available components can be used to suppress harmonics and other spurious signals. Bandswitching of such filters is

easily accomplished when necessary; it often is done using solid-state switches. Tube amplifiers, on the other hand, usually must be retuned on each band, and even for significant frequency movement within a band.

- Long life—Transistors and other semiconductor devices have extremely long lives if properly used and cooled. When employed in properly designed equipment, they should last for the entire useful life of the equipment—commonly 100,000 hours or more. Vacuum tubes wear out as their filaments (and sometimes other parts) deteriorate with time in normal operation; the useful life of a typical vacuum tube may be on the order of 10,000 to 20,000 hours.
- Manufacturing ease—Most solid-state devices are ideally suited for printed-circuit-board fabrication. The low voltages and low impedances that typify transistor and IC circuitry work very well on printed circuits (some circuits use the circuit board traces themselves as circuit elements); the high impedances found with vacuum tubes do not. The IC or transistor's physical size and shape also lends itself well to printed circuits and the devices usually can be soldered right to the board.

These advantages in fabrication mean reduced manufacturing costs. Based on all these facts, it might seem that there would be no place for vacuum tubes in a solid state world. Transistors and ICs do have significant limitations, however, especially in a practical sense. Individual RF power transistors available today cannot develop more than approximately 150 W output; this figure has not changed much in the past two decades.

Individual present-day transistors cannot generally handle the combination of current and voltage needed, nor can they safely dispose of the amount of heat dissipated, for RF amplification to higher power levels. So pairs of transistors, or even pairs of pairs, are usually employed in practical power amplifier designs, even at the 100-W level. Beyond the 300-W output level, somewhat exotic (at least for most radio amateurs) techniques of power combination from multiple amplifiers ordinarily must be used. Although this is commonly done in commercial equipment, it is an expensive proposition.

It also is far easier to ensure safe cooling of vacuum tubes, which operate satisfactorily at surface temperatures as high as 150-200°C and may be cooled by simply blowing sufficient ambient air past or through their relative large cooling sur-

faces. The very small cooling surfaces of power transistors should be held to 75–100°C to avoid drastically shortening their life expectancy. Thus, assuming worst-case 50°C ambient air temperature, the large cooling surface of a vacuum tube can be allowed to rise 100–150°C above ambient, while the small surface of a transistor must not be allowed to rise more than about 50°C. Moreover, power tubes are considerably more likely than transistors to survive, without significant damage, the rare instance of severe overheating.

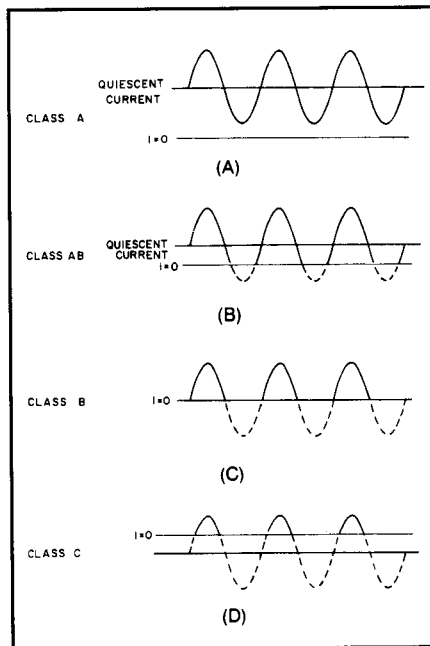

Furthermore, RF power transistors are much less tolerant of electrical abuse than are most vacuum tubes. An overvoltage spike lasting only microseconds can—and is likely to—destroy transistors costing \$75 to \$150 each. A comparable spike is unlikely to have any effect on a tube. So the important message is this: designing with expensive RF power transistors demands using extreme caution to ensure that adequate thermal and electrical protection is provided. It is an area best left to knowledgeable designers.

Even if one ignores the challenge of the RF portions of a high-power transistor amplifier, there is the dc power supply to consider. A solid-state amplifier capable of delivering 1 kW of RF output might require regulated (and transient-free) 50 V at more than 40 A. Developing that much current is a challenging and expensive task. These limitations considered, solid-state amplifiers have significant practical advantages up to a couple of hundred watts output. Beyond that point, and certainly at the kilowatt level, the vacuum tube still reigns for amateur constructors because of its cost-effectiveness and ease of equipment design.

## CLASSES OF OPERATION

The class of operation of an amplifier stage is defined by its conduction angle, the angular portion of each RF drive cycle, in degrees, during which plate current (or collector or drain current in the case of transistors) flows. This, in turn, determines the amplifier's gain, efficiency, linearity and input and output impedances.

- **Class A:** The conduction angle is 360°. DC bias and RF drive level are set so that the device is not driven to output current cutoff at any point in the driving-voltage cycle, so some device output current flows throughout the complete 360° of the cycle (see Fig 13.1A). Output voltage is generated by the variation of output current flowing through the load resistance. Maximum linearity and gain are achieved in a Class A amplifier, but the efficiency of

**Fig 13.1—Amplifying device output current for various classes of operation. All assume a sinusoidal drive signal.**

the stage is low. Maximum theoretical efficiency is 50%, but 25 to 30% is more common in practice.

- **Class AB:** The conduction angle is greater than 180° but less than 360° (see Fig 13.1B). In other words, dc bias and drive level are adjusted so device output current flows during appreciably more than half the drive cycle, but less than the whole drive cycle. Efficiency is much better than Class A, typically reaching 50–60% at peak output power. Class AB linearity and gain are not as good as that achieved in Class A, but are very acceptable for even the most rigorous high-power SSB applications in Amateur Radio.

Class AB vacuum tube amplifiers are further defined as class AB1 or AB2. In class AB1, the grid is not driven positive so no grid current flows. Virtually no drive power is required, and gain is quite high, typically 15–20 dB. The load on the driving stage is relatively constant throughout the RF cycle. Efficiency typically exceeds 50% at maximum output.

In Class AB2, the grid is driven positive on peaks and some grid current flows. Efficiency commonly reaches 60%, at the expense of greater demands placed on the driving stage and slightly reduced linearity. Gain commonly reaches 15 dB.

- **Class B:** Conduction angle = 180°. Bias

and RF drive are set so that the device is just cut off with no signal applied (see Fig 13.1C), and device output current flows during one half of the drive cycle. Efficiency commonly reaches as high as 65%, with fully acceptable linearity.

- **Class C:** The conduction angle is much less than 180°—typically 90°. DC bias is adjusted so that the device is cut off when no drive signal is applied. Output current flows only during positive crests in the drive cycle (see Fig 13.1D), so it consists of pulses at the drive frequency. Efficiency is relatively high—up to 80%—but linearity is extremely poor. Thus Class C amplifiers are not suitable for amplification of amplitude-modulated signals such as SSB or AM, but are quite satisfactory for use in on-off keyed stages or with frequency or phase modulation. Gain is lower than for the previous classes of operation, typically 10–13 dB.

- **Classes D through H** use various switched mode techniques and are not commonly found in amateur service. Their prime virtue is high efficiency, and they are used in a wide range of specialized audio and RF applications to reduce power-supply requirements and dissipated heat. These classes of RF amplifiers require fairly sophisticated design and adjustment techniques, particularly at high-power levels. The additional complexity and cost could rarely if ever be justified for amateur service.

Class of operation is independent of device type and circuit configuration (see **Analog Signal** chapter). The active amplifying device and the circuit itself must be uniquely applied for each operating class, but amplifier linearity and efficiency are determined by the class of operation. Clever amplifier design cannot improve on these fundamental limits. Poor design and implementation, though, can certainly prevent an amplifier from approaching its potential in efficiency and linearity.

## MODELING THE ACTIVE DEVICE

It is very useful to have a model for the active devices used in a real-world RF power amplifier. Although the actual active device used in an amplifier might be a vacuum tube, a transistor or an FET, each model has certain common characteristics.

See Fig 13.2A, where a vacuum tube is modeled as a current generator in parallel with a dynamic plate resistance  $R_p$  and a load resistance  $R_L$ . In this simplified model, any residual reactances (such as the inductance of connecting leads and the

output capacity of the tube) are not specifically shown. The control-grid voltage in a vacuum tube controls the stream of electrons moving between the cathode and the plate. An important measure for a tube is its *transconductance*, which is the change in plate current caused by a change in grid-cathode voltage. The plate current is:

$$i_p = g_m \times e_g \quad (1)$$

where

$i_p$  = plate current

$g_m$  = transconductance (also called mutual conductance) of tube  $\Delta i_p / \Delta e_g$

$e_g$  = grid RF voltage.

The concept of dynamic plate resistance is sometimes misunderstood. It is a measure of how the plate current changes with a change in plate voltage, given a constant grid voltage. The control-grid voltage is by far the major determinant of the plate current in a triode. In a tetrode or pentode vacuum tube, the screen grid “screens” the plate current even further from the effect of changes in the plate voltage. For small-signal operation (where the plate voltage does not swing below the screen voltage) the plate current in a pentode or tetrode changes remarkably little when the plate voltage is changed. Thus the dynamic plate resistance is very high in a tetrode or pentode that is operating linearly, and only somewhat less for a triode. The plate current delivered into the load resistance  $R_L$  creates RF power.

An FET operates much like the vacuum-tube model. Obviously, there is no vacuum inside the case of an FET, and the FET electrodes are called gate, drain and source instead of grid, plate and cathode, but the current-generator model is just as viable for an FET as for a vacuum tube.

In a transistor, the base current controls the flows of electrons (or holes) in the collector circuit. See Fig 13.2B. A transistor operating in a linear fashion resembles the operation of a tetrode or pentode vacuum tube since the equivalent collector dynamic output resistance is also high. This is so because the collector current is not affected greatly by the collector voltage—it is mainly determined by the base current. The collector current in the current-generator model for a transistor is:

$$i_c = \beta \times i_b \quad (2)$$

where

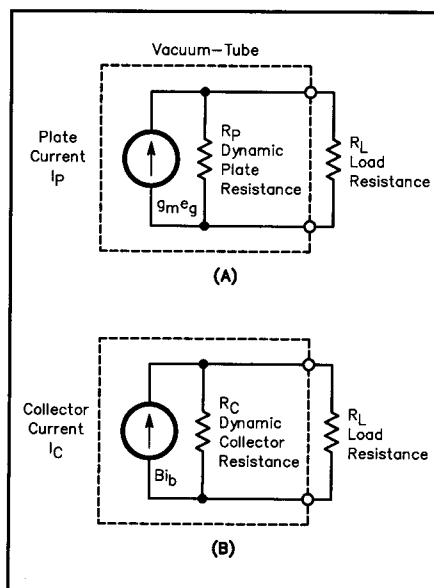

$i_c$  = collector current

$\beta$  = current gain of transistor

$i_b$  = base current.

## IMPEDANCE TRANSFORMATION —“MATCHING NETWORKS”

Over the years, some confusion in the

**Fig 13.2—At A, the current-generator model for a vacuum-tube amplifier operating linearly. Typical values for  $R_p$  and  $R_L$  for small-signal vacuum tubes are 100 k $\Omega$  and 5 k $\Omega$  respectively. The plate current  $I_p$  is equal to the product of the tube transconductance  $g_m$  times the grid voltage. At B, the current-generator model for a transistor. Typical values for  $R_c$  and  $R_L$  are on the same order as those for a small-signal vacuum tube.**

amateur ranks has resulted from imprecise use of the terms *matching* and *matching network*. The term “matching” was first used in the technical literature in connection with transmission lines. When a matching network such as a *Transmatch* is tuned properly, it “matches” (that is, makes equal) a particular load impedance to the fixed characteristic impedance of the transmission line used at the *Transmatch* input.

In this chapter, we are concerned with using active devices to generate useful RF power. For a given active device, RF power is generated most efficiently, and with the least distortion for a linear amplifier, when it delivers RF current into an *optimum value of load resistance*. For an amplifier, the output network transforms the load impedance (such as an antenna) into an optimum value of load resistance for the active device. In part to differentiate active power amplifiers from passive transmission lines, we prefer to call such a transforming network an *output network*, rather than a matching network.

## Output Networks and Class AB, B, and C Amplifiers

In Class AB, B and C amplifiers, we

select a load resistance that will keep the tube or transistor from dissipating too much power or, in the case of Class AB or B amplifiers, to achieve the desired linearity.

In these classes of amplifiers, the device output current is zero for large parts of the RF cycle. Because of this, the effective source resistance is no longer the simple dynamic plate resistance of a Class A amplifier. In fact, the value of  $R_p$  varies with the drive level. This means that, since the load resistance (of an antenna, for example) is constant, the efficiency of the amplifier also varies with the drive level.

It may at first appear contradictory that Class AB and B amplifiers use nonlinear devices but achieve “linear” operation nevertheless. The explanation is that the peak amplitude of device output current faithfully follows that of the drive voltage, even though its waveform does not. In tuned amplifiers, the flywheel effect of the resonant output network restores the missing part of each RF input cycle, as well as its sinusoidal waveform. In broadband transistor amplifiers, balanced push-pull circuitry commonly is used to restore the missing RF cycles, and low-pass filters on the output remove harmonics and thereby restore the sinusoidal RF waveform. The result in both cases is linear amplification of the input signal—by the clever application of nonlinear devices.

The usual practice in RF power amplifier design is to select an optimum load resistance that will provide the highest power output consistent with required linearity, while staying within the amplifying device’s ratings. The optimum load resistance is determined by the amplifying device’s current transfer characteristics and the amplifier’s class of operation. For a transistor amplifier, the optimum load resistance is approximately:

$$R_L = \frac{V_{CC}^2}{2P_O} \quad (6)$$

where

$R_L$  = the load resistance

$V_{CC}$  = the collector dc voltage

$P_O$  = the amplifier power output in watts.

Vacuum tubes have complex current transfer characteristics, and each class of operation produces different RMS values of RF current through the load impedance. The optimum load resistance for vacuum-tube amplifiers can be approximated by the ratio of the dc plate voltage to the dc plate current at maximum signal, divided by a constant appropriate to each class of operation. The load resistance, in turn, determines the maximum power output and efficiency the amplifier can provide.

The optimum tube load resistance is

$$R_L = \frac{V_P}{K \times I_P} \quad (7)$$

where

$R_L$  = the appropriate load resistance, in ohms

$V_P$  = the dc plate potential, in V

$I_P$  = the dc plate current, in A

$K$  = a constant that approximates the RMS current to dc current ratio appropriate for each class. For the different classes of operation:

Class A,  $K \approx 1.3$

Class AB,  $K \approx 1.5 - 1.7$

Class B,  $K \approx 1.57 - 1.8$

Class C,  $K \approx 2$ .

Graphical or computer-based analytical methods may be used to calculate more precisely the optimum plate load resistance for specific tubes and operating conditions, but the above "rules of thumb" generally provide satisfactory results for design.

The ultimate load for an RF power amplifier usually is a transmission line connected to an antenna or the input of another amplifier. It usually isn't practical, or even possible, to modify either of these load impedances to the optimum value needed for high-efficiency operation. An output network is thus used to transform the real load impedance to the optimum load resistance for the amplifying device. Two basic types of output networks are found in RF power amplifiers: tank circuits and transformers.

## TANK CIRCUITS

Parallel-resonant circuits and their equivalents have the ability to store energy. Capacitors store electrical energy in the electric field between their plates; inductors store energy in the magnetic field induced by the coil winding. These circuits are referred to as *tank circuits*, since they act as storage "tanks" for RF energy.

The energy stored in the individual tank circuit components varies with time. Consider for example the tank circuit shown in Fig 13.4. Assuming that  $R$  is zero, the tank circuit dissipates no power. Therefore, no power need be supplied by the source; hence no line current  $I_{LINE}$  flows. Only circulating current  $I_{CIRC}$  flows, and it is exactly the same through both  $L$  and  $C$  at any instant. Similarly, the voltage across  $L$  and  $C$  is always exactly the same. At some point the capacitor is fully charged, and the current through both the capacitor and inductor is zero. So the inductor has no magnetic field and therefore no energy stored in its field. All the energy in the tank is stored in the capacitor's electric field.

At this instant, the capacitor starts to discharge through the inductor. The current flowing in the inductor creates a magnetic field, and energy transferred from the capacitor is stored in the inductor's magnetic field. Still assuming there is no loss in the tank circuit, the increase in energy stored in the inductor's magnetic field is exactly equal to the decrease in energy stored in the capacitor's electric field. The total energy stored in the tank circuit stays constant; some is stored in the inductor, some in the capacitor. Current flow into the inductor is a function of both time and of the voltage applied by the capacitor, which decreases with time as it discharges into the inductor. Eventually, the capacitor's charge is totally depleted and all the tank circuit's energy is stored in the magnetic field of the inductor. At this instant, current flow through  $L$  and  $C$  is maximum and the voltage across the terminals of both  $L$  and  $C$  is zero.

Since energy no longer is being transferred to the inductor, its magnetic field begins to collapse and becomes a source of current, still flowing in the same direction as when the inductor was being driven by the capacitor. When the inductor becomes a current source, the voltage across its terminals reverses and it begins to recharge the capacitor, with opposite polarity from its previous condition. Eventually, all energy stored in the inductor's magnetic field is depleted as current decreases to zero. The capacitor is fully charged, and all the energy is then stored in the capacitor's electric field. The exchange of energy from capacitor to inductor and back to capacitor is then repeated, but with opposite voltage polarities and direction of current flow from the previous exchange. It can be shown mathematically that the "alternating" current and voltage produced by this process are sinusoidal in waveform, with a frequency of

$$f = \frac{1}{2\pi\sqrt{LC}} \quad (8)$$

which of course is the resonant frequency of the tank circuit. In the absence of a load or any losses to dissipate tank energy, the tank circuit current would oscillate forever.

In a typical tank circuit such as shown in Fig 13.4, the values for  $L$  and  $C$  are chosen so that the reactance ( $X_L$ ) of  $L$  is equal to the reactance ( $X_C$ ) of  $C$  at the frequency of the signal generated by the ac voltage source. If  $R$  is zero (since  $X_L$  is equal to  $X_C$ ), the line current  $I_{LINE}$  measured by M1 is close to zero. However, the circulating current in the loop made up of  $L$ ,  $R$  and  $C$  is definitely not zero. Examine what would happen if the circuit were sud-

denly broken at points A and B. The circuit is now made up of  $L$ ,  $C$  and  $R$ , all in series.  $X_L$  is equal to  $X_C$ , so the circuit is resonant. If some voltage is applied between points A and B, the magnitude of circulating current is limited only by resistance  $R$ . If  $R$  were equal to zero, the circulating current would be infinite!

## The Flywheel Effect

A tank circuit can be likened to a flywheel—a mechanical device for storing energy. The energy in a flywheel is stored in the angular momentum of the wheel.

As soon as a load of some sort is attached, the wheel starts to slow or even stop. Some of the energy stored in the spinning flywheel is now transferred to the load. In order to keep the flywheel turning at a constant speed, the energy drained by the load must be replenished. Energy has to be added to the flywheel from some external source. If sufficient energy is added to the flywheel, it maintains its constant rotational speed.

In the real world, of course, flywheels and tank circuits suffer from the same fate; system losses dissipate some of the stored energy without performing any useful work. Air resistance and bearing friction slow the flywheel. In a tank circuit, resistive losses drain energy.

## Tank Circuit Q

In order to quantify the ability of a tank circuit to store energy, a quality factor,  $Q$ , is defined.  $Q$  is the ratio of energy stored in a system during one complete RF cycle to energy lost.

$$Q = 2\pi \frac{W_S}{W_L} \quad (9)$$

where

$W_S$  = is the energy stored

$W_L$  = the energy lost to heat and the load.

**Fig 13.4—There are two currents in a tank circuit: the line current ( $I_{LINE}$ ) and the circulating current ( $I_{CIRC}$ ). The circulating current is dependent on tank  $Q$ .**

By algebraic substitution and appropriate integration, the  $Q$  for a tank circuit can be expressed as

$$Q = \frac{X}{R} \quad (10)$$

where

$X$  = the reactance of either the inductor or the capacitor

$R$  = the series resistance.

Since both circulating current and  $Q$  are proportional to  $1/R$ , circulating current is therefore proportional to  $Q$ . The tank circulating current is equal to the line current multiplied by  $Q$ . If the line current is 100 mA and the tank  $Q$  is 10, then the circulating current through the tank is 1 A. (This implies, according to Ohm's Law, that the voltage potentials across the components in a tank circuit also are proportional to  $Q$ .)

When there is no load connected to the tank, the only resistances contributing to  $R$  are the losses in the tank circuit. The unloaded  $Q$  ( $Q_U$ ) in that case is:

$$Q_U = \frac{X}{R_{\text{LOSS}}} \quad (11)$$

where

$X$  = the reactance of either the inductor or capacitor

$R_{\text{LOSS}}$  = the effective series loss resistance in the circuit.

A load connected to a tank circuit has exactly the same effect on tank operation as circuit losses. Both consume energy. It just happens that energy consumed by circuit losses becomes heat rather than useful output. When energy is coupled out of the tank circuit into a load, the loaded  $Q$  ( $Q_L$ ) is:

$$Q_L = \frac{X}{R_{\text{LOSS}} + R_{\text{Load}}} \quad (12)$$

where  $R_{\text{Load}}$  is the load resistance. Energy dissipated in  $R_{\text{LOSS}}$  is wasted as heat. Ideally, all the tank circuit energy should be delivered to  $R_{\text{Load}}$ . This implies that  $R_{\text{LOSS}}$  should be as small as practical, to yield the highest reasonable value of unloaded  $Q$ .

### Tank Circuit Efficiency

The efficiency of a tank circuit is the ratio of power delivered to the load resistance ( $R_{\text{Load}}$ ) to the total power dissipated by losses ( $R_{\text{Load}}$  and  $R_{\text{LOSS}}$ ) in the tank circuit. Within the tank circuit,  $R_{\text{Load}}$  and  $R_{\text{LOSS}}$  are effectively in series, and the circulating current flows through both. The power dissipated by each is therefore proportional to its resistance. The loaded tank efficiency can therefore be defined as

$$\text{Tank Efficiency} = \frac{R_{\text{Load}}}{R_{\text{Load}} + R_{\text{LOSS}}} \times 100 \quad (13)$$

where efficiency is stated as a percentage. By algebraic substitution, the loaded tank efficiency can also be expressed as

$$\text{Tank Efficiency} = \left( 1 - \frac{Q_L}{Q_U} \right) \times 100 \quad (14)$$

where

$Q_L$  = the tank circuit loaded  $Q$

$Q_U$  = the unloaded  $Q$  of the tank circuit.

It follows then that tank efficiency can be maximized by keeping  $Q_L$  low, which keeps the circulating current low and the  $I^2R$  losses down.  $Q_U$  should be maximized for best efficiency; this means keeping the circuit losses low.

The selectivity provided by a tank circuit helps suppress harmonic currents generated by the amplifier. The amount of harmonic suppression is dependent upon circuit loaded  $Q_L$ , so a dilemma exists for the amplifier designer. A low  $Q_L$  is desirable for best tank efficiency, but yields poorer harmonic suppression. High  $Q_L$  keeps amplifier harmonic levels lower at the expense of some tank efficiency. At HF, a compromise value of  $Q_L$  can usually be chosen such that tank efficiency remains high and harmonic suppression is also reasonable. At higher frequencies, tank  $Q_L$  is not always readily controllable, due to unavoidable stray reactances in the circuit. However, unloaded  $Q_U$  can always be maximized, regardless of frequency, by keeping circuit losses low.

### Tank Output Circuits

Tank circuit output networks need not take the form of a capacitor connected in parallel with an inductor. A number of equivalent circuits can be used to match the impedances normally encountered in a power amplifier. Most are operationally more flexible than a parallel-resonant tank. Each has its advantages and disadvantages for specific applications, but the final choice usually is based on practical construction considerations and the component values needed to implement a particular network. Some networks may require unreasonably high or low inductance or capacitance values. In that case, use another network, or a different value of  $Q_L$ . Several different networks may be investigated before an acceptable final design is reached.

The impedances of RF components and amplifying devices frequently are given in terms of a parallel combination of a resistance and a reactance, although

it is often easier to use a series R-X combination to design networks. Fortunately, there is a series impedance equivalent to every parallel impedance and vice versa. The equivalent circuits, and equations for conversion from one to the other, are given in Fig 13.7. In order to use most readily available design equations for computing matching networks, the parallel impedance must first be converted to its equivalent series form.

The  $Q_L$  of a parallel impedance can be derived from the series form as well. Substitution of the usual formula for calculating  $Q_L$  into the equations from Fig 13.7 gives

$$Q_L = \frac{R_P}{X_P} \quad (15)$$

where

$R_P$  = the parallel equivalent resistance

$X_P$  = the parallel equivalent reactance.

Several impedance-matching networks are shown in the **Receivers** chapter. A low-pass T network and two low-pass L networks are possible matching networks. Both types of matching networks provide good harmonic suppression. The pi network is also commonly used for amplifier matching. Harmonic suppression of a pi network is a function of the impedance transformation ratio and the  $Q_L$  of the circuit. Second-harmonic attenuation is approximately 35 dB for a load impedance of 2000  $\Omega$  in a pi network with a  $Q_L$  of 10. The third harmonic is typically 10 dB lower and the fourth approximately 7 dB below that. A typical pi network as used in the output circuit of a tube amplifier is shown in Fig 13.8.

You can calculate Pi-network matching-circuit values using the following equations. These equations are from Elmer (W5FD) Wingfield's August 1983 *QST*

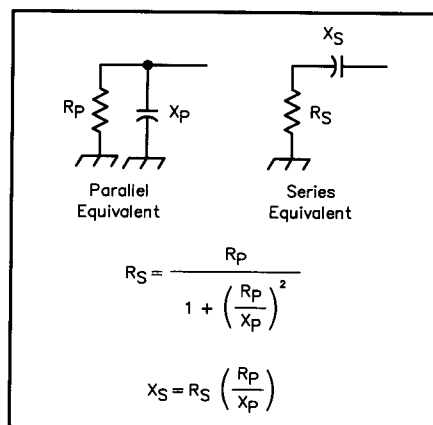

Fig 13.7—Parallel and series equivalent circuits and the formulas used for conversion.

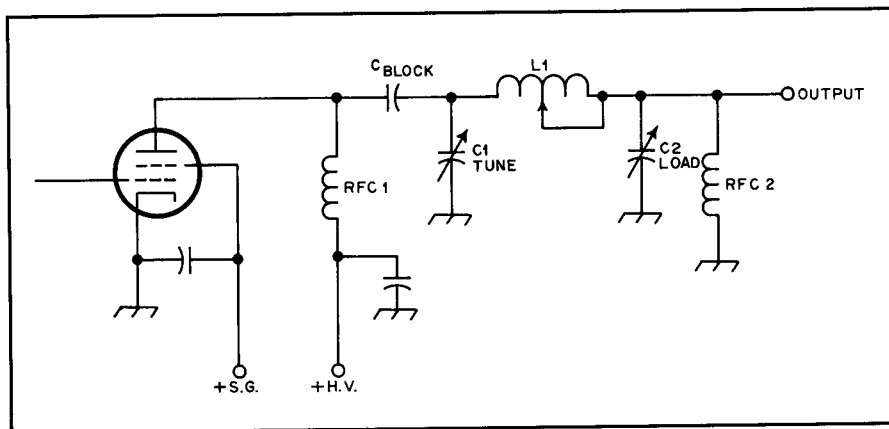

Fig 13.8—A pi matching network used at the output of a tetrode power amplifier. RFC2 is used for protective purposes in the event C<sub>BLOCK</sub> fails.

### Q<sub>1</sub> Based Pi-Network Equations

Wingfield's equations are a great improvement because they solve for the desired component values in terms of Q<sub>0</sub>, the desired output Q. When the minimum circuit capacitance (C<sub>min</sub>) is too great, however, the Q<sub>0</sub> based equations do not work. Then we must use Q<sub>1</sub> based equations to solve for Q and component values in terms of C<sub>min</sub>.

$$X_{C1} = \frac{R_1}{Q_1} \quad (A)$$

$$X_{C2} = \frac{\sqrt{R_1 \cdot R_2}}{Q_1^2 + 1 - \frac{R_1}{R_2}} \quad (B)$$

$$X_L = \sqrt{\frac{(R_1 \cdot Q_2) + \frac{R_1 \cdot R_2}{X_{C2}}}{Q_1^2 + 1}} \quad (C)$$

Given C<sub>min</sub>,

$$Q_1 = 2\pi f C_1 R_1 \quad (D)$$

Then solve for X<sub>C2</sub> using B and X<sub>L</sub> using C.

article, "New and Improved Formulas for the Design of Pi and Pi-L Networks," and Feedback in January 1984 *QST*. (See the Bibliography at the end of this chapter.) Table 13.1 shows some data from a computer program Wingfield wrote to calculate these values. This program (PI-CMIN.EXE) and a similar program to calculate Pi-L network values (PI-LCMIN.EXE) are on the diskette bundled with this book, along with several other useful Wingfield programs. The programs are for IBM PC and compatible

computers. A more complete set of tables is also available from ARRL as a template package. Write to the Technical Department Secretary and ask for template HBK-MATCH. Please include \$3 to cover copying and mailing costs.

The computer programs take into account the minimum practical capacitance (C<sub>min</sub>) you can expect to achieve with your circuit, based on your knowledge of the tube output capacitance, stray circuit capacitance, the minimum capacitance of the variable tuning capacitors and a reasonable amount of capacitance for tuning. (Start with a minimum capacitance of about 35 pF for vacuum variable capacitors and about 45 to 50 pF for air variable capacitors.) If the following equations lead to a capacitor value less than the minimum capacitance you expect to achieve, use the minimum value to recalculate the other quantities as shown in Q<sub>1</sub> Based Pi-Network Equations. This will result in a final circuit operating Q value that is larger than the selected value. (Wingfield uses Q<sub>0</sub> to represent this output Q, which is the same as Q<sub>1</sub> referred to earlier in this chapter. We will use Q<sub>0</sub> in the equations.) The program output includes this new calculated Q<sub>0</sub> value.

Use the following equations to calculate specific component values for a Pi-network matching circuit. Select the desired circuit operating Q, Q<sub>0</sub>, to satisfy these relationships, depending on whether the load resistance is higher or lower than the transformed resistance presented to the plate:

$$Q_0^2 > \frac{R_1}{R_2} - 1 \text{ and } Q_0^2 > \frac{R_2}{R_1} - 1 \quad (16)$$

where:

R<sub>1</sub> is the input resistance to be matched, in ohms

R<sub>2</sub> is the load (output) resistance to be

matched, in ohms.

Calculate the value of the input Q, Q<sub>1</sub>:

$$Q_1 = \frac{R_1 Q_0 - \sqrt{R_1 R_2 Q_0^2 - (R_1 - R_2)^2}}{R_1 - R_2} \quad (17)$$

We will work through an example as the equations are presented. Let's select Q<sub>0</sub> = 12, R<sub>1</sub> = 1500 Ω and R<sub>2</sub> = 50 Ω.

$$Q_1 = \frac{1500 \times 12 - \sqrt{1500 \times 50 \times 12^2 - (1500 - 50)^2}}{1500 - 50}$$

$$Q_1 = \frac{1.80 \times 10^4 - \sqrt{8.6975 \times 10^6}}{1450} = 10.38$$

Next calculate the value of the output Q, Q<sub>2</sub>:

$$Q_2 = Q_0 - Q_1 \quad (18)$$

$$Q_2 = 12 - 10.38 = 1.62$$

Now calculate the reactance of the input capacitor, output capacitor and inductor.

$$X_{C1} = \frac{R_1}{Q_1} \quad (19)$$

$$X_{C1} = \frac{1500}{10.38} = 144.5 \Omega$$

$$X_{C2} = \frac{R_2}{Q_2} \quad (20)$$

$$X_{C2} = \frac{50}{1.62} = 30.86 \Omega$$

$$X_L = \frac{R_1 Q_0}{Q_1^2 + 1} \quad (21)$$

$$X_L = \frac{1500 \times 12}{10.38^2 + 1} = \frac{1.80 \times 10^4}{108.74} = 165.5 \Omega$$

Finally, calculate the component values:

$$C_1 = \frac{1}{2\pi f X_{C1}} \quad (22)$$

where f is in Hz and X<sub>C1</sub> is in ohms.

For our example, let's find the component values at 3.75 MHz.

$$C_1 = \frac{1}{2\pi \cdot 3.75 \times 10^6 \times 144.5} = 294 \text{ pF}$$

$$C_2 = \frac{1}{2\pi f X_{C2}} \quad (23)$$

$$C_2 = \frac{1}{2\pi \cdot 3.75 \times 10^6 \times 30.86} = 1375 \text{ pF}$$

$$L = \frac{X_L}{2\pi f} \quad (24)$$

$$L = \frac{165.5}{2\pi \cdot 3.75 \times 10^6} = 7.02 \mu\text{H}$$

As an alternate method, after selecting the values for  $Q_0$ ,  $R_1$  and  $R_2$ , you can use the following equations:

$$X_L = \frac{Q_0(R_1 + R_2) + 2\sqrt{R_1 R_2 (Q_0^2 + 4)} - (R_1 + R_2)^2}{Q_0^2 + 4} \quad (25)$$

$$X_L = \frac{12(1500 + 50) + 2\sqrt{1500 \times 50 (12^2 + 4)} - (1500 + 50)^2}{12^2 + 4}$$

$$X_L = \frac{1.86 \times 10^4 + 2\sqrt{1.11 \times 10^7 - 2.4025 \times 10^6}}{148} = 165.5 \Omega$$

$$Q_1 = \sqrt{\frac{Q_0 R_1}{X_L} - 1} \quad (26)$$

$$Q_1 = \sqrt{\frac{12 \times 1500}{165.5} - 1} = 10.38$$

$$Q_2 = Q_0 - Q_1$$

or

$$Q_2 = \sqrt{\frac{Q_0 R_2}{X_L} - 1} \quad (27)$$

$$Q_2 = \sqrt{\frac{12 \times 50}{165.5} - 1} = 1.62$$

Use equations 19 and 20 to calculate the reactances of capacitors  $C_1$  and  $C_2$ . Equations 22, 23 and 24 give the capacitance and inductance values for the pi network.

The pi-L network is a combination of a pi network followed by an L network. The pi network transforms the load resistance to an intermediate impedance level called the image impedance. Typically, the image impedance is chosen to be between 300 and 700  $\Omega$ . The L section then transforms from the image impedance down to 50  $\Omega$ . The output capacitor of the pi network is combined with the input capacitor for the L network, as shown in Fig 13.9. The pi-L configuration attenuates harmonics better than a pi network. Second harmonic level for a pi-L network with a  $Q_L$  of

10 is approximately 52 dB below the fundamental. The third harmonic is attenuated 65 dB and the fourth harmonic approximately 75 dB.

The following equations help you calculate pi-L matching-network values. Select an image resistance value ( $R_m$ ) that the L network will supply as a load for the pi network. This value must be between the desired pi-L network input resistance ( $R_1$ ) and the output load resistance ( $R_2$ ). For example, you can use the value given:

$$R_m = \sqrt{R_1 R_2} \quad (28)$$

The computer program, PI-LCMIN. EXE, uses 300  $\Omega$  for  $R_m$  in its calculations. Changing the image resistance results in a different network solution. Use this equation to compute the L network Q value,  $Q_L$ :

$$Q_L = \sqrt{\frac{R_m}{R_2} - 1} \quad (29)$$

We will work through an example, using  $R_1 = 1500 \Omega$ ,  $R_2 = 50 \Omega$  and the desired pi-L network output Q,  $Q_0 = 12$ .

$$Q_L = \sqrt{\frac{300}{50} - 1} = 2.24$$

Use equations 30 and 31 to calculate the L-network reactances.

$$X_{L2} = Q_L R_2 \quad (30)$$

$$X_{L2} = 2.24 \times 50 = 112 \Omega \quad (31)$$

$$X_{P2} = \frac{R_m}{Q_L} \quad (32)$$

$$X_{P2} = \frac{300}{2.24} = 134 \Omega$$

Next calculate the desired Q of the pi-network section ( $Q_{0\pi}$ ).

$$Q_{0\pi} = Q_0 - Q_L \quad (33)$$

$$Q_{0\pi} = 12 - 2.24 = 9.76$$

Use equations 17 through 21 or 25 through 29 to calculate the pi-network reactances,  $X_{C1}$ ,  $X_{L1}$  and  $X_{P1}$  as shown in Fig 13.9. Be sure to use the value specified for  $R_m$  as  $R_2$  in these calculations. Also use the value just calculated for  $Q_{0\pi}$  as  $Q_0$ . Notice that  $X_{P1}$  is  $X_{C2}$  in equation 23.

$$Q_1 = \frac{R_1 Q_{0\pi} - \sqrt{R_1 R_m Q_{0\pi}^2 - (R_1 - R_m)^2}}{R_1 - R_m}$$

$$Q_1 =$$

$$\frac{1500 \times 9.76 - \sqrt{1500 \times 300 \times 9.76^2 - (1500 - 300)^2}}{1500 - 300}$$

$$Q_1 =$$

$$\frac{1.464 \times 10^4 - \sqrt{4.287 \times 10^7 - 1.44 \times 10^6}}{1200} = 6.84$$

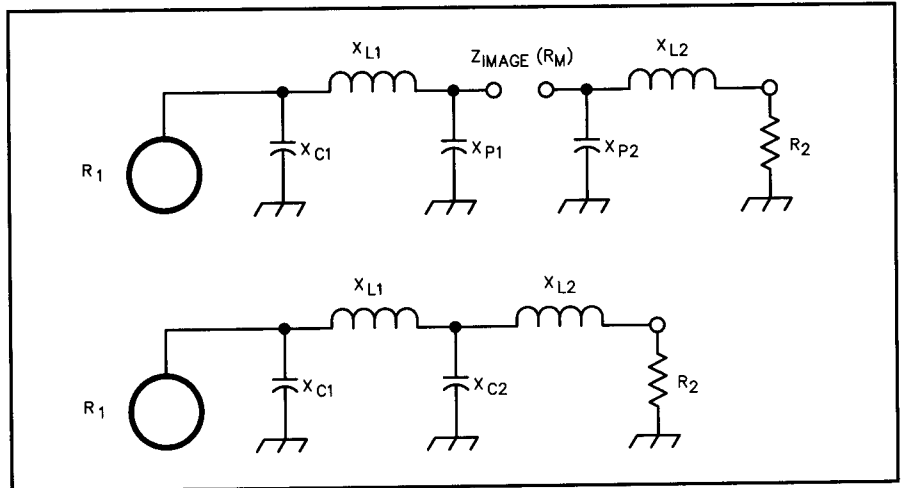

Fig 13.9—The pi-L network uses a pi network to transform the input impedances ( $R_1$ ) to the image impedance ( $Z_{IMAGE}$ ). An L network transforms  $Z_{IMAGE}$  to  $R_2$ .

$$Q_2 = Q_{0\pi} - Q_1 = 9.76 - 6.84 = 2.92$$

$$X_{C1} = \frac{R_1}{Q_1} = \frac{1500}{6.84} = 219.3 \Omega$$

$$X_{P1} = \frac{R_m}{Q_2} = \frac{300}{2.92} = 102.7 \Omega$$

$$X_{L1} = \frac{R_1 Q_{0\pi}}{Q_1^2 + 1} = \frac{1500 \times 9.76}{6.84^2 + 1} = 306.3 \Omega$$

Combine the two parallel capacitors, 5525  $X_{P1}$  and  $X_{P2}$  to find the Pi-L network  $X_{C2}$  value.

$$X_{C2} = \frac{X_{P1} X_{P2}}{X_{P1} + X_{P2}}$$

$$X_{C2} = \frac{102.7 \times 134}{102.7 + 134} = 58.3 \Omega$$

Finally, calculate the capacitance and inductance values using equations 22 through 24. Table 13.2 shows some data from Wingfield's program, PI-LCMIN. For the sample calculation shown here, we choose a frequency of 3.75 MHz.

$$C_1 = \frac{1}{2\pi f X_{C1}} = \frac{1}{2\pi \times 3.75 \times 10^6 \times 219.3}$$

$$C_1 = 193.5 \text{ pF}$$

$$C_2 = \frac{1}{2\pi f X_{C2}} = \frac{1}{2\pi \times 3.75 \times 10^6 \times 58.3}$$

$$C_2 = 730 \text{ pF}$$

$$L_1 = \frac{X_{L1}}{2\pi f} = \frac{306.3}{2\pi \times 3.75 \times 10^6} = 13.0 \mu\text{H}$$

$$L_2 = \frac{X_{L2}}{2\pi f} = \frac{112}{2\pi \times 3.75 \times 10^6} = 4.75 \mu\text{H}$$

The values for L and C in Tables 13.1 and 13.2 are based on purely resistive load

impedances and assume ideal capacitors and inductors. Any other circuit reactances will modify these values.

Stray circuit reactances, including tube capacitances and capacitor stray inductances, should be included as part of the matching network. It is not uncommon for such reactances to render the use of certain matching circuits impractical, because they require either unacceptable loaded Q values or unrealistic component values. If all matching network alternatives are investigated and found unworkable, some compromise solution must be found.

Above 30 MHz, transistor and tube reactances tend to dominate circuit impedances. At the lower impedances found in transistor circuits, the standard networks can be applied so long as suitable components are used. Above 50 MHz, capacitors often exhibit values far different from their marked values because of stray internal reactances and lead inductance, and this requires compensation. Tuned circuits are frequently fabricated in the form of strip lines or other transmission lines in order to circumvent the problem of building "pure" inductances and capacitances. The choice of components is often more significant than the type of network used.

The high impedances encountered in VHF tube-amplifier plate circuits are not easily matched with typical networks. Tube output capacitance is usually so large that most matching networks are unsuitable. The usual practice is to resonate the tube output capacitance with a low-loss inductance connected in series or parallel. The result can be a very high Q tank circuit. Component losses must be kept to an abso-

lute minimum in order to achieve reasonable tank efficiency. Output impedance transformation is usually performed by a link inductively coupled to the tank circuit or by a parallel transformation of the output resistance using a series capacitor.

## Transformers

Broadband transformers are often used in matching to the input impedance or optimum load impedance in a power amplifier. Multioctave power amplifier performance can be achieved by appropriate application of these transformers. The input and output transformers are two of the most critical components in a broadband amplifier. Amplifier efficiency, gain flatness, input SWR, and even linearity all are affected by transformer design and application. There are two basic RF transformer types, as described elsewhere in this *Handbook*: the conventional transformer and the transmission-line transformer.

The conventional transformer is wound much the same way as a power transformer. Primary and secondary windings are wound around a high-permeability core, usually made from a ferrite or pow-

(A)

(B)

Fig 13.10—The two methods of constructing the transformers outlined in the text. At A, the one-turn loop is made from brass tubing; at B, a piece of coaxial cable braid is used for the loop.

dered-iron material. Coupling between the secondary and primary is made as tight as possible to minimize leakage inductance. At low frequencies, the coupling between windings is predominantly magnetic. As the frequency rises, core permeability decreases and leakage inductance increases; transformer losses increase as well.

Typical examples of conventional transformers are shown in **Fig 13.10**. In **Fig 13.10A**, the primary windings consist of brass or copper tubes inserted into ferrite sleeves. The tubes are shorted together at one end by a piece of copper-clad circuit board material. The secondary winding is threaded through the tubes. Since the low-impedance winding is only a single turn, the transformation ratio is limited to the squares of integers; for example, 1, 4, 9, 16, and so on. The lowest effective transformer frequency is determined by the inductance of the one-turn winding. It should have a reactance, at the lowest frequency of intended operation, at least four times greater than the impedance it is connected to.

The coupling coefficient between the two windings is a function of the primary tube diameter and its length, and the diameters and insulation thickness of the wire used in the high-impedance winding. High impedance ratios, greater than 36:1, should use large-diameter secondary windings. Miniature coaxial cable (using only the braid as the conductor) works well. Another use for coaxial cable braid is illustrated in **Fig 13.10B**. Instead of using tubing for the primary winding, the secondary winding is threaded through copper braid. Performance of the two units is almost identical.

The cores used must be large enough so the core material will not saturate at the power level applied to the transformer. Core saturation can cause permanent changes to the core permeability, as well as overheating. Transformer nonlinearity also develops at core saturation. Harmonics and other distortion products are produced, clearly an undesirable situation. Multiple cores can be used to increase the power capabilities of the transformer.

Transmission-line transformers are similar to conventional transformers, but can be used over wider frequency ranges. In a conventional transformer, high-frequency performance deterioration is caused primarily by leakage inductance, which rises with frequency. In a transmission-line transformer, the windings are arranged so there is tight capacitive coupling between the two. A high coupling

coefficient is maintained up to considerably higher frequencies than with conventional transformers.

## Output Filtering

Amplifier output filtering is sometimes necessary to meet spurious signal requirements. Broadband amplifiers, by definition, provide little if any inherent suppression of harmonic energy. Even amplifiers using output tank circuits often require further attenuation of undesired harmonics. High-level signals from one transmitter, particularly at multiple transmitter sites, can be intercepted by an antenna connected to another transmitter, conducted down the feed line and mix in a power amplifier, causing spurious outputs. For example, an HF transceiver signal radiated from a tri-band beam may be picked up by a VHF FM antenna on the same mast. The signal saturates the low-power FM transceiver output stage, even with power off, and is reradiated by the VHF antenna. Proper use of filters can reduce such spurious energy considerably.

The filter used will depend on the application and the level of attenuation needed. Band-pass filters attenuate spurious signals above and below the pass-band for which they are designed. Low-pass filters attenuate only signals above the cutoff frequency, while high-pass filters reduce energy below the design cutoff frequency.

The **Filters** chapter includes detailed information about designing suitable filters. Tables of component values in the **References** chapter allow you to select a particular design and scale the values for different frequencies and impedance ranges as needed.

## TRANSMITTING DEVICE RATINGS

### Plate Dissipation

The ultimate factor limiting the power-handling capability of a tube often (but not always) is its maximum plate dissipation rating. This is the measure of how many watts of heat the tube can safely dissipate, if it is cooled properly, without exceeding critical temperatures. Excessive temperature can damage or destroy internal tube components or vacuum seals, resulting in tube failure. The same tube may have different voltage, current and power ratings depending on the conditions under which it is operated, but its safe temperature ratings must not be exceeded in any case! Important cooling considerations are discussed in more detail in the Amplifier Cooling section of this chapter.

The efficiency of a power amplifier may range from approximately 25% to 75%, depending on its operating class, adjustment, and circuit losses. The efficiency indicates how much of the dc power supplied to the stage is converted to useful RF output power; the rest is dissipated as heat, mostly by the plate. By knowing the plate-dissipation limit of the tube and the efficiency expected from the class of operation selected, the maximum power input and output levels can be determined. The maximum safe power output is

$$P_{OUT} = \frac{P_D N_P}{100 - N_P} \quad (34)$$

where

$P_{OUT}$  = the power output in W  
 $P_D$  = the plate dissipation in W  
 $N_P$  = the efficiency (10% = 10).

The dc input power would simply be

$$P_{IN} = \frac{100 P_D}{100 - N_P} \quad (35)$$

Almost all vacuum-tube power amplifiers in amateur service today operate as linear amplifiers (Class AB or B) with efficiencies of approximately 50% to 65%. That means that a useful power output of approximately 1 to 2.0 times the plate dissipation generally can be achieved. This requires, or course, that the tube is cooled enough to realize its maximum plate dissipation rating and that no other tube rating, such as maximum plate current or grid dissipation, is exceeded.

Type of modulation and duty cycle also influence how much output power can be achieved for a given tube dissipation. Some types of operation are less efficient than others, meaning that the tube must dissipate more heat. Some forms of modulation, such as CW or SSB, are intermittent in nature, causing less average heating than modulation formats such as RTTY in which there is continuous transmission. Power-tube manufacturers use two different rating systems to allow for the variations in service. CCS (Continuous Commercial Service) is the more conservative rating and is used for specifying tubes that are in constant use at full power. The second rating system is based on intermittent, low-duty-cycle operation, and is known as ICAS (Intermittent Commercial and Amateur Service). ICAS ratings are normally used by commercial manufacturers and individual amateurs who wish to obtain maximum power output consistent with reasonable tube life in CW and SSB service. CCS ratings should be used for FM, RTTY and SSTV applications. (Plate power transformers

for amateur service are also rated in CCS and ICAS terms.)

## Maximum Ratings

Tube manufacturers publish sets of maximum values for the tubes they produce. No maximum rated value should ever be exceeded. As an example, a tube might have a maximum plate-voltage rating of 2500 V, a maximum plate-current rating of 500 mA, and a maximum plate dissipation rating of 350 W. Although the plate voltage and current ratings might seem to imply a safe power input of  $2500 \text{ V} \times 500 \text{ mA} = 1250 \text{ W}$ , this is true only if the dissipation rating will not be exceeded. If the tube is used in class AB2 with an expected efficiency of 60%, the maximum safe dc power input is

$$P_{IN} = \frac{100 P_D}{100 - N_D} = \frac{100 \times 350}{100 - 60} = 875 \text{ W}$$

In this case, any combination of plate voltage and current whose product does not exceed 875 W (and which allows the tube to achieve the expected 60% efficiency) is acceptable. A good compromise might be 2000 V and 437 mA:  $2000 \times 0.437 = 874 \text{ W}$  input. If the maximum plate voltage of 2500 is used, then the plate current should be limited to 350 mA (not 500 mA) to stay within the maximum plate dissipation rating of 350 W.

## TRANSISTOR POWER DISSIPATION

RF power-amplifier transistors are limited in power-handling capability by the amount of heat the device can safely dissipate. Power dissipation for a transistor is abbreviated  $P_D$ . The maximum rating is based on maintaining a case temperature of  $25^\circ\text{C}$  ( $77^\circ\text{F}$ ), which is seldom possible if a conventional air-cooled heat sink is used in an ambient air temperature of  $70^\circ\text{F}$  or higher. For higher temperatures, the device must be derated (in terms of milliwatts or watts per degree C) as specified by the manufacturer for that particular device. The efficiency considerations described earlier in reference to plate dissipation apply here also. A rule of thumb for selecting a transistor suitable for a given RF power output level is to choose one that has a maximum dissipation (with the heat sink actually to be used) of twice the desired output power.

## MAXIMUM TRANSISTOR RATINGS

Transistor data sheets specify the maximum operating voltage for several conditions. Of particular interest is the  $V_{CEO}$  specification (collector to emitter voltage, with the base open). In RF amplifier service the collector to emitter voltage can rise to twice the dc supply potential. Thus,

**Table 13.3**

### Typical Tank-Capacitor Plate Spacings

Spacing Inches	Peak Voltage	Spacing Inches	Peak Voltage	Spacing Inches	Peak Voltage
0.015	1000	0.07	3000	0.175	7000
0.02	1200	0.08	3500	0.25	9000
0.03	1500	0.125	4500	0.35	11000
0.05	2000	0.15	6000	0.5	13000

if a 12-V supply is used, the transistor should have a  $V_{CEO}$  of 24 V or greater to preclude damage.

The maximum collector current is also specified by the manufacturer. This specification is actually limited by the current-carrying capabilities of the internal bonding wires. Of course, the collector current must stay below the level that generates heat higher than the allowable device power dissipation. Many transistors are also rated for the load mismatch they can safely withstand. A typical specification might be for a transistor to tolerate a 30:1 SWR at all phase angles.

Transistor manufacturers publish data sheets that describe all the appropriate device ratings. Typical operating results are also given in these data sheets. In addition, many manufacturers publish application notes illustrating the use of their devices in practical circuits. Construction details are usually given. Perhaps owing to the popularity of Amateur Radio among electrical engineers, many of the notes describe applications especially suited to the Amateur Service. Specifications for some of the more popular RF power transistors are found in the **Component Data** chapter.

## PASSIVE COMPONENT RATINGS

### Output Tank Capacitor Ratings

The tank capacitor in a high-power amplifier should be chosen with sufficient spacing between plates to preclude high-voltage breakdown. The peak RF voltage present across a properly loaded tank circuit, without modulation, may be taken conservatively as being equal to the dc plate or collector voltage. If the dc supply voltage also appears across the tank capacitor, this must be added to the peak RF voltage, making the total peak voltage twice the dc supply voltage. At the higher voltages, it is usually desirable to design the tank circuit so that the dc supply voltages do not appear across the tank capacitor, thereby allowing the use of a smaller capacitor with less plate spacing. Capacitor manufacturers usually rate their products in terms of the peak voltage between plates. Typical plate spacings are given in **Table 13.3**.

Output tank capacitors should be

mounted as close to the tube as temperature considerations will permit, to make possible the shortest path with the lowest possible inductive reactance from plate to cathode. Especially at the higher frequencies, where minimum circuit capacitance becomes important, the capacitor should be mounted with its stator plates well spaced from the chassis or other shielding. In circuits in which the rotor must be insulated from ground, the capacitor should be mounted on ceramic insulators of a size commensurate with the plate voltage involved and—most important of all, from the viewpoint of safety to the operator—a well-insulated coupling should be used between the capacitor shaft and the knob. The section of the shaft attached to the control knob should be well grounded. This can be done conveniently by means of a metal shaft bushing at the panel.

### High-Frequency Tank Coils

Tank coils should be mounted at least half their diameter away from shielding or other large metal surfaces, such as blower housings, to prevent a marked loss in Q. Except perhaps at 24 and 28 MHz, it is not essential that the coil be mounted extremely close to the tank capacitor. Leads up to 6 or 8 inches are permissible. It is more important to keep the tank capacitor, as well as other components, out of the

**Table 13.4**

### Copper Conductor Sizes for Transmitting Coils for Tube Transmitters

Power Output (Watts)	Band (MHz)	Minimum Conductor Size
1500	1.8-3.5	10
	7-14	8 or 1/8"
	18-28	6 or 3/16"
500	1.8-3.5	12
	7-14	10
	18-28	8 or 1/8"
150	1.8-3.5	16
	7-14	12
	18-28	10

\*Whole numbers are AWG; fractions of inches are tubing ODs.

immediate field of the coil.

The principal practical considerations in designing a tank coil usually are to select a conductor size and coil shape that will fit into available space and handle the required power without excessive heating. Excessive power loss as such is not necessarily the worst hazard in using too-small a conductor: it is not uncommon for the heat generated to actually unsolder joints in the tank circuit and lead to physical damage or failure. For this reason it's extremely important, especially at power levels above a few hundred watts, to ensure that all electrical joints in the tank circuit are secured mechanically as well as soldered. **Table 13.4** shows recommended conductor sizes for amplifier tank coils, assuming loaded tank circuit  $Q$ s of 15 or less on the 24 and 30 MHz bands and 8 to 12 on the lower frequency bands.

In the case of input circuits for screen-grid tubes where driving power is quite small, loss is relatively unimportant and almost any physically convenient wire size and coil shape is adequate.

The conductor sizes in Table 13.4 are based on experience in continuous-duty amateur CW, SSB, and RTTY service and assume that the coils are located in a reasonably well ventilated enclosure. If the tank area is not well ventilated and/or if significant tube heat is transferred to the coils, it is good practice to increase AWG wire sizes by two (for example, change from AWG 12 to AWG 10) and tubing sizes by  $1/16$  inch.

Larger conductors than required for current handling are often used to maximize unloaded  $Q$ , particularly at higher frequencies. Where skin depth effects increase losses, the greater surface area of large diameter conductors can be beneficial. Small-diameter copper tubing, up to  $3/8$  inch outer diameter, can be used successfully for tank coils up through the lower VHF range. Copper tubing in sizes suitable for constructing high-power coils is generally available in 50 ft rolls from plumbing and refrigeration equipment suppliers. Silver plating the tubing further reduces losses. This is especially true as the tubing ages and oxidizes. Silver oxide is a much better conductor than copper oxides, so silver-plated tank coils maintain their low-loss characteristics even after years of use.

At VHF and above, tank circuit inductances do not necessarily resemble the familiar coil. The inductances required to resonate tank circuits of reasonable  $Q$  at these higher frequencies are small enough that only strip lines or sections of transmission line are practical. Since these are constructed from sheet metal or large-di-

ameter tubing, current-handling capabilities normally are not a relevant factor.

## RF Chokes

The characteristics of any RF choke vary with frequency. At low frequencies the choke presents a nearly pure inductance. At some higher frequency it takes on high impedance characteristics resembling those of a parallel-resonant circuit. At a still higher frequency it goes through a series-resonant condition, where the impedance is lowest—generally much too low to perform satisfactorily as a shunt-feed plate choke. As frequency increases further, the pattern of alternating parallel and series resonances repeats. Between resonances, the choke will show widely varying amounts of inductive or capacitive reactance.

In series-feed circuits, these characteristics are of relatively small importance because the RF voltage across the choke is negligible. In a shunt-feed circuit such as is used in most high-power amplifiers, however, the choke is directly in parallel with the tank circuit, and is subject to the full tank RF voltage. If the choke does not present a sufficiently high impedance, enough power will be absorbed by the choke to burn it out. To avoid this, the choke must have a sufficiently high reactance to be effective at the lowest frequency (at least equal to the plate load resistance), and yet have no series resonances near any of the higher frequency bands. A resonant-choke failure in a high-power amplifier can be very dramatic and damaging!

Thus any choke intended for shunt-feed use should be carefully investigated with a dip meter. The choke must be shorted end-to-end with a direct, heavy braid or strap. Because nearby metallic objects affect the resonances, it should be mounted in its intended position, but disconnected from the rest of the circuit. A dip meter coupled an inch or two away from one end of the choke nearly always will show a deep, sharp dip at the lowest series-resonant frequency and shallower dips at higher series resonances.

Any choke to be used in an amplifier for the 1.8 to 28 MHz bands requires careful (or at least lucky!) design to perform well on *all* amateur bands within that range. Most simply put, the challenge is to achieve sufficient inductance that the choke doesn't "cancel" a large part of tuning capacitance on 1.8 MHz. At the same time, try to position all its series resonances where they can do no harm. In general, close wind enough #20 to #24 magnet wire to provide about 135  $\mu$ H inductance on a  $3/4$  to 1-inch diameter cylindrical form of ceramic, Teflon, or fiberglass. This

gives a reactance of 1500  $\Omega$  at 1.8 MHz and yet yields a first series resonance in the vicinity of 25 MHz. Before the advent of the 24.9 MHz band this worked fine. But trying to "squeeze" the resonance into the narrow gaps between the 21, 24, and/or 28 MHz bands is quite risky unless sophisticated instrumentation is available. If the number of turns on the choke is selected to place its first series resonance at 23.2 MHz, midway between 21.45 and 24.89 MHz, the choke impedance will typically be high enough for satisfactory operation on the 21, 24 and 28 MHz bands. The choke's first series resonance should be measured very carefully as described above using a dip meter and calibrated receiver or RF impedance bridge, with the choke mounted in place on the chassis.

Investigations with a vector impedance meter have shown that "trick" designs, such as using several shorter windings spaced along the form, show little if any improvement in choke resonance characteristics. Some commercial amplifiers circumvent the problem by bandswitching the RF choke. Using a larger diameter (1 to 1.5 inch) form does move the first series resonance somewhat higher for a given value of basic inductance. Beyond that, it is probably easiest for an all-band amplifier to add or subtract enough turns to move the first resonance to about 35 MHz and settle for a little less than optimum reactance on 1.8 MHz.

## Blocking Capacitors

A series capacitor is usually used at the input of the amplifier output circuit. Its purpose is to block dc from appearing on matching circuit components or the antenna. As mentioned in the section on tank capacitors, output-circuit voltage requirements are considerably reduced when only RF voltage is present.

To provide a margin of safety, the voltage rating for a blocking capacitor should be at least 25 to 50% greater than the dc voltage applied. A large safety margin is desirable, since blocking capacitor failure can bring catastrophic results.

To avoid affecting the amplifier's tuning and matching characteristics, the blocking capacitor should have a low impedance at all operating frequencies. Its reactance at the lowest operating frequency should be not more than about 5% of the plate load resistance.

The capacitor also must be capable of handling, without overheating or significantly changing value, the substantial RF current that flows through it. This current usually is greatest at the highest frequency of operation where tube output capacitance constitutes a significant part of the

total tank capacitance. A significant portion of circulating tank current therefore flows through the blocking capacitor. As a conservative and very rough rule of thumb, the maximum RF current in the blocking capacitor (at 28 MHz) is

$$I_{\text{CBlock}} \approx I_p + 0.15 \times C_{\text{OUT}} \times V_{\text{dc}} \quad (36)$$

where

$I_{\text{CBlock}}$  = maximum RMS current through blocking capacitor, in A

$C_{\text{OUT}}$  = output capacitance of the output tubes, in pF

$V_{\text{dc}}$  = dc plate voltage, in kV

$I_p$  = dc plate current at full output, in A.

Transmitting capacitors are rated by their manufacturers in terms of their RF current-carrying capacity at various frequencies. Below a couple hundred watts at the high frequencies, ordinary disc ceramic capacitors of suitable voltage rating work well in high-impedance tube amplifier output circuits. Some larger disk capacitors rated at 5 to 8 kV also work well for higher power levels at HF; for example, two inexpensive Centralab type DD-602 discs (0.002  $\mu\text{F}$ , 6 kV) in parallel have proved to be a reliable blocking capacitor for 1.5-kW amplifiers operating at plate voltages to about 2.5 kV. At very high power and voltage levels and at VHF, ceramic "doorknob" transmitting capacitors are needed for their low losses and high current handling capabilities. So-called "TV doorknobs" may break down at high RF current levels and should be avoided.

The very high values of  $Q_L$  found in many VHF and UHF tube-type amplifier tank circuits often require custom fabrication of the blocking capacitor. This can usually be accommodated through the use of a Teflon "sandwich" capacitor. Here, the blocking capacitor is formed from two parallel plates separated by a thin layer of Teflon. This capacitor often is part of the tank circuit itself, forming a very low-loss blocking capacitor. Teflon is rated for a minimum breakdown voltage of 2000 V per mil of thickness, so voltage breakdown should not be a factor in any practically realized circuit. The capacitance formed from such a Teflon sandwich can be calculated from the information presented elsewhere in this *Handbook* (use a dielectric constant of 2.1 for Teflon). In order to prevent any potential irregularities caused by dielectric thickness variations (including air gaps), Dow-Corning DC-4 silicone grease should be evenly applied to both sides of the Teflon dielectric. This grease has properties similar to Teflon, and will fill in any surface irregularities that might cause problems.

The very low impedances found in transistorized amplifiers present special prob-

lems. In order to achieve the desired low blocking-capacitor impedance, large-value capacitors are required. Special ceramic chips and mica capacitors are available that meet the requirements for high capacitance, large current carrying capability and low associated inductance. These capacitors are more costly than standard disk-ceramic or silver-mica units, but their level of performance easily justifies their price. Most of these special-purpose capacitors are either leadless or come with wide straps instead of normal wire leads. Disc-ceramic and other wire-lead capacitors are generally not suitable for transistor power-amplifier service.

## SOURCES OF OPERATING VOLTAGES

### Tube Filament or Heater Voltage

The heater voltage for the indirectly heated cathode tubes found in low-power classifications may vary 10% above or below rating without seriously reducing the life of the tube. A power vacuum tube can use either a directly heated filament or an indirectly heated cathode. The filament voltage for either type should be held within 5% of rated voltage. Because of internal tube heating at UHF and higher, the manufacturers' filament voltage rating often is reduced at these higher frequencies. The derated filament voltages should be followed carefully to maximize tube life. Series dropping resistors may be required in the filament circuit to attain the correct voltage. The voltage should be measured at the filament pins of the tube socket while the amplifier is running. The filament choke and interconnecting wiring all have voltage drops associated with them. The high current drawn by a power-tube heater circuit causes substantial voltage drops to occur across even small resistances. Also, make sure that the plate power drawn from the power line does not cause the filament voltage to drop below the proper value when plate power is applied.

Thoriated filaments lose emission when the tube is overloaded appreciably. If the overload has not been too prolonged, emission sometimes may be restored by operating the filament at rated voltage, with all other voltages removed, for a period of 30 to 60 minutes. Alternatively, you might try operating the tube at 20% above rated filament voltage for five to ten minutes.

### Vacuum-Tube Plate Voltage

DC plate voltage for the operation of RF amplifiers is most often obtained from a transformer-rectifier-filter system (see the **Power Supplies** chapter) designed to deliver the required plate voltage at the

required current. It is not unusual for a power tube to arc over internally (generally from the plate to the screen or control grid) once or twice, especially soon after it is first placed into service. The flashover by itself is not normally dangerous to the tube, provided that instantaneous maximum plate current to the tube is held to a safe value and the high-voltage plate supply is shut off very quickly.

A good protective measure against this is the inclusion of a high-wattage power resistor in series with the plate high-voltage circuit. The value of the resistor, in ohms, should be approximately 10 to 15 times the no-load plate voltage in kV. This will limit peak fault current to 67 to 100 A. The series resistor should be rated for 25 or 50 W power dissipation; vitreous enamel coated wire-wound resistors of the common Ohmite or Clarostat types have been found to be capable of handling repeated momentary fault-current surges without damage. Aluminum-cased resistors such as some made by Dale are not recommended for this application. Each resistor also must be large enough to safely handle the maximum value of normal plate current; the wattage rating required may be calculated from  $P = I^2 R$ . If the total filter capacitance exceeds 25  $\mu\text{F}$ , it is a good idea to use 50-W resistors in any case. Even at high plate-current levels, the addition of the resistors does little to affect the dynamic regulation of the plate supply.

Since tube (or other high-voltage circuit) arcs are not necessarily self-extinguishing, a fast-acting plate overcurrent relay or primary circuit breaker also is recommended to quickly shut off ac power to the HV supply when an arc begins. Using this protective system, a mild HV flashover may go undetected, while a more severe one will remove ac power from the HV supply. (The cooling blower should remain energized however, since the tube may be hot when the HV is removed due to an arc.) If effective protection is not provided, however, a "normal" flashover, even in a new tube, is likely to damage or destroy the tube, and also frequently destroys the rectifiers in the power supply as well as the plate RF choke. A power tube that flashes over more than about 3 to 5 times in a period of several months likely is defective and will have to be replaced before long.

### Grid Bias

The grid bias for a linear amplifier should be highly filtered and well regulated. Any ripple or other voltage change in the bias circuit modulates the amplifier. This causes hum and/or distortion to appear on the signal. Since most linear amplifiers draw only small amounts of grid current, these bias-supply requirements

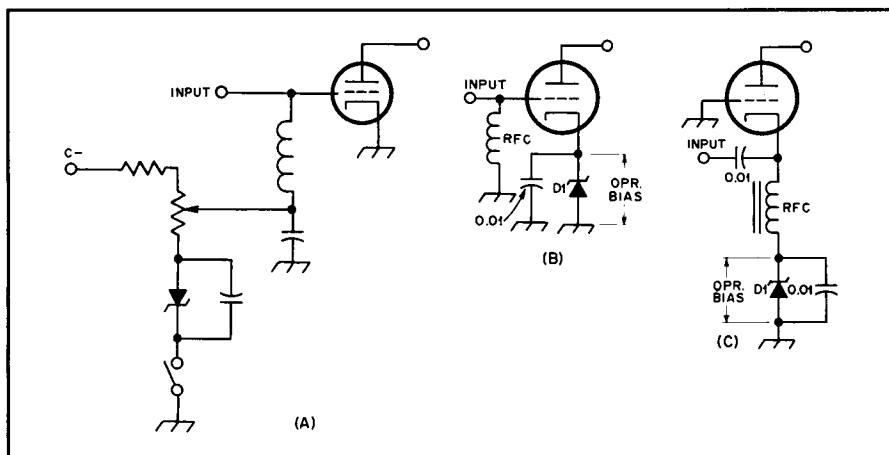

Fig 13.11—Various techniques for providing operating bias with tube amplifiers.

Fig 13.12—A Zener-regulated screen supply for use with a tetrode. Protection is provided by a fuse and a varistor.

are not difficult to achieve.

Fixed bias for class AB1 tetrode and pentode amplifiers is usually obtained from a variable-voltage regulated supply. Voltage adjustment allows setting bias level to give the desired resting plate current. Fig 13.11A shows a simple Zener-diode-regulated bias supply. The dropping resistor is chosen to allow approximately 10 mA of Zener current. Bias is then reasonably well regulated for all drive conditions up to 2 or 3 mA of grid current. The potentiometer allows bias to be adjusted between Zener and approximately 10 V higher. This range is usually adequate to allow for variations in the characteristics of different tubes. Under standby conditions, when it is desirable to cut off the tube entirely, the Zener ground return is interrupted so the full bias supply voltage is applied to the grid.

In Fig 13.11B and C, bias is obtained from the voltage drop across a Zener diode in the cathode (or filament center-tap) lead. Operating bias is obtained by the voltage drop across D1 as a result of plate (and screen) current flow. The diode voltage drop effectively raises the cathode potential relative to the grid. The grid is

therefore negative with respect to the cathode by the Zener voltage of the diode. The Zener-diode wattage rating should be twice the product of the maximum cathode current times the rated zener voltage. Therefore, a tube requiring 15 V of bias with a maximum cathode current of 100 mA would dissipate 1.5 W in the Zener diode. To allow a suitable safety factor, the diode rating should be 3 W or more. The circuit of Fig 13.11C illustrates how D1 would be used with a cathode driven (grounded grid) amplifier as opposed to the grid driven example at B.

In all cases, the Zener diode should be bypassed by a 0.01-μF capacitor of suitable voltage. Current flow through any type of diode generates shot noise. If not bypassed, this noise would modulate the amplified signal, causing distortion in the amplifier output.

### Screen Voltage For Tubes

Power tetrode screen current varies widely with both excitation and loading. The current may be either positive or negative, depending on tube characteristics and amplifier operating conditions. In a linear amplifier, the screen voltage should be

well regulated for all values of screen current. The power output from a tetrode is very sensitive to screen voltage, and any dynamic change in the screen potential can cause distorted output. Zener diodes are commonly used for screen regulation.

Fig 13.12 shows a typical example of a regulated screen supply for a power tetrode amplifier. The voltage from a fixed dc supply is dropped to the Zener stack voltage by the current-limiting resistor. A screen bleeder resistor is connected in parallel with the zener stack to allow for the negative screen current developed under certain tube operating conditions. Bleeder current is chosen to be roughly 10 to 20 mA greater than the expected maximum negative screen current, so that screen voltage is regulated for all values of current between maximum negative screen current and maximum positive screen current. For external-anode tubes in the 4CX250 family, a typical screen bleeder current value would be 20 mA. For the 4CX1000 family, a screen-bleeder current of 70 mA is required.

Screen voltage should never be applied to a tetrode unless plate voltage and load also are applied; otherwise the screen tends to act like an anode and will draw excessive current. Supplying the screen through a series dropping resistor from the plate supply affords a measure of protection, since the screen voltage only appears when there is plate voltage. Alternatively, a fuse can be placed between the regulator and the bleeder resistor. The fuse should not be installed between the bleeder resistor and the tube, because the tube should never be operated without a load on the screen. Without a load, the screen potential tends to rise to the anode voltage. Any screen bypass capacitors or other associated circuits are likely be damaged by this high voltage.

In Fig 13.12, a varistor is connected from screen to ground. If, because of some circuit failure, the screen voltage should rise substantially above its nominal level, the varistor will conduct and clamp the screen voltage to a low level. If necessary to protect the varistor or screen dropping resistors, a fuse or overcurrent relay may be used to shut off the screen supply so that power is interrupted before any damage occurs. The varistor voltage should be approximately 30 to 50% higher than normal screen voltage.

### Transistor Biasing

Solid-state power amplifiers generally operate in Class C or AB. When some bias is desired during Class C operation (Fig 13.13A), a resistance of the appropriate value can be placed in the emitter return as shown. Most transistors will operate in Class C without adding bias externally, but

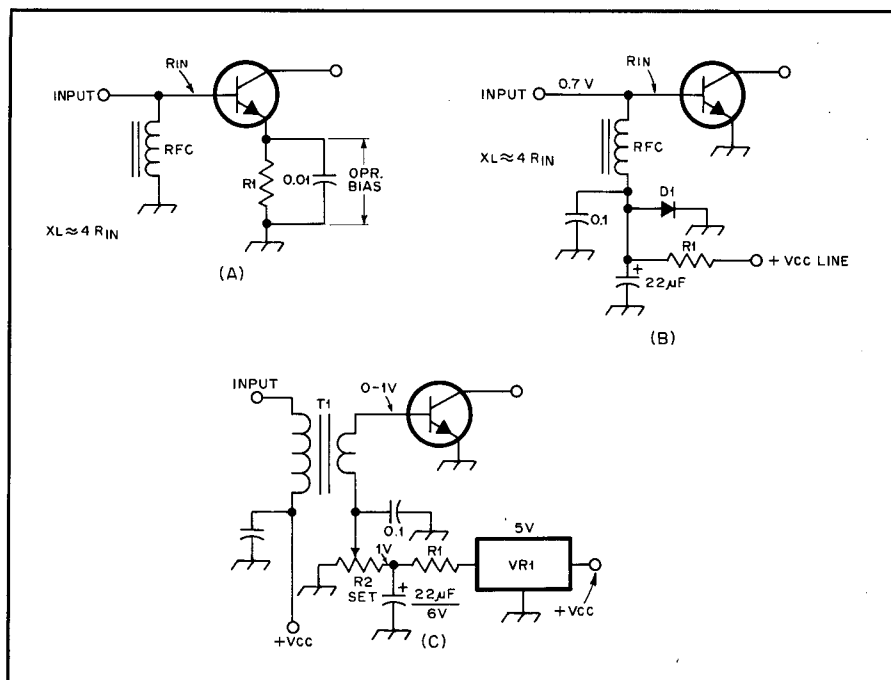

Fig 13.13—Biasing methods for use with transistor amplifiers.

in some instances the amplifier efficiency can be improved by means of emitter bias. Reverse bias supplied to the base of the Class C transistor should be avoided because it will lead to internal breakdown of the device during peak drive periods. The damage is frequently a cumulative phenomenon, leading to gradual destruction of the transistor junction.

A simple method for Class AB biasing is shown in Fig 13.13B. D1 is a silicon diode that acts as a bias clamp at approximately 0.7 V. This forward bias establishes linear-amplification conditions. That value of bias is not always optimum for a specified transistor in terms of IMD. Variable bias of the type illustrated in Fig 13.13C permits the designer sufficient flexibility to position the operating point for best linearity. The diode clamp or the reference sensor for another type of regulator is usually thermally bonded to the power transistor or its heat sink. The bias level then tracks the thermal characteristics of the output transistor. Since a transistor's current transfer characteristics are a function of temperature, thermal tracking of the bias is necessary to maintain device linearity and, in the case of bipolar devices, to prevent thermal runaway and the subsequent destruction of the transistor.

## AMPLIFIER COOLING

### Tube Cooling

Vacuum tubes must be operated within the temperature range specified by the manufacturer if long tube life is to be achieved. Tubes having glass envelopes

and rated at up to 25-W plate dissipation may be used without forced-air cooling if the design allows a reasonable amount of convection cooling. If a perforated metal enclosure is used, and a ring of 1/4 to 3/8-inch-diameter holes is placed around the tube socket, normal convective air flow can be relied on to remove excess heat at room temperatures.

For tubes with greater plate dissipation ratings, and even for very small tubes operated close to maximum rated dissipa-

tion, forced-air cooling with a fan or blower is needed. Most manufacturers rate tube cooling requirements for continuous-duty operation. Their literature will indicate the required volume of air flow, in cubic feet per minute (CFM), at some particular back pressure. Often this data is given for several different values of plate dissipation, ambient air temperature and even altitude above sea level.

One extremely important consideration is often overlooked by power-amplifier designers and users alike: a tube's plate dissipation rating is only its maximum *potential* capability. The power that it can *actually* dissipate safely depends directly on the cooling provided. The actual power capability of virtually all tubes used in high-power amplifiers for amateur service depends on the volume of air forced through the tube's cooling structure.

This requirement usually is given in terms of cubic feet of air per minute, (CFM), delivered into a "back pressure" representing the resistance of the tube cooler to air flow, stated in inches of water. Both the CFM of air flow required and the pressure needed to force it through the cooling system are determined by ambient air temperature and altitude (air density), as well as by the amount of heat to be dissipated. The cooling fan or blower must be capable of delivering the specified air flow into the corresponding back pressure. As a result of basic air flow and heat transfer principles, the volume of air flow required through the tube cooler increases considerably faster than the plate dissipation, and back pressure increases even faster than air flow. In addition, blower

Fig 13.14—Air is forced into the chassis by the blower and exists through the tube socket. The manometer is used to measure system back pressure, which is an important factor in determining the proper size blower.

air output decreases with increasing back pressure until, at the blower's so-called "cut-off pressure," actual air delivery is zero. Larger and/or faster-rotating blowers are required to deliver larger volumes of air at higher back pressure.

Values of CFM and back pressure required to realize maximum rated plate dissipation for some of the more popular tubes, sockets and chimneys (with 25°C ambient air and at sea level) are given in Table 13.5. Back pressure is specified in inches of water and can be measured easily in an operational air system as indicated in Figs 13.14 and 13.15. The pressure differential between the air passage and atmospheric pressure is measured with a device called a manometer. A manometer is nothing more than a piece of clear tubing, open at both ends and fashioned in the shape of a "U." The manometer is temporarily connected to the chassis and is removed after the measurements are completed. As shown in the diagrams, a small amount of water is placed in the tube. At Fig 13.15A the blower is "off" and the water seeks its own level, because the air pressure (ordinary atmospheric pressure) is the same at both ends of the manometer tube. At B, the blower is "on" (socket, tube and chimney in place) and the pressure difference, in terms of inches of water, is measured. For most applications a standard ruler used for measurement will yield sufficiently accurate results.

Table 13.6 gives the performance specifications for a few of the many Dayton blowers which are available through Grainger catalog outlets in all 50 states. Other blowers having wheel diameters, widths and rotational speeds similar to any in Table 13.6 likely will have similar flow and back-pressure characteristics. If in doubt about specifications, consult the manufacturer. Tube temperature under actual operating conditions is the ultimate criterion for cooling adequacy and may be determined using special crayons or lacquers which melt and change appearance at specific temperatures. The setup of Fig 13.15, however, nearly always gives sufficiently accurate information.

As an example, consider the cooling design of a linear amplifier to use one 3CX800A7 tube, to operate near sea level with the air temperature not above 25°C. The tube, running 1150-W dc input, easily delivers 750-W continuous output, resulting in 400 W plate dissipation ( $P_{Dis} = P_{IN} - P_{OUT}$ ). According to the manu-

Fig 13.15—At A the blower is "off" and the water will seek its own level in the manometer. At B the blower is "on" and the amount of back pressure in terms of inches of water can be measured as indicated.

facturer's data, adequate tube cooling at 400 W  $P_D$  requires at least 6 CFM of air at 0.09 inches of water back pressure. Referring to Table 13.6, a Dayton no. 2C782 will do the job with a good margin of safety.

If the same single tube were to be operated at 2.3 kW dc input to deliver 1.5 kW output (substantially exceeding its maximum electrical ratings!),  $P_{IN}$  would be about 2300 W and  $P_D \approx 800$  W. The minimum cooling air required would be about 19 CFM at 0.5 inches of water pressure—doubling  $P_{DIS}$ , more than tripling the CFM of air flow required and increasing back pressure requirements on the blower by a factor of 5.5!

However, two 3CX800A7 tubes are needed to deliver 1.5 kW of continuous maximum legal output power in any case. Each tube will operate under the same conditions as in the single-tube example above, dissipating 400-W. The total cooling air requirement for the two tubes is therefore 12 CFM at about 0.09 inches of water, only two-thirds as much air volume and one-fifth the back pressure required by a single tube. While this may seem surprising, the reason lies in the previously mentioned fact that both the airflow required by a tube and the resultant back pressure increase much more rapidly than  $P_D$  of the tube. Blower air delivery capability, conversely, decreases as back pressure is increased. Thus a Dayton 2C782 blower can cool two 3CX800A7 tubes dissipating 800 W total, but a much larger (and probably noisier) no. 4C440 would be required to handle the same power with a single tube.

In summary, three very important considerations to remember are these:

- A tube's actual safe plate dissipation capability is *totally dependent* on the amount of cooling air forced through its cooling system. Any air-cooled power tube's maximum plate dissipation rating is meaningless unless the specified amount of cooling air is supplied.
- Two tubes will always safely dissipate a given power with a significantly smaller (and quieter) blower than is required to dissipate the same power with a single tube of the same type. A corollary is that a given blower can virtually always dissipate more power when cooling two tubes than when cooling a single tube of the same type.
- Blowers vary greatly in their ability to deliver air against back pressure so blower selection should not be taken lightly.

A common method for directing the flow of air around a tube involves the use of a pressurized chassis. This system is shown in Fig 13.14. A blower attached to the chassis forces air around the tube base, often through holes in its socket. A chimney is used to

guide air leaving the base area around the tube envelope or anode cooler, preventing it from dispersing and concentrating the flow for maximum cooling.

A less conventional approach that offers a significant advantage in certain situations is shown in Fig 13.16. Here the anode compartment is pressurized by the blower. A special chimney is installed between the anode heat exchanger and an exhaust hole in the compartment cover. When the blower pressurizes the anode compartment, there are two parallel paths for air flow: through the anode and its chimney, and through the air system socket. Dissipation, and hence cooling air required, generally is much greater for the anode than for the tube base. Because high-volume anode airflow need not be forced through restrictive air channels in the base area, back pressure may be very significantly reduced with certain tubes and sockets. Only airflow actually needed is bled through the base area. Blower back pressure requirements may sometimes be reduced by nearly half through this approach.

Table 13.5 also contains the part numbers for air-system sockets and chimneys available for use with the tubes that are listed. The builder should investigate which of the sockets listed for the 4CX250R, 4CX300A, 4CX1000A and 4CX1500A best fit the circuit needs. Some of the sockets have certain tube elements grounded internally through the socket. Others have elements bypassed to ground through capacitors that are integral parts of the sockets.

Depending on one's design philosophy and tube sources, some compromises in the cooling system may be appropriate. For example, if glass tubes are available inexpensively as broadcast pulls, a shorter life span may be acceptable. In such a case, an increase of convenience and a reduction in cost, noise, and complexity can be had by using a pair of "muffin" fans. One fan may be used for the filament seals and one for the anode seal, dispensing with a blower and air-system socket and chimney. The air flow with this scheme is not as uniform as with the use of a chimney. The tube envelope mounted in a cross flow has flow stagnation points and low heat transfer in certain regions of the envelope. These points become hotter than the rest of the envelope. The use of multiple fans to disturb the cross air flow can significantly reduce this problem. Many amateurs have used this cooling method successfully in low-duty-cycle CW and SSB operation but it is not recommended for AM, SSTV or RTTY service. The true test of the effectiveness of a forced air cooling system is the amount of heat carried away from the tube by the air

**Fig 13.16—Anode compartment pressurization may be more efficient than grid compartment pressurization. Hot air exits upwards through the tube anode and through the chimney. Cool air also goes down through the tube socket to cool tube's pins and the socket itself.**

stream. The power dissipated can be calculated from the air flow temperatures. The dissipated power is

$$P_D = 169 Q_A \left[ \frac{T_1}{T_2} - 1 \right] \quad (37)$$

where

$P_D$  = the dissipated power, in W

$Q_A$  = the air flow, in CFM (cubic feet per minute)

$T_1$  = the inlet air temperature, kelvins (normally quite close to room temperature)

$T_2$  = the amplifier exhaust temperature, kelvins.

The exhaust temperature can be measured with a cooking thermometer at the air outlet. The thermometer should not be placed inside the anode compartment because of the high voltage present.

## Transistor Cooling

Transistors used in power amplifiers dissipate significant amounts of power, and the heat so generated must be effectively removed to maintain acceptable device temperatures. Some bipolar power transistors have the collector connected directly to the case of the device, as the collector creates most of the heat generated when the transistor is in operation. Others have the emitter connected to the case. However, if operated close to maximum rated dissipation, even the larger case designs cannot normally conduct heat away fast enough to keep the operating temperature of the device within the safe area—the maximum temperature that a device can stand without damage. Safe area is usually specified in a device data sheet, often in graphical form. Germanium power transistors theoretically may be operated at internal temperatures up to 100°C, while silicon

devices may be run at up to 200°C. However, to assure long device lifetimes much lower case temperatures—not greater than 50° to 75°C for germanium and 75° to 100°C for silicon—are highly desirable. Leakage currents in germanium devices can be very high at elevated temperatures; thus, silicon transistors are preferred for most power applications.

A properly chosen heat sink often is essential to help keep the transistor junction temperature in the safe area. For low-power applications a simple clip-on heat sink will suffice, while for 100 W or higher input power a massive cast-aluminum finned radiator usually is necessary. The appropriate size heat sink can be calculated based on the thermal resistance between the transistor case and ambient air temperature. The first step is to calculate the total power dissipated by the transistor:

$$P_D = P_{DC} + R_{FIn} - P_{RFout} \quad (38)$$

where

$P_D$  = the total power dissipated by the transistor in W

$P_{DC}$  = the dc power into the transistor, in W

$P_{RFIn}$  = the RF (drive) power into the transistor in W

$P_{RFout}$  = the RF output power from the transistor in W.

The value of  $P_D$  is then used to obtain the  $\theta_{CA}$  value from

$$\theta_{CA} = (T_C - T_A)/P_D \quad (39)$$

where

$\theta_{CA}$  = the thermal resistance of the device case to ambient

$T_C$  = the device case temperature in °C

$T_A$  = the ambient temperature (room temperature) in °C.

A suitable heat sink, capable of radiating to ambient air all heat generated by the transistor, can then be chosen from the manufacturer's specifications for  $\theta_{CA}$ . A well-designed heat-sink system minimizes thermal path lengths and maximizes their cross-sectional areas. The contact area between the transistor and heat sink should have very low thermal resistance. The heat sink's mounting surface must be flat and the transistor firmly attached to the heat sink so intimate contact—without gaps or air voids—is made between the two. The use of silicone-based heat sink compounds can provide considerable improvement in thermal transfer. The thermal resistance of such grease is considerably lower than that of air, but not nearly

as good as that of copper or aluminum. The quantity of grease should be kept to an absolute minimum. Only enough should be used to fill in any small air gaps between the transistor and heat sink mating surfaces. The maximum temperature rise in the transistor junction may easily be calculated by using the equation

$$T_J = (\theta_{JC} + \theta_{CA}) P_D + T_A \quad (40)$$

where

$T_J$  = the transistor junction temperature in °C

$\theta_{JC}$  = the manufacturer's published thermal resistance of the transistor

$\theta_{CA}$  = the thermal resistance of the device case to ambient

$P_D$  = the power dissipated by the transistor

$T_A$  = the ambient temperature in °C.

The value of  $T_J$  should be kept well below the manufacturer's recommended maximum to prevent premature transistor failure. Measured values of the ambient temperature and the device case temperature can be used in the preceding formulas to calculate junction temperature. **The Real World Components** chapter contains a more detailed discussion of transistor cooling.

## Design Guidelines and Examples

Most of the problems facing an amplifier designer are not theoretical, but have to do with real-world component limitations. **The Real World Components** chapter discusses the differences between ideal and real components

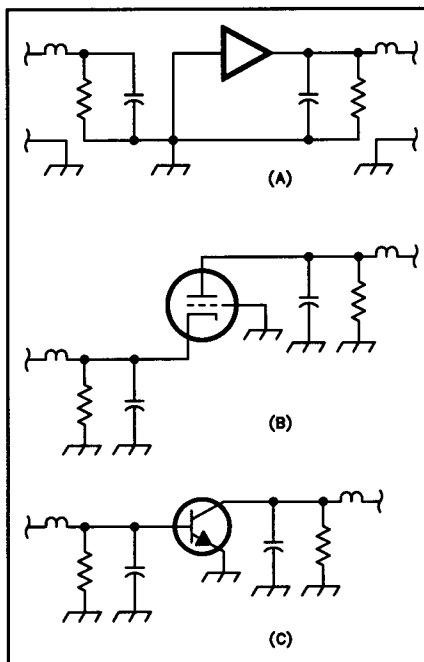

A simplified equivalent schematic of an amplifying device is shown in Fig 13.17A. The input is represented by a series (parasitic) inductance feeding a resistance in parallel with a capacitance. The output consists of a current generator in parallel with a resistance and capacitance, followed by a series inductance. This is a reasonably accurate description of both transistors and vacuum tubes, regardless of circuit configuration (as demonstrated in Figs 13.17B and C). Both input and output impedances have a resistive component in parallel with a reactive component. Each also has a series inductive reactance, which represents connecting leads within the device. These inductances, unlike the other components of input and output impedance, often are not characterized in manufacturers' device specifications.

The amplifier input and output matching networks must transform the com-

plex impedances of the amplifying device to the source and load impedances (often 50-Ω transmission lines). Imped-

ances associated with other parts of the amplifier circuit, such as a dc-supply choke, must also be considered in designing the matching networks. The matching networks and other circuit components are influenced by each other's presence, and these mutual effects must be given due consideration.

Perhaps the best way to clarify the considerations that enter into designing various types of RF power amplifiers is through example. The following examples illustrate common problems associated with power-amplifier design. They are not intended as detailed construction plans, but only demonstrate typical approaches useful in designing similar projects.

**Fig 13.17—The electrical equivalents for power amplifiers. At A, the input is represented by a series stray inductance, then a resistor in parallel with a capacitor. The output is a current source in parallel with a resistor and capacitor, followed by a series stray inductance. These effects are applied to tubes and transistors in B and C.**

C2 and L1 form the input pi network. C3 is a blocking capacitor to isolate the exciter from the cathode dc potential. Note that when the tube's average input resistance is close to  $50\ \Omega$ , as in the case of the 8877, a simple parallel-resonant tank often can successfully perform the tuning and flywheel functions, since no impedance transformation is necessary. In this case it is important to minimize stray lead inductance between the tank and tube to avoid undesired impedance transformation.

The filament or "heater" in indirectly heated tubes such as the 8877 must be very close to the cathode to heat the cathode efficiently. A capacitance of several picofarads exists between the two. Particularly at very high frequencies, where these few picofarads represent a relatively low reactance, RF drive intended for the cathode can be capacitively coupled to the lossy filament and dissipated as heat. To avoid this, above about 50 MHz, the filament must be kept at a high RF impedance above ground. The high impedance (represented by choke RFC1 in Fig 13.18) minimizes RF current flow in the filament circuit so that RF dissipated in the filament becomes negligible. The choke's low-frequency resistance should be kept to a minimum to lessen voltage drops in the high-current filament circuit.

The choke most commonly used in this application is a pair of heavy-gauge insulated wires, bifilar-wound over a ferrite rod. The ferrite core raises the inductive reactance throughout the HF region so that a minimum of wire is needed, keeping filament-circuit voltage drops low. The bifilar winding technique assures that both filament terminals are at the same RF potential.

Below 30 MHz, the use of such a choke seldom is necessary or beneficial, but actually can introduce another potential problem. Common values of cathode-to-heater capacitance and heater-choke inductance often are series resonant in the 1.8 to 29.7 MHz HF range. A capacitance of 5 pF and an inductance of  $50\ \mu\text{H}$ , for example, resonate at 10.0 MHz; the actual components are just as likely to resonate near 7 or 14 MHz. At resonance, the circuit constitutes a relatively low impedance shunt from cathode to ground, which affects input impedance and sucks out drive signal. An unintended resonance like this near any operating frequency usually increases input SWR and decreases gain on that one particular band. While aggravating, the problem rarely completely disables or damages the amplifier, and so is seldom pursued or identified.

Fortunately, the entire problem is easily

avoided—below 30 MHz the heater choke can be deleted. At VHF-UHF, or wherever a heater isolation choke is used for any reason, the resonance can be moved below the lowest operating frequency by connecting a sufficiently large capacitance (about 1000 pF) between the tube cathode and one side of the heater. It is good practice also to connect a similar capacitor between the heater terminals. It also would be good practice in designing other VHF/UHF amplifiers, such as those using 3CX800A7 tubes, unless the builder can insure that the actual series resonance is well outside of the operating frequency range.

Plate voltage is supplied to the tube through RFC2. C5 is the plate blocking capacitor. The output pi-L network consists of tuning capacitor C6, loading capacitor C7, pi coil L2, and L coil L3. RFC3 is a high-inductance RF choke placed at the output for safety purposes. Its value, usually  $100\ \mu\text{H}$  to 2 mH, is high enough so that it appears as an open circuit across the output connector for RF. However, should the plate blocking capacitor fail and allow high voltage onto the output matching network, RFC3 would short the dc to ground and blow the power-supply fuse or breaker. This prevents dangerous high voltage from appearing on the feed line or antenna. It also prevents electrostatic charge—from the antenna or from blocking capacitor leakage—from building up on the tank capacitors and causing periodic dc discharge arcs to ground. If such a dc discharge occurs while the amplifier is transmitting, it can trigger a potentially damaging RF arc.

Our next step is designing the input matching network. As stated earlier, tube input impedance varies moderately with plate voltage and load resistance as well as bias, but is approximately  $50\text{--}55\text{-}\Omega$  paralleled by  $C_{\text{IN}}$  of 38 pF, including stray capacitance. A simple parallel-resonant tank of  $Q_{\text{IN}} = 2$  to 3 can provide an input

SWR not exceeding 1.5:1, provided all wiring from RF input connector to tank to cathode is heavy and short. On each band a  $Q_{\text{IN}}$  between 2 to 3 requires an  $X_{\text{Ctot}} = X_{\text{Lin}}$  between 25 and  $17\ \Omega$ .

A more nearly perfect match, with greater tolerance for layout and wiring variations, may be achieved by using the pi input tank as shown in Fig 13.18. Design of this input matching circuit is straightforward. Component values are computed using a  $Q_{\text{IN}}$  between 2 or 3. Higher  $Q_{\text{IN}}$  values reduce the network's bandwidth, perhaps even requiring a front-panel tuning control for the wider amateur bands. The purpose of this input network is to present the desired input impedance to the exciter, not to add selectivity. As with a parallel tank, the value of the capacitor at the tube end of the pi network should be reduced by 38 pF; stray capacity plus tube  $C_{\text{IN}}$  is effectively in parallel with the input pi network's output.

The output pi-L network must transform the nominal  $50\text{-}\Omega$  amplifier load to a pure resistance of  $2200\ \Omega$ . We previously calculated that the 8877 tube's plate must see  $2200\ \Omega$  for optimum performance. In practice, real antenna loads are seldom purely resistive or exactly  $50\ \Omega$ ; they often exhibit SWRs of 2:1 or greater on some frequencies. It's desirable that the amplifier output network be able to transform any complex load impedance corresponding to an SWR up to about 2:1 into a resistance of  $2200\ \Omega$ . The network also must compensate for tube  $C_{\text{OUT}}$  and other stray plate-circuit reactances, such as those of interconnecting leads and the plate RF choke. These reactances, shown in Fig 13.19, must be taken into account when designing the matching networks. Because the values of most stray reactances are not accurately known, the most satisfactory approach is to estimate them, and then allow sufficient flexibility in the matching network to accommodate modest errors.

Fig 13.19 shows the principal reactances in the amplifier circuit.  $C_{\text{OUT}}$  is the

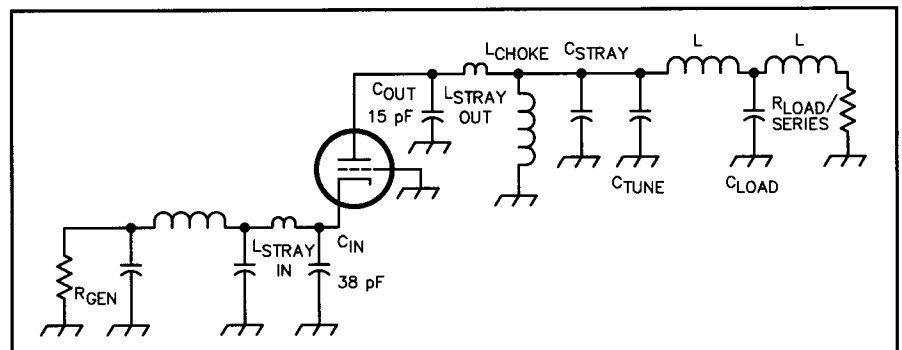

Fig 13.19—The effective reactances for the amplifier in Fig 13.18.

actual tube output capacitance of 10 pF plus the stray capacitance between its anode and the enclosure metalwork. This stray  $C$  varies with layout; we will approximate it as 5 pF, so  $C_{OUT}$  is roughly 15 pF.  $L_{OUT}$  is the stray inductance of leads from the tube plate to the tuning capacitor (internal to the tube as well as external circuit wiring.) External-anode tubes like the 8877 have essentially no internal plate leads, so  $L_{OUT}$  is almost entirely external. It seldom exceeds about 0.3  $\mu$ H and is not very significant below 30 MHz.  $L_{CHOKE}$  is the reactance presented by the plate choke, which usually is significant only below 7 MHz.  $C_{STRAY}$  represents the combined stray capacitances to ground of the tuning capacitor stator and of interconnecting RF plate circuit leads. In a well constructed, carefully thought out power amplifier,  $C_{STRAY}$  can be estimated to be approximately 10 pF. Remaining components  $C_{TUNE}$ ,  $C_{LOAD}$ , and the two tuning inductors, form the pi-L network proper.

The tables presented earlier in this chapter greatly simplify the task of selecting output circuit values. Both the pi and pi-L design tables are calculated for a  $Q_{OUT}$  value of 12. A pi network loaded  $Q$  much lower than 10 does not provide adequate harmonic suppression; a value much higher than 15 increases matching network losses caused by high circulating currents. For pi networks, a  $Q_{OUT}$  of 12 is a good compromise between harmonic suppression and circuit losses. In practice, it often is most realistic and practical with both pi and pi-L output networks to accept somewhat higher  $Q_{OUT}$  values on the highest HF frequencies—perhaps as large as 18 or even 20 at 28 MHz. When using a pi-L on the 1.8 and 3.5 MHz bands, it often is desirable to choose a moderately lower  $Q_{OUT}$ , perhaps 8 to 10, to permit using a more reasonably-sized plate tuning capacitor.

Nominal pi-L network component values for 2200- $\Omega$  plate impedance can be taken directly from Table 13.2. These values can then be adjusted to allow for circuit reactances outside the pi-L proper. First, low-frequency component values should be examined. At 3.5 MHz, total tuning capacitance  $C_1$  value from Table 13.2 is 140 pF. From Fig 13.19 we know that three other stray reactances are directly in parallel with  $C_{TUNE}$  (assuming that  $L_{OUT}$  is negligible at the operating frequency, as it should be). The tube's internal and external plate capacitance to ground,  $C_{OUT}$ , is about 15 pF. Strays in the RF circuit,  $C_{STRAY}$ , are roughly 10 pF.

The impedance of the plate choke,  $X_{CHOKE}$ , is also in parallel with  $C_{TUNE}$ . Plate chokes with self-resonance charac-

teristics suitable for use in amateur HF amplifiers typically have inductances of about 90  $\mu$ H. At 3.5 MHz this is an inductive reactance of +1979  $\Omega$ . This appears in parallel with the tuning capacitance, effectively canceling an equal value of capacitive reactance. At 3.5 MHz, an  $X_C$  of 1979  $\Omega$  corresponds to 23 pF of capacitance—the amount by which tuning capacitor  $C_{TUNE}$  must be increased at 3.5 MHz to compensate for the effect of the plate choke.

The pi-L network requires an effective capacitance of 140 pF at its input at 3.5 MHz. Subtracting the 25 pF provided by  $C_{OUT}$  and  $C_{STRAY}$  and adding the 23 pF canceled by  $X_{CHOKE}$ , the actual value of  $C_{TUNE}$  must be  $140 - 25 + 23 = 138$  pF. It is good practice to provide at least 10% extra capacitance range to allow matching loads having SWRs up to 2:1. So, if 3.5 MHz is the lower frequency limit of the amplifier, a variable tuning capacitor with a maximum value of at least 150 to 160 pF should be used.

Component values for the high end of the amplifier frequency range also must be examined, for this is where the most losses will occur. At 29.7 MHz, the values in Table 13.2 are chosen to accommodate a minimum pi-L input capacitance of 35 pF, yielding  $Q_{OUT} = 21.3$ . Since  $C_{OUT}$  and  $C_{STRAY}$  contribute 25 pF,  $C_{TUNE}$  must have a minimum value no greater than 10 pF. A problem exists, because this value is not readily achievable with a 150 to 160 pF air variable capacitor suitable for operation with a 3100 V plate supply. Such a capacitor typically has a minimum capacitance of 25 to 30 pF. Usually, little or nothing can be done to reduce the tube's  $C_{OUT}$  or the circuit  $C_{STRAY}$ , and in fact the estimates of these may even be a little low. If 1.8 MHz capability is desired, the maximum tuning capacitance will be at least 200 to 250 pF, making the minimum-capacitance problem at 29.7 MHz even more severe.

There are three potential solutions to this dilemma. We could accept the actual minimum value of pi-L input capacitance, around 50 to 55 pF, realizing that this will raise the pi-L network's loaded  $Q$  to about 32. This results in very large values of circulating tank current. To avoid damage to tank components—particularly the bandswitch and pi inductor—by heat due to  $I^2R$  losses, it will be necessary to either use oversize components or reduce power on the highest-frequency bands. Neither option is appealing.

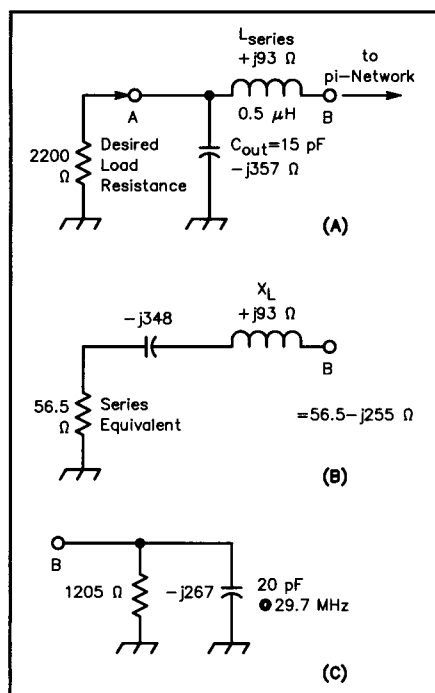

A second potential solution is to reduce the minimum capacitance provided by  $C_{TUNE}$ . We could use a vacuum variable capacitor with a 300-pF maximum and a

5-pF minimum capacity. These are rated at 5 to 15 kV, and are readily available. This reduces the minimum effective circuit capacitance to 30 pF, allowing use of the pi-L table values for  $Q_{OUT} = 12$  on all bands from 1.8 through 29.7 MHz. While brand new vacuum variables are quite expensive, suitable models are widely available in the surplus and used markets for prices not much higher than the cost of a new air variable. A most important caveat in purchasing a vacuum capacitor is to ensure that its vacuum seal is intact and that it is not damaged in any way. The best way to accomplish this is to "hi-pot" test the capacitor throughout its range, using a dc or peak ac test voltage of 1.5 to 2 times the amplifier plate supply voltage. For all-band amplifiers using plate voltages in excess of about 2500 V, the initial expense and effort of securing and using a vacuum variable input tuning capacitor often is well repaid in efficient and reliable operation of the amplifier.

A third possibility is the use of an additional inductance connected in series between the tube and the tuning capacitor. In conjunction with  $C_{OUT}$  of the tube, the added inductor acts as an L network to transform the impedance at the input of the pi-L network up to the 2200- $\Omega$  load resistance needed by the tube. This is shown in Fig 13.20A. Since the impedance at the input of the main pi-L matching network is reduced, the loaded  $Q_{OUT}$  for the total capacitance actually in the circuit is lower. With lower  $Q_{OUT}$ , the circulating RF currents are lower, and thus tank losses are lower.

$C_{OUT}$  in Fig 13.20 is the output capacitance of the tube, including stray  $C$  from the anode to metal enclosure.  $X_L$  is the additional series inductance to be added. As determined previously, the impedance seen by the tube anode must be a 2200  $\Omega$  resistance for best linearity and efficiency, and we have estimated  $C_{OUT}$  of the tube as 15 pF. If the network consisting of  $C_{OUT}$  and  $X_L$  is terminated at A by 2200- $\Omega$ , we can calculate the equivalent impedance at point B, the input to the pi-L network, for various values of series  $X_L$ . The pi-L network must then transform the nominal 50- $\Omega$  load at the transmitter output to this equivalent impedance.

We work backwards from the plate of the tube towards the  $C_{TUNE}$  capacitor. First, calculate the series-equivalent impedance of the parallel combination of the desired 2200- $\Omega$  plate load and the tube  $X_{OUT}$  (15 pF at 29.7 MHz =  $-j357 \Omega$ ). The series-equivalent impedance of this parallel combination is  $56.5 - j348 \Omega$ , as shown in Fig 13.20B. Now suppose we use a 0.5  $\mu$ H inductor, having an impedance of

**Fig 13.20—The effect of adding a small series inductance in vacuum tube output circuit. At A, a 0.5  $\mu\text{H}$  coil  $L_{\text{SERIES}}$  is connected between anode and the output pi network, and this represents a reactance of  $+j93\Omega$  at 29.7 MHz. The 15 pF output capacity ( $C_{\text{OUT}}$ ) of the tube has a reactance of  $-j357\Omega$  at 29.7 MHz. At B, the equivalent series network for the parallel 2200- $\Omega$  desired load resistance and the  $-j357\Omega$   $C_{\text{OUT}}$  is 56.5  $\Omega$  in series with  $-j348\Omega$ . At C, this series-equivalent is combined with the series  $+j93\Omega$   $X_{\text{SERIES}}$  and converted back to the parallel equivalent, netting an equivalent parallel network of 1205  $\Omega$  shunted by a 20 pF capacitor. The pi tuning network must transform the load impedance (usually 50  $\Omega$ ) into the equivalent parallel combination and absorb the 20-pF parallel component. The series inductor has less effect as the operating frequency is lowered from 29.7 MHz.**

at 29.7 MHz, as the series inductance  $X_L$ . The resulting series-equivalent impedance is  $56.5 - j348 + j93$ , or  $56.5 - j255\Omega$ . Converting back to the parallel equivalent gives the network of Fig 13.20C: 1205  $\Omega$  resistance in parallel with  $-j267\Omega$ , or 20 pF at 29.7 MHz. The pi-L tuning network must now transform the 50- $\Omega$  load to a resistive load of 1205  $\Omega$  at B, and absorb the shunt capacity of 20 pF.

Using the pi-L network formulas in this chapter for  $R_1 = 1205$  and  $Q_{\text{OUT}} = 15$  at 29.7 MHz yields a required total capacitive reactance of  $1205/15 = 80.3\Omega$ , which is 66.7 pF at 29.7 MHz. Note that for the same loaded  $Q_{\text{OUT}}$  for a 2200- $\Omega$  load line,

the capacitive reactance is  $2200/15 = 146.7\Omega$ , which is 36.5 pF. When the 20 pF of transformed input capacity is subtracted from the 66.7 pF total needed, the amount of capacity is 46.7 pF. If the minimum capacity in  $C_{\text{TUNE}}$  is 25 pF and the stray capacity is 10 pF, then there is a margin of  $46.7 - 35 = 10.7$  pF beyond the minimum capacity for handling SWRs greater than 1:1 at the load.

The series inductor should be a high-Q coil wound from copper tubing to keep losses low. This inductor has a decreasing, yet significant effect, on progressively lower frequencies. A similar calculation to the above should be made on each band to determine the transformed equivalent plate impedance, before referring to Table 13.2. The impedance-transformation effect of the additional inductor decreases rapidly with decreasing frequency. Below 21 MHz, it usually may be ignored and pi-L network values taken directly from the pi-L tables for  $R_1 = 2200\Omega$ .

The nominal 90- $\mu\text{H}$  plate choke remains in parallel with  $C_{\text{TUNE}}$ . It is rarely possible to calculate the impedance of a real HF plate choke at frequencies higher than about 5 MHz because of self-resonances. However, as mentioned previously, the choke's reactance should be sufficiently high that the tables are useful if the choke's first series-resonance is at 23.2 MHz.

This amplifier is made operational on multiple bands by changing the values of inductance at L2 and L3 for different bands. The usual practice is to use inductors for the lowest operating frequency, and short out part of each inductor with a switch, as necessary, to provide the inductance needed for each individual band. Wiring to the switch and the switch itself add stray inductance and capacitance to the circuit. To minimize these effects at the higher frequencies, the unswitched 10-m L2 should be placed closest to the high-impedance end of the network at C6. Stray capacitance associated with the switch then is effectively in parallel with C7, where the impedance level is around 300  $\Omega$ . The effects of stray capacitance are relatively insignificant at this low impedance level. This configuration also minimizes the peak RF voltage that the switch insulation must withstand.

Pi and L coil tap positions that yield desired values of inductance may be determined with fairly good accuracy by using a dip meter and a small mica capacitor of 5% tolerance. The pi and L coils and bandswitch should be mounted in the amplifier and their common point connected only to the bandswitch rotors. Starting at the highest-frequency switch position, lightly tack solder a short length of copper

braid or strap to the pi or L switch stator terminal for that band. Using the shortest leads possible, tack a 50 to 100 pF, 5% dipped mica capacitor between the braid and a trial tap position on the appropriate coil. Lightly couple the dip meter and find the resonant frequency. The inductance then may be calculated from the equation

$$L = \frac{1,000,000}{C(2\pi f)^2} \quad (41)$$

where

$L$  = inductance in  $\mu\text{H}$

$C$  = capacitor value in pF

$f$  = resonant frequency in MHz.

As each tap is located, it should be securely wired with strap or braid and the process repeated for successively lower bands.

The impedance match in both the input and output networks can be checked without applying dc voltage, once the amplifier is built. In operation, the tube input and output resistances are the result of current flow through the tube. Without filament power applied, these resistances are effectively infinite but  $C_{\text{IN}}$  and  $C_{\text{OUT}}$  are still present because they are passive physical properties of the tube. The tube input resistance can be simulated by an ordinary 5% 1/4-W to 2-W composition or film resistor (don't use wirewound, though; they are more inductive than resistive at RF). A resistor value within 10% of the tube input resistance, connected in parallel with the tube input, presents approximately the same termination resistance to the matching network as the tube does in operation.

With the input termination resistor temporarily soldered in place using very short leads, input matching network performance can be determined by means of a noise bridge or an SWR meter that does not put out more RF power than the temporary termination resistor is capable of dissipating. Any good self- or dipper-powered bridge or analyzer should be satisfactory. Connect the bridge to the amplifier input and adjust the matching network, as necessary, for lowest SWR. Be sure to remove the terminating resistor before powering up the amplifier!

The output matching network can be evaluated in exactly the same fashion, even though the plate load resistance is not an actual resistance in the tube like the input resistance. According to the reciprocity principle, if the impedance presented at the output of the plate matching network is 50- $\Omega$  resistive when the network input is terminated with  $R_L$ , then the tube plate will "see" a resistive load equal to  $R_L$  at the input when the output is terminated in a 50- $\Omega$  resistance (and vice versa).

In this case, a suitable 2200- $\Omega$  resistor should be connected as directly as possible from the tube plate to chassis. If the distance is more than a couple of inches, braid should be used to minimize stray inductance. The bridge is connected to the amplifier output. If coil taps have been already been established as described previously, it is a simple matter to evaluate the output network by adjusting the tune and load capacitors, band by band, to show a perfect 50- $\Omega$  match on the SWR bridge.

When these tests are complete, the amplifier is ready to be tested for parasitic oscillations in preparation for full-power operation. Refer to Amplifier Stabilization, later in this chapter.

## DESIGN EXAMPLE 2: A MEDIUM-POWER 144-MHZ AMPLIFIER

For several decades the 4CX250 family of power tetrodes has been used successfully up through 500 MHz. They are relatively inexpensive, produce high gain and lend themselves to relatively simple amplifier designs. In amateur service at VHF, the 4CX250 is an attractive choice for an amplifier. Most VHF excitors used now by amateurs are solid state and often develop 10 W or less output. The drive requirement for the 4CX250 in grounded cathode, Class AB operation ranges between 2 and 8 W for full power output, depending on frequency. At 144 MHz, manufacturer's specifications suggest an available output power of over 300 W. This is clearly a substantial improvement over 10 W, so a 4CX250B will be used in this amplifier.

The first design step is the same as in the previous example: verify that the proposed tube will perform as desired while staying within the manufacturer's ratings. Again assuming a basic amplifier efficiency of 60% for Class AB operation, 300 W of output requires a plate input power of 500 W. Tube dissipation is rated at 250 W, so plate dissipation is not a problem, as the tube will only be dissipating 200 W in this amplifier. If the recommended maximum plate potential of 2000 V is used, the plate current for 500-W input will be 250 mA, which is within the manufacturer's ratings. The plate load resistance can now be calculated. Using the same formula as before, the value is determined to be 5333  $\Omega$ .

The next step is to investigate the output circuit. The manufacturer's specification for  $C_{OUT}$  is 4.7 pF. The inevitable circuit strays along with the tuning capacitor add to the circuit capacitance. A carefully built amplifier might only have 7 pF of stray capacitance, and a specially made tuning capacitor can be fabricated to have a

midrange value of 3 pF. The total circuit capacitance adds up to about 15 pF. At 144 MHz this represents a capacitive reactance of only 74  $\Omega$ . The  $Q_L$  of a tank circuit with this reactance with a plate load resistance of 5333  $\Omega$  is  $5333/74 = 72$ . A pi output matching network would be totally impractical, because the L required would be extremely small and circuit losses would be prohibitive. The simplest solution is to connect an inductor in parallel with the circuit capacitance to form a parallel-resonant tank circuit.

To keep tank circuit losses low with such a high  $Q_L$ , an inductor with very high unloaded Q must be used. The lowest-loss inductors are formed from transmission line sections. These can take the form of either coaxial lines or strip lines. Both have their advantages and disadvantages, but the strip line is so much easier to fabricate that it is almost exclusively used in VHF tank circuits today.

The reactance of a terminated transmission line section is a function of both its characteristic impedance and its length (see the **Transmission Lines** chapter). The reactance of a line terminated in a short circuit is

$$X_{IN} = Z_0 \tan \ell \quad (42)$$

where

$X_{IN}$  = is the circuit reactance

$Z_0$  = the line's characteristic impedance

$\ell$  = the transmission line length in degrees.

For lines shorter than a quarter wavelength (90°) the circuit reactance is inductive. In order to resonate with the tank circuit capacitive reactance, the transmission line reactance must be the same value, but inductive. Examination of the formula for transmission-line circuit reactance suggests that a wide range of lengths can yield the same inductive reactance, as long as the line  $Z_0$  is appropriately scaled. Based on circuit Q considerations, the best bandwidth for a tank circuit results when the ratio of  $Z_0$  to  $X_{IN}$  is between one and two. This implies that transmission line lengths between 26.5° and 45° give the best bandwidth. Between these two limits, and with some adjustment of  $Z_0$ , practical transmission lines can be designed. A transmission line length of 35° is 8 inches long at 144 MHz, a workable dimension mechanically. Substitution of this value into the transmission-line equation gives a  $Z_0$  of 105  $\Omega$ .

The width of the strip line and its placement relative to the ground planes determine the line impedance. Other stray capacitances such as mounting standoffs also affect the impedance. Accurate calculation of the line impedance for most

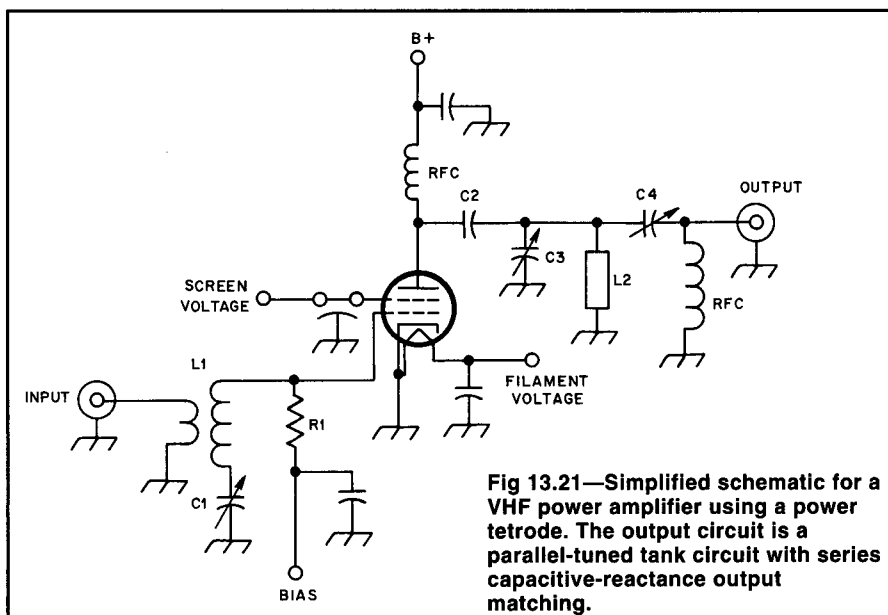

physical configurations requires extensive application of Maxwell's equations and is beyond the scope of this book. The specialized case in which the strip line is parallel to and located halfway between two ground planes has been documented in *Reference Data for Radio Engineers* (see Bibliography). According to charts presented in that book, a 105- $\Omega$  strip line impedance is obtained by placing a line with a width of approximately 0.4 times the ground plane separation halfway between the ground planes. Assuming the use of a standard 3-inch-deep chassis for the plate compartment, this yields a strip-line width of 1.2 inches. A strip line 1.2 inches wide located 1.5 inches above the chassis floor and grounded at one end has an inductive reactance of 74  $\Omega$  at 144 MHz.

The resulting amplifier schematic diagram is shown in Fig 13.21. L2 is the strip-line inductance just described. C3 is the tuning capacitor, made from two parallel brass plates whose spacing is adjustable. One plate is connected directly to the strip line while the other is connected to ground through a wide, low-inductance strap. C2 is the plate blocking capacitor. This can be either a ceramic doorknob capacitor such as the Centralab 850 series or a homemade "Teflon sandwich." Both are equally effective at 144 MHz.

Impedance matching from the plate resistance down to 50  $\Omega$  can be either through an inductive link or through capacitive reactance matching. Mechanically, the capacitive approach is simpler to implement. Fig 13.22 shows the development of reactance matching through a series capacitor (C4 in Fig 13.21). By using the parallel equivalent of the capacitor in series with the 50- $\Omega$  load, the load resistance can be transformed to the 5333- $\Omega$  plate resistance. Substitution of the known values into the parallel-to-series equivalence formulas reveals that a 2.15 pF capacitor at C4 matches the 50- $\Omega$  load to the plate resistance. The resulting parallel equivalent for the load is 5333  $\Omega$  in parallel with 2.13 pF. The 2.13-pF capacitor is effectively in parallel with the tank circuit.

A new plate line length must now be calculated to allow for the additional capacitance. The equivalent circuit diagram containing all the various reactances is shown in Fig 13.23. The total circuit capacitance is now just over 17 pF, which is a reactance of 64  $\Omega$ . Keeping the strip-line width and thus its impedance constant at 105  $\Omega$  dictates a new resonant line length of 31°. This calculates to be 7.14 inches for 144 MHz.

The alternative coupling scheme is through the use of an inductive link. The

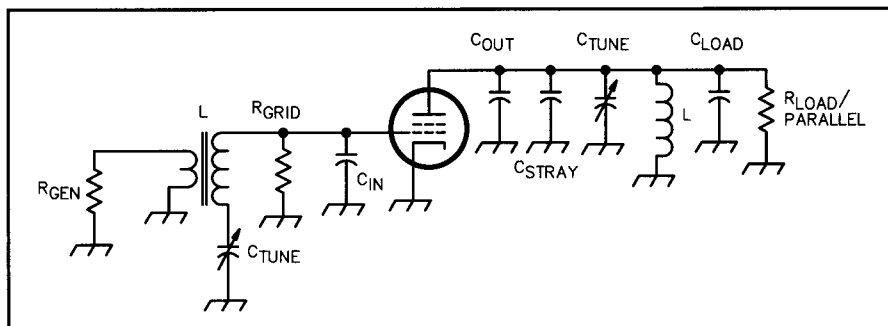

capacitors are effectively in series (through the ground return). A 20-pF variable at C1 set to 18.5 pF gives an effective circuit capacitance of 9.25 pF. This will resonate at 144 MHz with an inductance of 0.13  $\mu$ H at L1. L1 can be wound on a toroid core for mechanical convenience. The 50- $\Omega$  input impedance is then matched by link coupling to the toroid. The grid impedance is primarily determined by the value for R1, the grid bias feed resistor.

### DESIGN EXAMPLE 3: A BROADBAND HF SOLID-STATE AMPLIFIER

Linear power amplifier design using transistors at HF is a fundamentally simple process, although a good understanding of application techniques is important to insure that the devices are effectively protected against damage or destruction due to parasitic self-oscillations, power transients, load mismatch and/or overdrive.

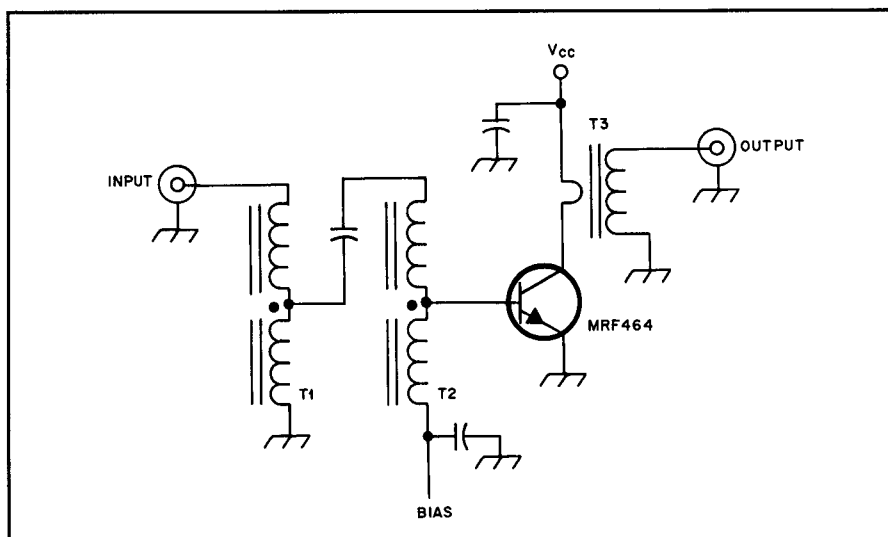

An appropriate transistor meeting the desired performance specifications is selected on the basis of dissipation and power output. Transistor manufacturers greatly simplify the design by specifying each type of power transistor according to its frequency range and power output. The amplifier designer need only provide suit-

link can be either tuned or untuned. The length of the link can be estimated based on the amplifier output impedance, in this case, 50  $\Omega$ . For an untuned link, the inductive reactance of the link itself should be approximately equal to the output impedance, 50  $\Omega$ . For a tuned link, the length depends on the link loaded Q,  $Q_L$ . The link  $Q_L$  should generally be greater than two, but usually less than five. For a  $Q_L$  of three this implies a capacitive reactance of 150  $\Omega$ , which at 144 MHz is just over 7 pF. The self-inductance of the link should of course be such that its impedance at 144 MHz is 150  $\Omega$  (0.166  $\mu$ H). Adjustment of the link placement determines the transformation ratio of the circuit line. Some fine adjustment of this parameter can be made through adjustment of the link series tuning capacitor. Placement of the link relative to the plate inductor is an empirical process.

The input circuit is shown in Figs 13.21 and 13.23.  $C_{IN}$  is specified to be 18.5 pF for the 4CX250. This is only  $-j60 \Omega$  at 2 m, so the pi network again is unsuitable. Since a surplus of drive is available with a 10-W exciter, circuit losses at the ampli-

fier input are not as important as at the output. An old-fashioned "split stator" tuned input can be used. L1 in Fig 13.21 is series tuned by  $C_{IN}$  and C1. The two

able impedance matching to the device input and output, along with appropriate dc bias currents to the transistor.

The Motorola MRF464 is an RF power transistor capable of 80 W PEP output with low distortion. Its usable frequency range extends through 30 MHz. At a collector potential of 28 V, a collector efficiency of 40% is possible. **Fig 13.24** shows the schematic diagram of a 2 to 30-MHz broadband linear amplifier using the MRF464. The input impedance of the transistor is specified by the manufacturer to be  $1.4 - j0.30 \Omega$  at 30 MHz and decreases to  $9.0 - j5.40 \Omega$  at 2 MHz. Transformers T1 and T2 match the 50- $\Omega$  amplifier input impedance to the median value of the transistor input impedance. They are both 4:1 step-down ratio transmission-line transformers. A single 16:1 transformer could be used in place of T1 and T2, but 16:1 transformers are more difficult to fabricate for broadband service.

The specified transistor output resistance is approximately 6  $\Omega$  (in parallel with a corresponding output capacitance) across the frequency range. T3 is a ferrite-loaded conventional transformer with a step-up ratio of approximately 8:1. This matches the transistor output to 50  $\Omega$ .

The amplifier has a falling gain characteristic with rising frequency. To flatten out gain across the frequency range, negative feedback could be applied. However, most power transistors have highly reactive input impedances and large phase errors would occur in the feedback loop. Instability could potentially occur.

A better solution is to use an input correction network. This network is used as a frequency-selective attenuator for amplifier drive. At 30 MHz, where transistor gain is least, the input power loss is designed to be minimal (less than 2 dB). The loss increases at lower frequencies to compensate for the increased transistor gain. The MRF464 has approximately 12 dB more gain at 1.8 MHz than at 30 MHz; the compensation network is designed to have 12 dB loss at 1.8 MHz. A properly designed compensation network will result in an overall gain flatness of approximately 1 dB.

## AMPLIFIER STABILIZATION

### Stable Operating Conditions

Purity of emissions and the useful life (or even survival) of the active devices in a tube or transistor circuit depend heavily on stability during operation. Oscillations can occur at the operating frequency or far from it, because of undesired positive feedback in the amplifier. Unchecked, these oscillations pollute the RF spectrum

and can lead to tube or transistor over-dissipation and subsequent failure. Each type of oscillation has its own cause and its own cure.

In a linear amplifier, the input and output circuits operate on the same frequency. Unless the coupling between these two circuits is kept to a small enough value, sufficient energy from the output may be coupled in phase back to the input to cause the amplifier to oscillate. Care should be used in arranging components and wiring of the two circuits so that there will be negligible opportunity for coupling external to the tube or transistor itself. A high degree of shielding between input and output circuits usually is required. All RF leads should be kept as short as possible and particular attention should be paid to the RF return paths from input and output tank circuits to emitter or cathode.

In general, the best arrangement using a tube is one in which the input and output circuits are on opposite sides of the chassis. Individual shielded compartments for the input and output circuitry add to the isolation. Transistor circuits are somewhat more forgiving, since all the impedances are relatively low. However, the high currents found on most amplifier circuit boards can easily couple into unintended circuits. Proper layout, the use of double-sided circuit board (with one side used as a ground plane and low-inductance ground return), and heavy doses of bypassing on the dc supply lines often are sufficient to prevent many solid-state amplifiers from oscillating.

### VHF and UHF Parasitic Oscillations

RF power amplifier circuits contain parasitic reactances that have the potential to cause so-called parasitic oscillations at frequencies far above the normal operating frequency. Nearly all vacuum-tube amplifiers designed for operation in the 1.8 to 29.7 MHz frequency range exhibit tendencies to oscillate somewhere in the VHF-UHF range—generally between about 75 and 250 MHz depending on the type and size of tube. A typical parasitic resonant circuit is highlighted by bold lines in **Fig 13.25**. Stray inductance between the tube plate and the output tuning capacitor forms a high-Q resonant circuit with the tube's  $C_{OUT}$ .  $C_{OUT}$  normally is much smaller (higher  $X_C$ ) than any of the other circuit capacitances shown. The tube's  $C_{IN}$  and the tuning capacitor  $C_{TUNE}$  essentially act as bypass capacitors, while the various chokes and tank inductances shown have high reactances at VHF. Thus the values of these components have little influence on the parasitic resonant frequency.

Oscillation is possible because the VHF resonant circuit is an inherently high-Q parallel-resonant tank that is not coupled to the external load. The load resistance at the plate is very high, and thus the voltage gain at the parasitic frequency can be quite high, leading to oscillation.

The parasitic frequency,  $f_r$ , is approximately:

$$f_r = \frac{1000}{2\pi\sqrt{L_P C_{OUT}}} \quad (43)$$

where

$f_r$  = parasitic resonant frequency in MHz

$L_P$  = total stray inductance between tube plate and ground via the plate tuning capacitor (including tube internal plate lead) in  $\mu$ H

$C_{OUT}$  = tube output capacitance in pF.

In a well-designed HF amplifier,  $L_P$  might be in the area of 0.2  $\mu$ H and  $C_{OUT}$  for an 8877 is about 10 pF. Using these figures, the equation above yields a potential parasitic resonant frequency of

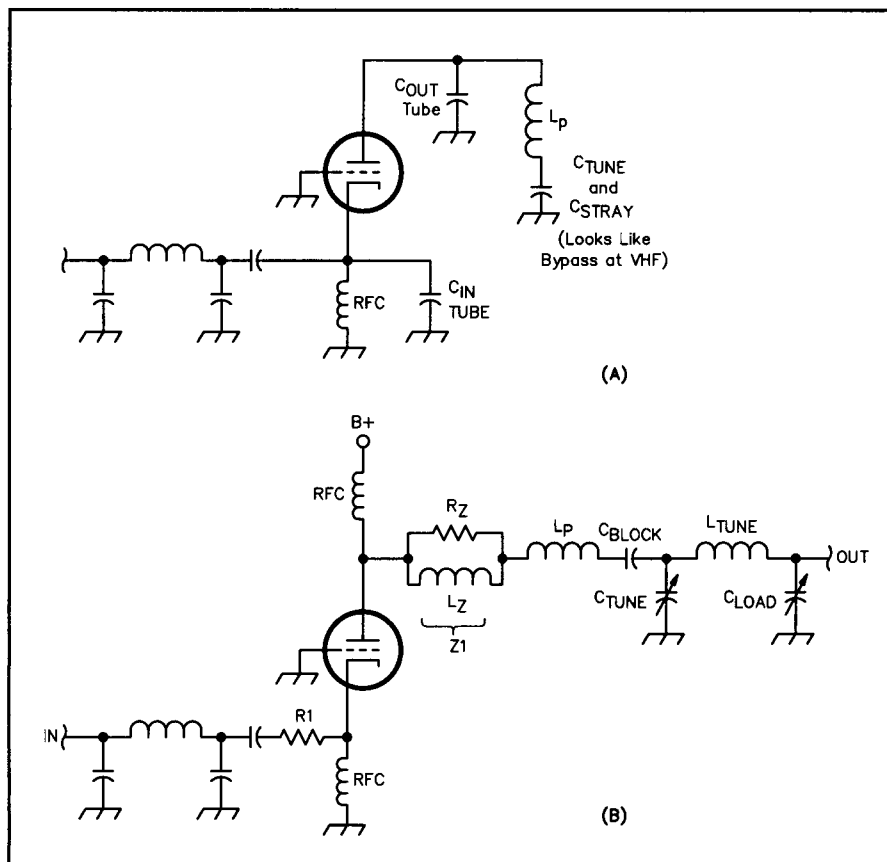

$$f_r = \frac{1000}{2\pi\sqrt{0.2 \times 10}} = 112.5 \text{ MHz}$$

For a smaller tube, such as the 3CX800A7 with  $C_{OUT}$  of 6 pF,  $f_r = 145$  MHz. Circuit details affect  $f_r$  somewhat, but these results do in fact correspond closely to actual parasitic oscillations experienced with these tube types. VHF-UHF parasitic oscillations can be prevented (*not* just minimized!) by reducing the loaded Q of the parasitic resonant circuit so that gain at its resonant frequency is insufficient to support oscillation. This is possible with any common tube, and it is especially easy with modern external-anode tubes like the 8877, 3CX800A7, and 4CX800A.

Z1 of **Fig 13.25B** is a parasitic suppressor. Its purpose is to add loss to the parasitic circuit and reduce its Q enough to prevent oscillation. This must be accomplished without significantly affecting normal operation.  $L_z$  should be just large enough to constitute a significant part of the total parasitic tank inductance (originally represented by  $L_P$ ), and located right at the tube plate terminal(s). If  $L_z$  is made quite lossy, it will reduce the Q of the parasitic circuit as desired.

The inductance and construction of  $L_z$  depend substantially on the type of tube used. Popular glass tubes like the 3-500Z and 4-1000A have internal plate leads made of wire. This significantly increases  $L_P$  when compared to external-anode tubes. Consequently,  $L_z$  for these large glass tubes usually must be larger in order to constitute an adequate portion of the total value of  $L_P$ . Typically a coil of 3 to

**Fig 13.25—At A, typical VHF/UHF parasitic resonance in plate circuit. The HF tuning inductor in the pi network looks like an RF choke at VHF/UHF. The tube's output capacity and series stray inductance combine with the pi-network tuning capacity and stray circuit capacity to create a VHF/UHF pi network, presenting a very high impedance to the plate, increasing its gain at VHF/UHF. At B,  $Z_1$  lowers the Q and therefore gain at parasitic frequency.**

5 turns of #10 wire, 0.25 to 0.5 inches in diameter and about 0.5 to 1 inches long is sufficient. For the 8877 and similar tubes it usually is convenient to form a "horse-shoe" in the strap used to make the plate connection. A "U" about 1 inch wide and 0.75 to 1 inch deep usually is sufficient. In either case,  $L_z$  carries the full operating-frequency plate current; at the higher frequencies this often includes a substantial amount of circulating tank current, and  $L_z$  must be husky enough to handle it without overheating even at 29 MHz.

Regardless of the form of  $L_z$ , loss may be introduced as required by shunting  $L_z$  with one or more suitable noninductive resistors. In high-power amplifiers, two composition or metal film resistors, each 100  $\Omega$ , 2 W, connected in parallel across  $L_z$  usually are adequate. For amplifiers up to perhaps 500 W a single 47- $\Omega$ , 2-W resistor may suffice. The resistance and power capability required to prevent VHF/UHF parasitic oscillations, while not overheating as a result of normal plate circuit current flow, depend on circuit parameters. Operating-frequency voltage drop

across  $L_z$  is greatest at higher frequencies, so it is important to use the minimum necessary value of  $L_z$  in order to minimize power dissipation in  $R_z$ .

The parasitic suppressors described above very often will work without modification, but in some cases it will be necessary to experiment with both  $L_z$  and  $R_z$  to find a suitable combination. Some designers use nichrome or other resistance wire for  $L_z$ , but there is no credible evidence of any fundamental difference in performance as a result. Amplifier manufacturer W4ETO has never seen an HF amplifier using modern tubes that could not be made completely free of VHF parasitics by using one of the simple parasitic suppressor constructions described above.

In exceptionally difficult cases, particularly when using glass tetrodes or pentodes, additional parasitic suppression may be attained by connecting a low value resistor (about 10 to 15  $\Omega$ ) in series with the tube input, near the tube socket. This is illustrated by R1 of Fig 13.25B. If the tube has a relatively low input impedance, as is

typical of grounded-grid amplifiers and some grounded-cathode tubes with large  $C_{IN}$ , R1 may dissipate a significant portion of the total drive power.

### Testing Tube Amplifiers for VHF-UHF Parasitic Oscillations

Every high-power amplifier should be tested before being placed in service, to insure that it is free of parasitic oscillations. For this test, nothing is connected to either the RF input or output terminals, and the bandswitch is first set to the lowest-frequency range. If the input is tuned and can be bandswitched separately, it should be set to the highest-frequency band. The amplifier control system should provide monitoring for both grid current and plate current, as well as a relay, circuit breaker, or fast-acting fuse to quickly shut off high voltage in the event of excessive plate current. To further protect the tube grid, it is a good idea to temporarily insert in series with the grid current return line a resistor of approximately 1000  $\Omega$  to prevent grid current from soaring in the event a vigorous parasitic oscillation breaks out during initial testing.

Apply filament and bias voltages to the amplifier, leaving plate voltage off and/or cutoff bias applied until any specified tube warmup time has elapsed. Then apply the lowest available plate voltage and switch the amplifier to transmit. Some idling plate current should flow. If it does not, it may be necessary to increase plate voltage to normal or to reduce bias so that at least 100 mA or so does flow. Grid current should be zero. Vary the plate tuning capacitor slowly from maximum capacitance to minimum, watching closely for any grid current or change in plate current, either of which would indicate a parasitic oscillation. If a tunable input network is used, its capacitor (the one closest to the tube if a pi circuit) should be varied from one extreme to the other in small increments, tuning the output plate capacitor at each step to search for signs of oscillation. If at any time either the grid or plate current increases to a large value, shut off plate voltage immediately to avoid damage! If moderate grid current or changes in plate current are observed, the frequency of oscillation can be determined by loosely coupling an RF absorption meter or a spectrum analyzer to the plate area. It will then be necessary to experiment with parasitic suppression measures until no signs of oscillation can be detected under any conditions. This process should be repeated using each bandswitch position.

When no sign of oscillation can be found, increase the plate voltage to its normal operating value and calculate plate

dissipation (idling plate current times plate voltage). If dissipation is at least half of, but not more than, its maximum safe value, repeat the previous tests. If plate dissipation is much less than half of maximum safe value, it is desirable (but not absolutely essential) to reduce bias until it is. If no sign of oscillation is detected, the temporary grid resistor should be removed and the amplifier is ready for normal operation.

### Parasitic Oscillations in Solid-State Amplifiers

In low-power solid-state amplifiers, parasitic oscillations can be prevented by using a small amount of resistance in series with the base or collector lead, as shown in Fig 13.26A. The value of R1 or R2 typically should be between 10 and 22  $\Omega$ . The use of both resistors is seldom necessary, but an empirical determination must be made. R1 or R2 should be located as close to the transistor as practical.

At power levels in excess of approximately 0.5 W, the technique of parasitic suppression shown in Fig 13.26B is effective. The voltage drop across a resistor would be prohibitive at the higher power levels, so one or more ferrite beads placed over connecting leads can be substituted (Z1 and Z2). A bead permeability of 125 presents a high impedance at VHF and above without affecting HF performance. The beads need not be used at both circuit locations. Generally, the terminal carrying the least current is the best place for these suppression devices. This suggests that the resistor or ferrite beads should be connected in the base lead of the transistor.

C3 of Fig 13.27 can be added to some power amplifiers to dampen VHF/UHF parasitic oscillations. The capacitor should be low in reactance at VHF and UHF, but must present a high reactance at the operating frequency. The exact value selected will depend upon the collector impedance. A reasonable estimate is to use an  $X_C$  of 10 times the collector impedance at the operating frequency. Silver-mica or ceramic chip capacitors are suggested for this application. An additional advantage is the resultant bypassing action for VHF and UHF harmonic energy in the collector circuit. C3 should be placed as close to the collector terminal as possible, using short leads.

The effects of C3 in a broadband amplifier are relatively insignificant at the operating frequency. However, when a narrow-band collector network is used, the added capacitance of C3 must be absorbed into the network design in the same manner as the  $C_{OUT}$  of the transistor.

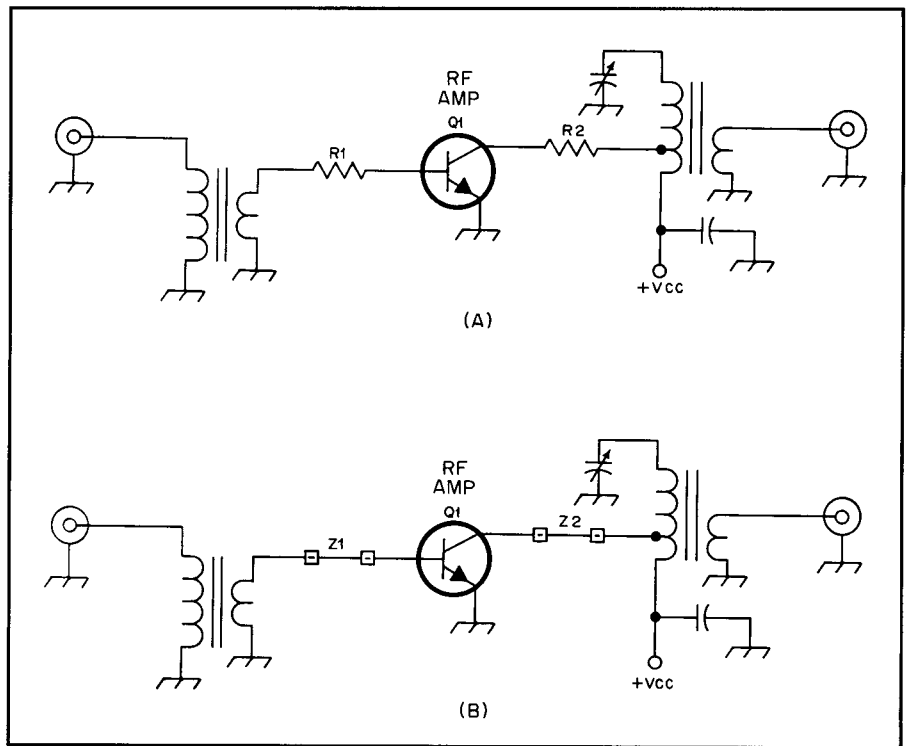

Fig 13.26—Suppression methods for VHF and UHF parasitics in solid-state amplifiers.

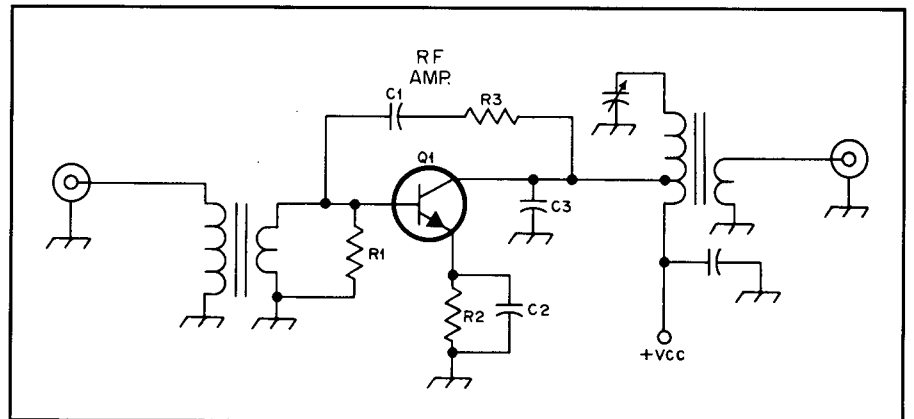

Fig 13.27—Illustration of shunt feedback in a transistor amplifier. C1 and R3 make up the feedback network.

### Low-Frequency Parasitic Oscillations

Bipolar transistors exhibit a rising gain characteristic as the operating frequency is lowered. To preclude low-frequency instabilities because of the high gain, shunt and degenerative feedback are often used. In the regions where low-frequency self-oscillations are most likely to occur, the feedback increases by nature of the feedback network, reducing the amplifier gain. In the circuit of Fig 13.27, C1 and R3 provide negative feedback, which increases progressively as the frequency is

lowered. The network has a small effect at the desired operating frequency but has a pronounced effect at the lower frequencies. The values for C1 and R3 are usually chosen experimentally. C1 will usually be between 220 pF and 0.0015  $\mu$ F for HF-band amplifiers while R3 may be a value from 51 to 5600  $\Omega$ .

R2 of Fig 13.27 develops emitter degeneration at low frequencies. The bypass capacitor, C2, is chosen for adequate RF bypassing at the intended operating frequency. The impedance of C2 rises progressively as the frequency is lowered, thereby increasing the degenerative feed-

back caused by R2. This lowers the amplifier gain. R2 in a power stage is seldom greater than  $10\ \Omega$ , and may be as low as  $1\ \Omega$ . It is important to consider that under some operating and layout conditions R2 can cause instability. This form of feedback should be used only in those circuits in which unconditional stability can be achieved.

R1 of Fig 13.27 is useful in swamping the input of an amplifier. This reduces the chance for low-frequency self oscillations, but has an effect on amplifier performance in the desired operating range. Values from  $3$  to  $27\ \Omega$  are typical. When connected in shunt with the normally low base impedance of a power amplifier, the resistors lower the effective device input impedance slightly. R1 should be located as close to the transistor base terminal as possible, and the connecting leads must be kept short to minimize stray reactances. The use of two resistors in parallel reduces the amount of inductive reactance introduced compared to a single resistor.

Although the same concepts can be applied to tube-type amplifiers, the possibility of self-oscillations at frequencies lower than VHF is significantly lower than in solid-state amplifiers. Tube amplifiers will usually operate stably as long as the input-to-output isolation is greater than the stage gain. Proper shielding and dc-power-lead bypassing essentially eliminate feedback paths, except for those through the tube itself.

On rare occasions tube-type amplifiers will oscillate at frequencies in the range of about  $50$  to  $500\ \text{kHz}$ . This is most likely with high-gain tetrodes using shunt feed of dc voltages to both grid and plate through RF chokes. If the resonant frequency of the grid RF choke and its associated coupling capacitor occurs close to that of the plate choke and its blocking capacitor, conditions may support a tuned-plate tuned-grid oscillation. For example, using typical values of  $1\ \text{mH}$  and  $1000\ \text{pF}$ , the expected parasitic frequency would be around  $160\ \text{kHz}$ .

Make sure that there is no low-impedance, low-frequency return path to ground through inductors in the input matching networks in series with the low impedances reflected by a transceiver output transformer. Usually, oscillation can be prevented by changing choke or capacitor values to insure that the input resonant frequency is much lower than that of the output.

### Amplifier Neutralization

Depending on stage gain and inter-electrode capacitances, sufficient positive feedback may occur to cause oscillation at

the operating frequency. This should not occur in well-designed grounded-grid amplifiers, nor with tetrode or pentodes operating at gains up to about  $15\ \text{dB}$  as is current practice at HF where  $50$  to  $100\ \text{W}$  of drive is almost always available. If triodes are grid-driven, however, and under certain other circumstances, neutralization may be necessary because of output energy capacitively coupled back to the input as shown in Fig 13.28. Neutralization involves coupling a small amount of output energy back to the amplifier input out of phase, to cancel the unwanted in-phase (positive) feedback. A typical circuit is given in Fig 13.29. L2 provides a  $180^\circ$  phase reversal because it is center tapped. C1 is connected between the plate and the lower half of the grid tank. C1 is then adjusted so that the energy coupled from the tube output through the neutralization circuit is equal in amplitude and exactly  $180^\circ$  out of phase with the energy coupled from the output back through the tube. The two signals then cancel and oscillation is impossible.

The easiest way to adjust a neutralization circuit is to connect a low-level RF source to the amplifier output tuned to the amplifier operating frequency. A sensitive

RF detector like a receiver is then connected to the amplifier input. The amplifier must be turned off for this test. The amplifier tuning and loading controls, as well as any input network adjustments are then peaked for maximum indication on the RF detector connected at the input. C1 is then adjusted for minimum response on the detector. This null indicates that the neutralization circuit is canceling energy coupled from the amplifier output to its input through tube, transistor, or circuit capacitances.

### Screen-Grid Tube Stabilization

The plate-to-grid capacitance in a screen-grid tube is reduced to a fraction of a picofarad by the interposed grounded screen. Nevertheless, the power gain of these tubes may be so great in some circuits that only a very small amount of feedback is necessary to start oscillation. To assure a stable tetrode amplifier, it is usually necessary to load the grid circuit, or to use a neutralizing circuit.

### Grid Loading

The need for a neutralizing circuit may often be avoided by loading the grid circuit to reduce stage gain, provided that the driving stage has some power capacity to spare. Loading by tapping the grid down on the grid tank coil, or by placing a "swamping" resistor from grid to cathode, is effective to stabilize an amplifier. Either measure reduces the gain of the amplifier, lessening the possibility of oscillation. If a swamping resistor is connected between grid and cathode with very short leads, it may help reduce any tendency toward VHF-UHF parasitic oscillations as well. In a class AB1 amplifier, which draws no grid current, a swamping resistor can be used to replace the bias supply choke if parallel feed is used.

Often, reducing stage gain to the value

Fig 13.28—The equivalent feedback path due to the internal capacitance of the tube grid-plate structure in a power amplifier.

Fig 13.29—Example of neutralization of a single-ended RF amplifier.

Fig 13.30—A neutralization circuit may use either C1 or C2 to cancel the effect of the tube internal capacitance.

required by available drive power is sufficient to assure stability. If this is not practical or effective, the bridge neutralizing system for screen-grid tubes shown in Fig 13.30 may be used. C1 is the neutralizing capacitor. The value of C1 should be chosen so that at some adjustment of C1,

$$\frac{C1}{C3} = \frac{C_{gp}}{C_{in}} \quad (44)$$

where

$C_{gp}$  = tube grid-plate capacitance  
 $C_{in}$  = tube input capacitance.

The grid-to-cathode capacitance must include all strays directly across the tube capacitance, including the capacitance of the tuning capacitor.

## A 1500-W LINEAR AMPLIFIER USING 3-500Z TUBES

Here is a modern linear amplifier with features not always available on commercial amplifiers. The amplifier uses a pair of 3-500Z high-mu power triodes, and operates on the 80, 40, 20, 17, 15, 12 and 10-m bands. It produces 1500-W PEP with about 100 W of drive. Information is included to take you through the steps necessary to ensure that the amplifier functions properly when completed. Dick Stevens, W1QWJ, designed and built this amplifier.

Fig 13.31 shows the completed amplifier on top of the power supply cabinet. The amplifier cabinet is home-made, using sheet aluminum and aluminum angle stock. The power supply cabinet is much larger than necessary, but is one the author had available. It provides a solid base for the amplifier and the combination fits nicely beside the operating table or desk.

There are many practical reasons for building your own amplifier. You can build an amplifier that will perform better than many lower-priced commercial amplifiers. Using off-the-shelf new parts, the cost of this 1.5-kW amplifier should be around \$1000. Searching flea markets for parts will reduce the cost even further. One word of caution: *do not buy used tubes*. The **References** chapter lists addresses of possible components suppliers for this amplifier.

### FEATURES

When you buy a pair of 3-500Z tubes for approximately \$250, you need to provide protective circuits to ensure long tube

life. Filament in-rush current is a common concern. When the filaments are cold their resistance is very low and the initial filament current will be high. This will

Fig 13.31—The (2) 3-500Z amplifier and HV supply.

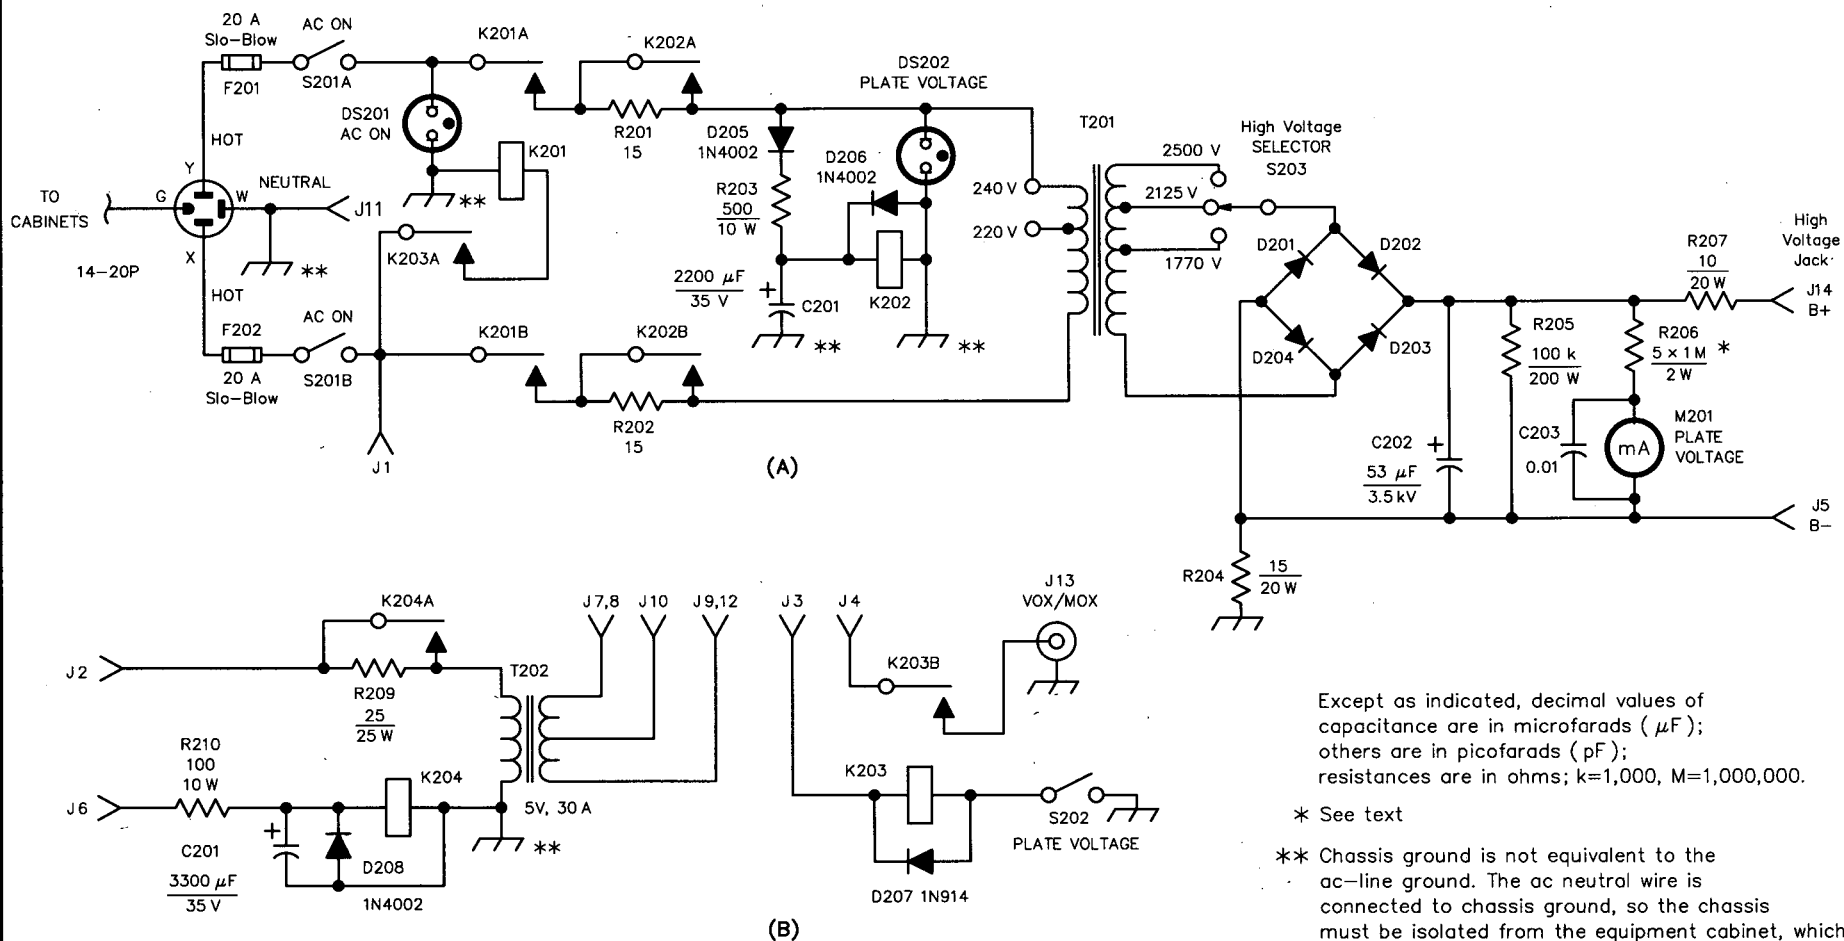

shorten tube life. Remember, you will turn the filaments on and off many times over the life of your amplifier. A relay, resistor and a few other small parts provide a protective circuit.

No matter how careful you are when tuning up the amplifier, it is very easy to exceed the maximum grid current rating. A transistor, relay and a few small parts provide a "grid-trip" circuit to protect the grid from excessive current. You may be surprised how many times the grid-trip circuit operates during initial tune up and testing.

Sequential keying protects the amplifier against "hot" relay switching. With this circuit, the antenna transfer relays are operated and the amplifier is in a ready condition before *any* RF is applied to the tubes. This circuit also protects the driving transceiver, which in many cases can sink a limited amount of external TR current. This sequential keying circuit requires less than 5 mA, and will work with any modern transceiver.

Automatic level control (ALC) is also provided. This circuit helps prevent excessive drive to the amplifier. Do not, however, run the transceiver and amplifier "flat out" and expect the ALC to perform miracles. Remember that the amplifier can be overdriven before the ALC circuit does its job. The short delay before drive is reduced can introduce distortion. If you build a clean amplifier and run it conservatively, it will help ensure a clean signal.

Parasitic suppression is a beast that can

Except as indicated, decimal values of capacitance are in microfarads ( $\mu$ F); others are in picofarads (pF); resistances are in ohms; k=1,000, M=1,000,000.

**S203**—High-voltage selector switch, see text.

**T201**—Hipersil power transformer, 220, 240 V ac primary; 1770, 2125, 2500 V ac, 1.5 A secondary, ICAS (Peter W. Dahl Co. no. ARRL-002 or equiv).

**T202**—Filament transformer, 120 V ac primary; 5 V ac, 30 A center-tapped secondary (Hammond type 167 X5 or equiv).

haunt all amplifiers, whether commercial or home built. Parasitic oscillation can destroy expensive vacuum tubes. This amplifier incorporates the method of parasitic suppression described by Richard Measures, AG6K, in the plate circuit. The suppressors are described in more detail later in this write-up.

## POWER SUPPLY DESCRIPTION

The high-voltage power supply is a full-wave-bridge design that delivers user-selectable voltages of 2.5, 3.0, or 3.5 kV at 1A. The voltage regulation is excellent, due in part to a Peter Dahl Hipersil transformer and a large 53- $\mu$ F, 3.5-kV, oil-filled filter capacitor. (If the builder cannot locate such a capacitor, a suitable replacement should be at least 25  $\mu$ F at a similar voltage rating.)

Transformer T201 has a 240-V ac primary with a 220-V input tap, and output taps at 1770, 2125 and 2500-V ac. The transformer is rated for 1.5 A intermittent commercial and amateur service (ICAS).

Fig 13.32 is the schematic diagram of

## Conversion of RADIOKIT No. 245 Capacitor to a Two-Section Capacitor

Step 1. Make two tie-rod-support plates as shown in Fig A. The back tie rod plate has a half circle notch at the bottom to clear the ground lug rivet.

Step 2. Locate the hole between the two rivets that hold the stator supports. This hole is predrilled with a #35 bit. Tap this hole with a #6-32 tap.

Step 3. Mount the front and back tie-rod plates to the capacitor with #6-32  $\times$  1/2-inch machine screws.

Step 4. Measure the distance between the inside faces of the tie-rod plates. (This distance should be very close to 8 3/4 inches) Cut a piece of 1/4-inch aluminum rod to just fit between the tie-rod plates. With a #35 bit, drill a hole in the end of the 1/4-inch rod to a depth of 1/2 inch. Tap this hole for a #6-32 screw. Mount the completed tie rod between the tie-rod mounting plates.

Step 5. The new tie rod will hold the capacitor together for the next operation. Remove all nuts on the stator tie rods and remove the tie rods. All stator plates and spacers will come loose. Be careful not to lose any of these parts.

Step 6. Using the brass stator tie rods as stock, cut two new tie rods 6 7/8 inches long and two new tie rods 2 3/4 inches long. With a #10-32 die, cut new threads on the plain ends to a length of 1/2 inches

Step 7. Slide a shaft collar over the 1/4-inch rotor shaft all the way to the front end plate. Lock the set screw to hold the shaft to the front end plate. This will prevent the small ball bearings from falling out of position. Remove all three 1/4-inch tie rods for complete disassembly of the capacitor. Be very careful not to lose the single ball bearing that centers the rotor shaft to the rear bearing. Loosen and remove the nut that holds the rotor plates to the shaft. Count from the rear of the rotor shaft and remove the sixth rotor plate. Where the sixth plate was you should now have two spacers. Replace the nut and tighten it. Reassemble the capacitor and the rotor, securing the frame with the three 1/4-inch tie rods. Be sure to replace the single ball bearing at the rear of the rotor.

Step 8. Reassemble the front stator. Count off 21 stator plates and 40 spacers. Using the 6 7/8-inch brass tie rod, assemble the stator. Install the finished stator on the front support insulators. Install #10 nylon washers between the locking nuts and the insulators to prevent the insulators from breaking. Slide the 2 3/4-inch tie rods into the rear insulators. Add one #10 nylon washer and two #10-32 nuts. Next, add one plate and then a spacer. Continue adding plates and spacers until you have 4 plates and three spacers. Lock the assembly together with #10-32 nuts. Add a #10 nylon washer and #10-32 nut to the outside of the tie rods.

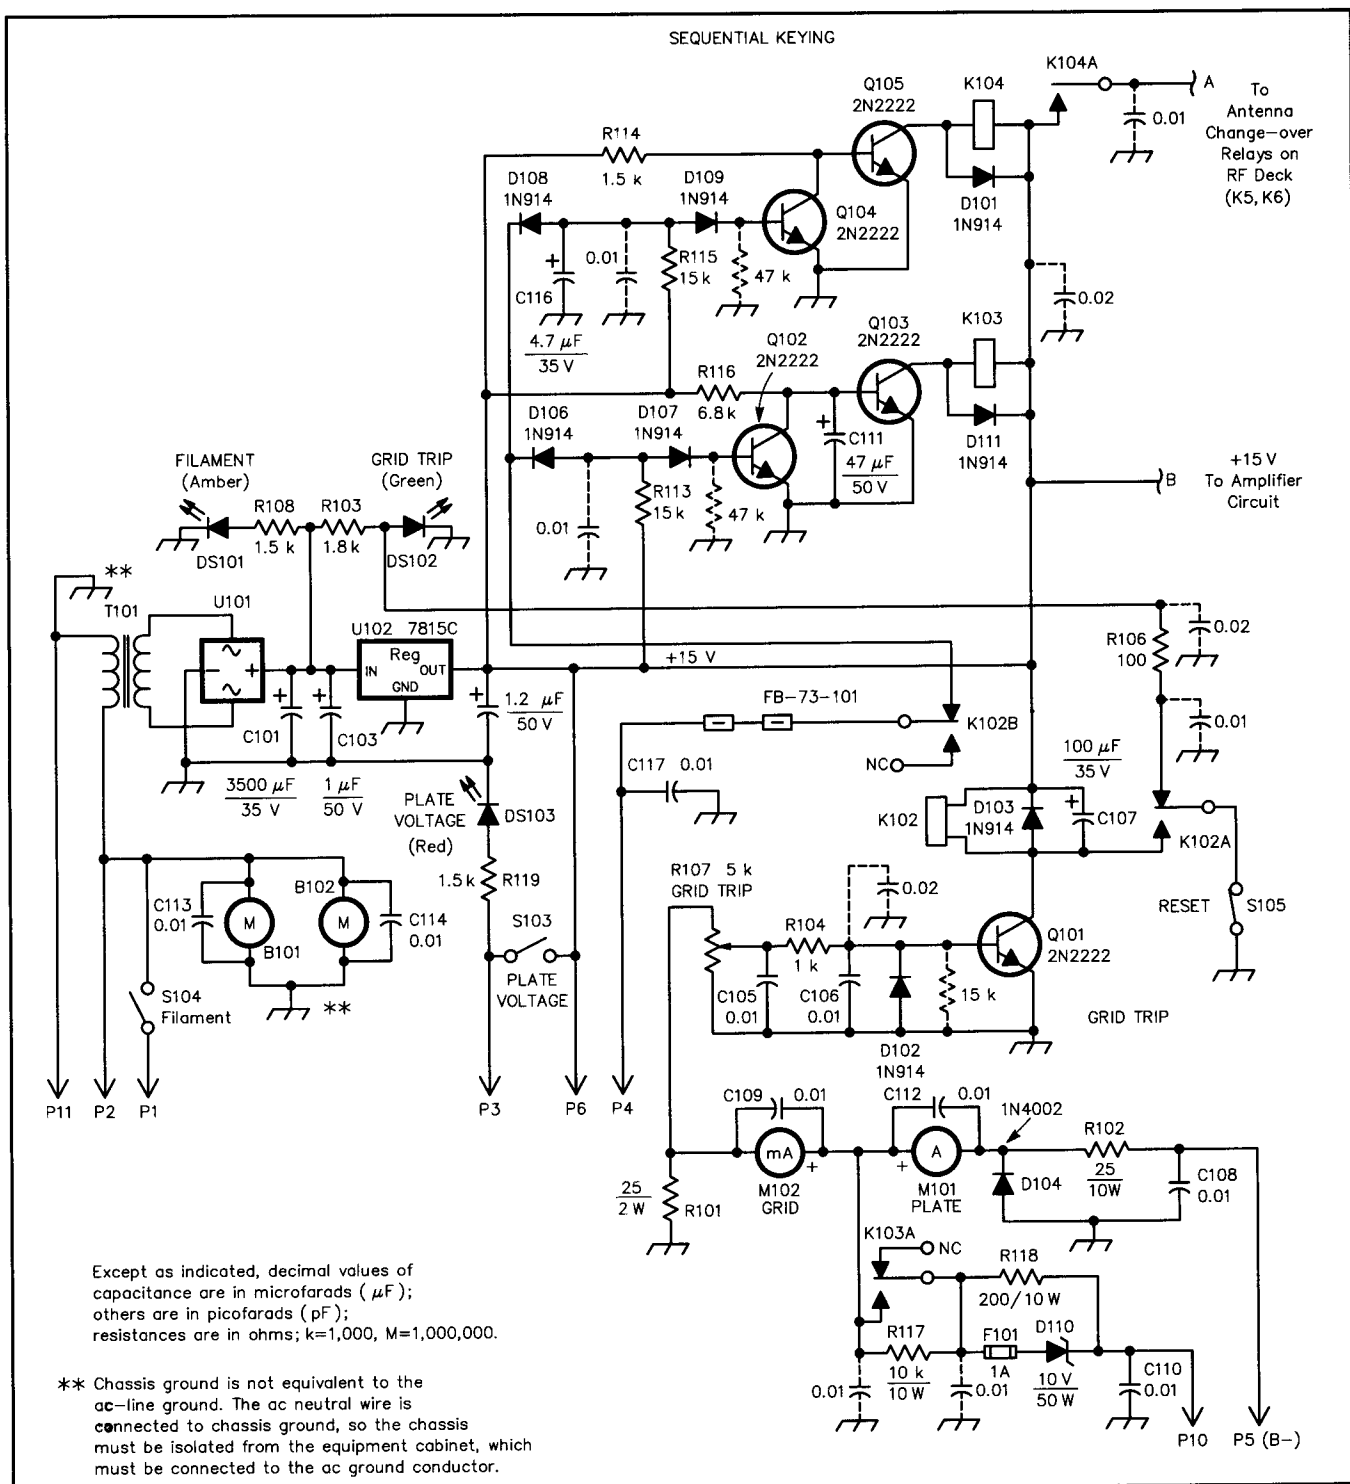

Step 9. Adjust the #10-32 nuts so you have proper spacing between the stator and rotor plates and tighten all locking nuts to hold the assembly in proper alignment.

The measured capacity of the larger section should be 200 pF maximum and 30 pF minimum. The measured capacitance of the smaller section should be 43 pF maximum and 12 pF minimum.

The finished capacitor should have 5 rotor and 4 stator plates on the rear section and 21 rotor and 21 stator plates on the front section.

**Fig A**—Make two end plates as shown to hold the modified capacitor together after the stator-support rods have been cut to form the two sections.

**Fig 13.33—Schematic diagram of the 3-500Z amplifier control circuitry. Resistors are  $\frac{1}{4}$  W unless noted. Capacitors are disc ceramic unless noted and those marked with a + are electrolytic. Addresses for parts suppliers are given in the References chapter.**

**Fig 13.34**—Interior view of the power-supply cabinet. The high-voltage supply is on the bottom. The filter capacitor and bleeder resistor are visible on the left and the high-voltage transformer is on the right. The filament transformer and 15-V dc supply for the control circuit are mounted on the shelf in the top right corner. The high-voltage SELECTOR switch is clearly visible in the center of the photo.

the high-voltage supply. (The HV circuit is hand wired; the photo shows general parts-placement information.) A protective circuit limits the in-rush current when the supply is initially switched on. S203 is a high-voltage switch (with large contacts and ceramic insulation) used to select the output voltage. Under normal conditions, the 3-kV (dc) position is selected. The 2.5-kV position can be used while tuning and the 3.5-kV position may be selected if the input voltage is a bit low.

Along with the high-voltage supply, the power-supply cabinet also houses the filament transformer and in-rush current-protection relay. (Fig 13.32 shows these circuits.) There is not sufficient room on the amplifier chassis to mount the transformer.

The 15-V dc control-circuit power supply is also located in the power-supply cabinet, although this circuit is shown as part of the control circuit in Fig 13.33. (The control circuit is built on perfboard; no etching pattern or parts-placement diagram is needed.) Fig 13.34 shows the layout inside the power-supply cabinet. The high-voltage supply is on the bottom and the filament transformer and 15-V dc supply are on the shelf. Notice the 53- $\mu$ F filter

capacitor and the 100-k $\Omega$  bleeder resistor on the left side.

The B+ lead to the amplifier is made with high-voltage insulated wire (30-kV insulation, #22 wire) and a high-voltage connector. A braid ground strap bonds the power supply to the amplifier chassis.

### Circuit Operation

When switch S201 is closed, 240-V ac is available to the power supply. Neon bulb DS201 lights, showing that power is available to the power supply and 120-V ac is available to the amplifier via pin 2 of the 12-pin Jones connector.

When the filament switch (S104 in the control-circuit diagram, Fig 13.33) is closed, 120-V ac is applied (through pin 2 of the Jones plug and R209) to the filament transformer, T202. The resistor limits the filament in-rush current. The control circuit also applied 15-V dc to R210 and relay K204. When capacitor C204 has charged sufficiently to operate the relay, contacts K204A close, applying the full 120-V to T202.

To energize the HV supply, switches S103 and S202 must be closed. This applies 15-V dc from the control circuit to relay K203. Relay K203 operates and closes contacts K201A and B, sending 240 V through resistors R201 and R202 to the primary of T201. Indicator DS202 lights.

Resistors R201 and R202 limit the charging current through diodes D201-D204, protecting them from the high charging-current demands of the filter capacitor, C202. The ac voltage applied to the diode D205 is rectified and passed to the RC filter consisting of R203 and C201. After about 1 second, the voltage across C201 will reach 15 to 20-V dc and relay K202 will operate. Contacts K202A and K202B then close and the full 240-V ac is applied to T201. Diodes across the relay coils suppress voltage spikes.

The negative return (B-) is isolated slightly above ground by R204. This is required for amplifier metering purposes. R207 acts somewhat like a high-voltage fuse and protects the 3-500Z amplifier tubes in case of an arc-over. Meter M201 measures plate voltage; it is a 0 to 1 mA movement with a 5-M $\Omega$  multiplier resistor, R206. R206 consists of five 1-M $\Omega$ , 2-W, 2% resistors in series. If a different meter movement is used, a new value for the multiplier resistor must be calculated. R205 is a 100-k $\Omega$ , 200-W bleeder resistor.

To protect the amplifier from drive without plate voltage on the tubes, the VOX/MOX signal from the transceiver is

routed through power-supply control relay contacts, K203B. Unless the supply is operating, a VOX/MOX signal from the transceiver won't reach the input and output relays, so the amplifier is bypassed.

### RF DECK

The RF deck includes two 3-500Z triodes, the control circuit board, ALC board, input filters and the output pi network. It is built into an aluminum cabinet. Two small muffin fans blow cooling air directly onto the tubes, and there is a vent hole directly over the tubes. A piece of aluminum screening covers the hole; #6 hardware holds the screen in place. The screen edges are covered with glass-fiber electrical tape to prevent fraying. Figs 13.35 and 13.36 show the internal construction of the amplifier.

To avoid a cluttered diagram, only part of the input circuit is shown in Fig 13.37. Each band has its own input filter, and the component values for these filters are given in Fig 13.38. One capacitor in each filter is adjustable, so the filters can be tuned for lowest SWR (1.5:1 or better). The inductors are wound on toroids. The core and winding information is also given in Fig 13.38.

The filter board is mounted facing the rear panel. An access hole cut in the panel allows easy adjustment. A piece of aluminum serves as a cover plate; it is held in place by two machine screws and PEM nuts (which press fit into holes in the panel).

Each tube has a parasitic-suppression network connected directly to the plate lead. Each network includes a choke, which consists of 3 turns of #18 nichrome or stainless steel wire with a 7 mm inside diameter. Two 100- $\Omega$ , 2-W metal film resistors are parallel-connected to each other and the coil. *It is important that the resistors do not go through the center of the coil.* This network is clearly visible in Fig 13.36.

The amplifier output goes through a low-pass filter (B & W Model FL-10/1500) to reduce harmonic energy above 30 MHz. This filter is mounted on the back panel.

### ALC Circuit

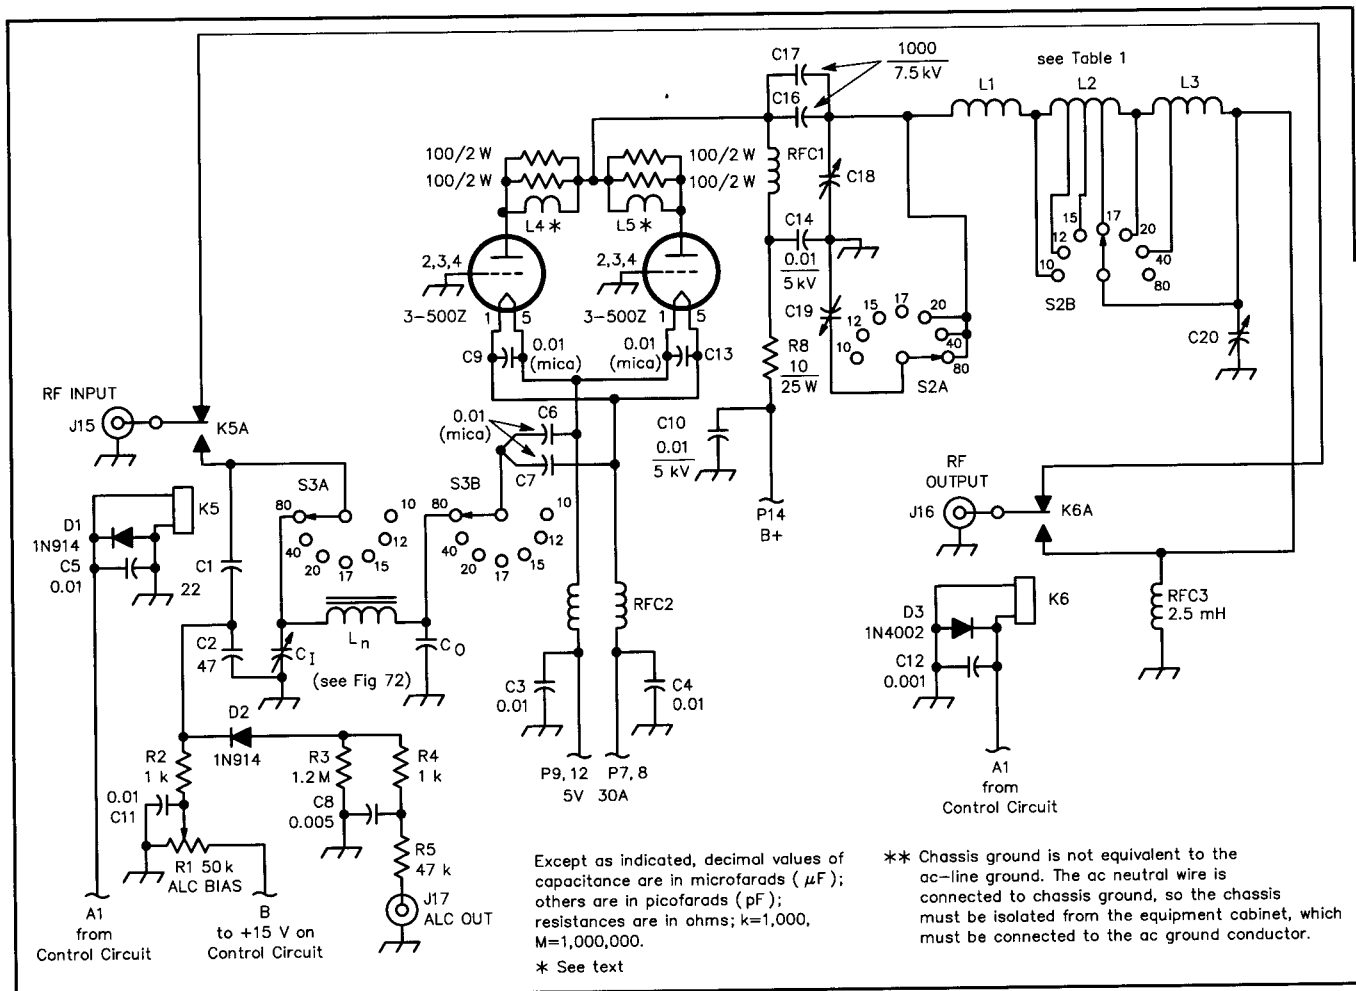

The ALC circuit samples RF drive through a voltage divider circuit, C1 and C2. The sampled voltage is rectified by diode D2, and filtered by C8. R1 sets the threshold voltage, or operating point, of the ALC. When the rectified sample voltage exceeds the threshold voltage set by R1, a dc voltage is sent to the driving transceiver to lower its output. The threshold

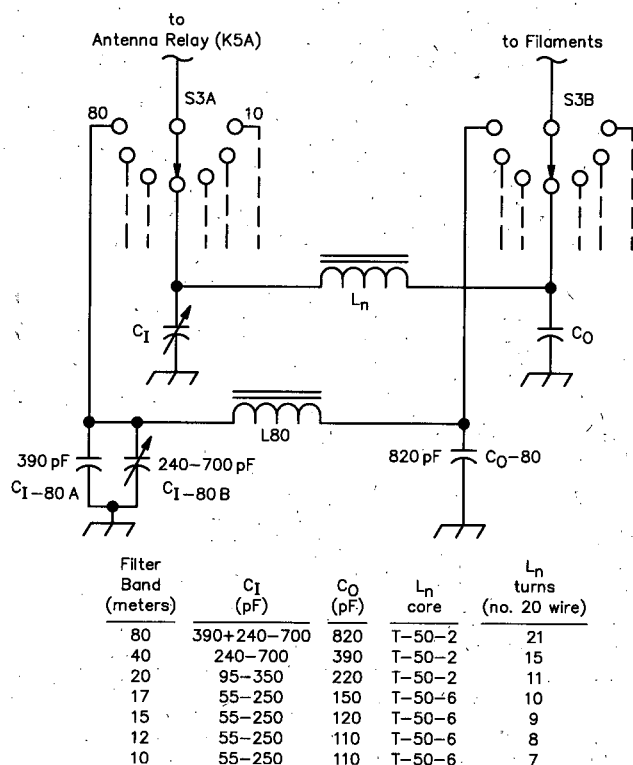

**Fig 13.35**—Photo of the amplifier chassis bottom. The chain-drive arrangement visible at the bottom of the photo connects the input-filter band switch (S3 on Fig 13.37) with the output network band switch (S2 on Fig 13.37). One knob on the front panel operates both switches. The control-circuit board is visible in the lower-right corner of the chassis and the ALC board is along the left edge. The input-filter circuits (and band switch S3) are near the top of the photo. The B & W TVI filter is at the top of the photo. The bifilar filament choke is across the center of the chassis.

**Fig 13.36**—Photo of the top side of the amplifier deck. The neat, uncluttered appearance of the RF section is evident. Notice the plate choke at right and the parasitic suppressors at the tube plates. The modified RADIOKIT capacitor is at the left and the inductors are in the center. Careful inspection of the coil stock shows the different turns spacing of the two coils, as well as the solder joint between the two sections. The 10-m coil mounts perpendicular to the other coils. The chain-driven band switch arrangement is at the bottom of the photo, but the output BAND switch is hidden by the inductors.

**Fig 13.38**—Details of the eight input filters are shown. Each filter connects to the appropriate position on the band switch. The chart gives capacitor values and inductor winding information. The output capacitors (C<sub>O</sub>) are all silver-mica units. The input capacitors (C<sub>I</sub>) are mica compression trimmers. The 80-m input capacitor has a 390 pF silver-mica capacitor in parallel with the trimmer. ARCO part numbers for the trimmer capacitors are: 240-700 pF, 4215; 95-350 pF, 428; 55-250 pF, 426.

**Fig 13.37**—Schematic diagram of the 3-500Z amplifier RF deck. Resistors are 1/4 W unless noted. Capacitors are disc ceramic unless noted, and those marked with a + are electrolytic. See Fig 13.38 for details of the input filter section. Addresses for parts suppliers are given in the References chapter.

C18—12.5 to 43 pF section of modified RADIOKIT no. 245 capacitor (or equiv). See the Sidebar for modification instructions.  
 C19—30.5 to 200 pF, 4500 V, section of modified RADIOKIT capacitor.  
 C20—40 to 1500 pF, 1700 V, air-variable capacitor, such as RADIOKIT no. 1600 (or equiv).  
 J15, J16—RF connectors to suit builder. The author used a BNC input connector and an N connector on the output.

 K5—SPDT relay, 12 V dc coil (Radio Shack 275-248 is suitable).  
 K6—SPDT coaxial relay, 12 V dc, 160 mA coil (Toh.Tsu. Electric Co. Ltd. CX-600 N, or equiv).  
 P7, P8, P9, P12—Pin numbers of male 12-pin Jones connector used for connections between the amplifier and power supply.

P14—High-voltage connector (male) and able (see text).  
 RFC1—Plate choke, wound on 3/4-inch diameter Teflon rod. See text for winding details.  
 RFC2—30 A filament choke, such as B & W FC-25A.  
 RFC3—2 1/2 mH choke.  
 S2—Output rotary switch, nonshorting 2-section, 7-position high-voltage ceramic wafer switch with 30° indexing. (The author used 2 wafers of a Radio Switch Corporation Model 86-4-8-30 4-wafer, 8-position switch.)  
 S3—Input rotary switch, nonshorting 2-section, 7-position ceramic wafer switch with 30° indexing. The author used an 11-position Centralab 2513 switch.

voltage is adjustable to cover nearly any operating condition of any transceiver.

**Fig 13.39** is a parts-placement diagram.

### Control Circuit

The control circuit is shown in Fig 13.33. When the transceiver VOX/MOX line is grounded (transmit), pin 4 of the Jones connector (P4) is grounded. This ground is connected through K102B to diodes D106, D107, D108 and D109.

This causes Q104 and Q102 to stop conducting. Q105 then conducts, and relay K104 activates, sending 15-V dc to the antenna change-over relays (K5 and K6 on the RF deck; see Fig 13.37). A short time later Q103 conducts, actuating relay K103. This puts the amplifier in the operating condition. (The delay is set by the time it takes C111 to charge after Q102 stops conducting. This time delay allows the antenna relays to close before the amplifier is keyed.)

Grid-current protection is provided by Q101. Grid current is sensed from the voltage drop across R101. The level is set by R107. When the grid current reaches a level of 215 mA, Q101 conducts, causing relay K102 to activate. This opens contacts K102A close to light DS102 (indicating a grid-trip condition) and provide a latched ground for the relay coil through S105. K102 will remain on until the RESET switch, S105, is opened or the power supply is switched off.

The control circuits are made on a printed circuit board. A full-size etching is available from the Technical Department Secretary. Write, call, fax or e-mail ARRL HQ and ask for the "95 Handbook 3-500Z Amps" package. **Fig 13.40** (on the next page) is a control board parts-placement diagram. The author's amplifier exhibited an RFI problem in the control circuit during 80-m operation. The control-circuit relays cycled on and off when the amplifier output exceeded about 500 W with the plate voltage set to 3 or 3.5 kV. A few circuit modifications were made to cure this problem. Each lead to the control circuit board was filtered with an FB-73-801 bead and a 0.01-μF disk capacitor to ground. (See Fig 13.40 detail.) Several other bypass capacitors were added at various points in the circuit. In addition, 47-kΩ resistors were added between the base and emitter leads of Q102 and Q104. A 15-kΩ resistor was added between the base and emitter of Q101. The capacitors and resistors were added to the underside of the circuit board, and are shown with dashed lines on Fig 13.33 and the parts-placement diagram.

about  $1\frac{1}{16}$  inch) The next section is 46 turns (about  $1\frac{1}{16}$  inches). Wind 21 turns (a little less than  $\frac{1}{2}$  inch) for the third section. The last section is 17 turns (about  $\frac{3}{8}$  inch). Complete the plate choke with a protective coating of Q-dope or similar varnish. Although this winding technique was used in this project, its benefits are minimal. See the discussion under RF chokes earlier in this chapter.

## TUNING AND OPERATION

Use an ohmmeter to check all circuit paths in the power supply and RF deck for possible short circuits. Check the HV supply for proper operation before connecting it to the RF deck. Before installing the tubes in their sockets, verify the operation of all control circuits. Connect the Jones power-supply cable and a heavy braid ground strap between the amplifier and power-supply cabinets. (Don't connect the high-voltage lead between the RF deck and the power-supply cabinet. With the jack of the HV connector mounted on the supply cabinet, you needn't worry about a live high-voltage lead accidentally touching the chassis or operator. You must, however, activate the HV supply to make the control circuit operational.)

Turn on the power-supply main power switch and the amplifier POWER switch. The blowers should run and you should measure about 5 V ac at the tube sockets. Switch on the PLATE VOLTAGE at the power supply and then the PLATE voltage switch on the amplifier. After a few seconds the relays should engage. Next, ground the amplifier VOX/MOX line and check to see that the control-circuit relays activate as expected. When everything is working properly, turn off all power and carefully install the tubes. Install the top and bottom covers on the amplifier chassis.

Connect the HV lead to the amplifier. Attach a transceiver (capable of delivering about 100 W) through a wattmeter to the RF INPUT. Route the amplifier RF OUTPUT through a second wattmeter to a suitable dummy load. Install a VOX/MOX lead from the transceiver to the amplifier VOX/MOX line to make the amplifier transmit during the test.

Flip on the power-supply main power switch and then the amplifier POWER switch to activate the filament supply. You should see the tubes begin to glow. Set the high-voltage SELECTOR switch to 2500, and then close the PLATE VOLTAGE switch on the power supply followed by the PLATE switch on the amplifier. (CAUTION: Never operate the high-voltage SELECTOR

**Table 13.8**

### Amplifier Operating Conditions Measured in ARRL Lab, Pair 3-500Zs

$V_p = 2500$

Frequency (MHz)	Grid Current (mA)	Drive (W)	Output (W)
3.8	230	115	940
7.1	140	100	930
14.2	140	100	940
18.1	150	100	960
21.2	140	100	960
24.9	150	100	800
28.5	120	100	720

$V_p = 3500$

Frequency (MHz)	Grid Current (mA)	Drive (W)	Output (W)
3.8	180	110	1480
7.1	180	100	1470
14.1	150	100	1320
18.1	160	100	1280
21.2	160	100	1080
24.9	160	100	1290
28.5	140	100	940

$V_p = 3000$

Frequency (MHz)	Grid Current (mA)	Drive (W)	Output (W)
3.8	160	110	1250
7.1	160	100	1250
14.2	140	100	1120
18.1	140	100	1070
21.2	150	100	1110
24.9	150	100	930
28.5	160	100	800

switch with the plate voltage on! Severe arcing will occur across the switch contacts and you may destroy the switch.) With the exciter set to transmit SSB, press the mike PTT switch and note the idling plate-current reading. It should be about 120 mA.

With the amplifier set to operate on 80 m, apply about 10 W of CW drive and adjust the input-filter capacitor for that band to achieve the lowest possible SWR. (You should have no trouble adjusting the filter for an SWR of 2:1 or better.) Now adjust the TUNE and LOAD controls for maximum output. (The easiest way to tune this amplifier is to observe a wattmeter connected to the output and tune for maximum power.) Recheck the input SWR with the amplifier running at full output.

Adjust the input filter for each band in turn. Turn off the PLATE VOLTAGE and select 3000 V (and then 3500 V), running

**Fig 13.41—Worst-case spectral photograph of the 3-500Z amplifier.** Power output is 950 W on 7.1 MHz with the plate voltage set at 2500 V. Each vertical division is 10 dB and each horizontal division is 5 MHz. All harmonics and spurious emissions are at least 46 dB down. This amplifier complies with current FCC spectral-purity requirements.

**Fig 13.42—Worst-case spectral display of the amplifier output during two-tone intermodulation distortion (IMD) testing.** The third-order products are approximately 40 dB below PEP output. Vertical divisions are 10 dB; horizontal divisions are 2 kHz. The amplifier was operated at 900 W PEP output on 14.1 MHz with the plate voltage set at 2500 V.

through the amplifier-tuning process again each time. Keep detailed notes of the plate and grid currents for each band at each plate-voltage setting. You should normally operate with 3000 V (use the 3500-V switch position to get 3000 V if the line voltage is low at your location).

**Table 13.8** summarizes the operating conditions measured in the ARRL Lab. **Fig 13.41** shows the spectral output of the amplifier, with the signals going through the B & W FL-10/1500 low-pass filter. **Fig 13.42** shows the worst-case results of the Lab's intermodulation-distortion (IMD) test.

## 6-M AMPLIFIER USING THE 3CX800A7

The amplifier described here uses an EIMAC 3CX800A7 in a grounded-grid circuit. With 2200 V on the plate and 20-W drive, it will provide about 700-W output—enough for weak-signal work such as meteor scatter. The 3CX800A7 is well suited for this application. It combines low drive requirements normally associated with tetrodes, yet it offers the stability of

grounded-grid triodes. Figs 13.55 through 13.61 depict the amplifier. Dick Stevens, W1QWJ, designed and built this project.

### CIRCUIT DETAILS

Fig 13.56 is a schematic diagram of the amplifier. The RF deck includes everything except the high-voltage power supply. This amplifier requires 2000- to 2200-V at about

half an ampere. The plate tank circuit is a pi-L network consisting of C11, C12, L3 and L4. This configuration gives somewhat better harmonic suppression than a standard pi network. The cathode input circuit is a T network consisting of L1, L2 and C8. A filament choke is recommended above 50 MHz to keep the filament above ground for RF. RFC2 is bifilar wound on a ferrite rod. According to sources at EIMAC, use of a center-tapped transformer at T1 is not necessary. If you have a transformer of the correct voltage, but without a center tap, go ahead and use it.

R1, in the B+ line, will protect the tube and power supply in case of a high-voltage arc. In this case, R1 was mounted in the power supply. It doesn't matter if you mount it in the power supply or the RF deck, but the use of this resistor is highly recommended. Cathode bias is provided by a 5.1-V Zener diode, D5. R3 prevents the cathode voltage from soaring if D5 fails. F2 will blow if excessive cathode current is drawn. R4 nearly cuts the tube off on receive.

All metering is done in the negative return lead for safety. C9, C10, D3 and D4 protect the meters. The antenna relay is located externally but is powered from the amplifier.

A grid overcurrent trip circuit is included to protect the 3CX800A7 from damage. The cost of the tube makes protection circuitry a must! Grid current is sensed across R5. If the grid current exceeds a preset value, Q1 conducts and actuates K1. Contact K1A, in the K2 coil supply line, opens and removes power from K2, placing the amplifier in STANDBY. To restore normal circuit operation, turn S2 to the off position; this will reset K1. S2 is "on" for normal operation. This switch provides an additional function: It controls the VOX circuit and antenna bypass relay circuit, so that the amplifier can be switched in and out of the line between antenna and transceiver.

### CONSTRUCTION

The amplifier is built on a 10×12×3-inch chassis (LMB 10123C). For the best possible RF shielding, the plate circuitry is built inside its own 5×10×3-inch chassis (LMB 5103C) that is mounted on top of the main chassis. The chassis is attached to a standard 19×7 inches aluminum rack panel (Hammond PBPA 19 007). The meters are mounted to the front panel with bezels.

Fig 13.56—Schematic diagram of the 6-m amplifier using the 3CX800A7. Resistors are 1/4-W carbon types unless noted. Capacitors are disc ceramic types unless noted. S.M. means silver-mica. Capacitors marked with polarity are electrolytic. See parts list on facing page. →

Fig 13.55—The 3CX800A7 6-m amplifier is mounted on a rack panel. Meters are mounted behind the panel with bezels.

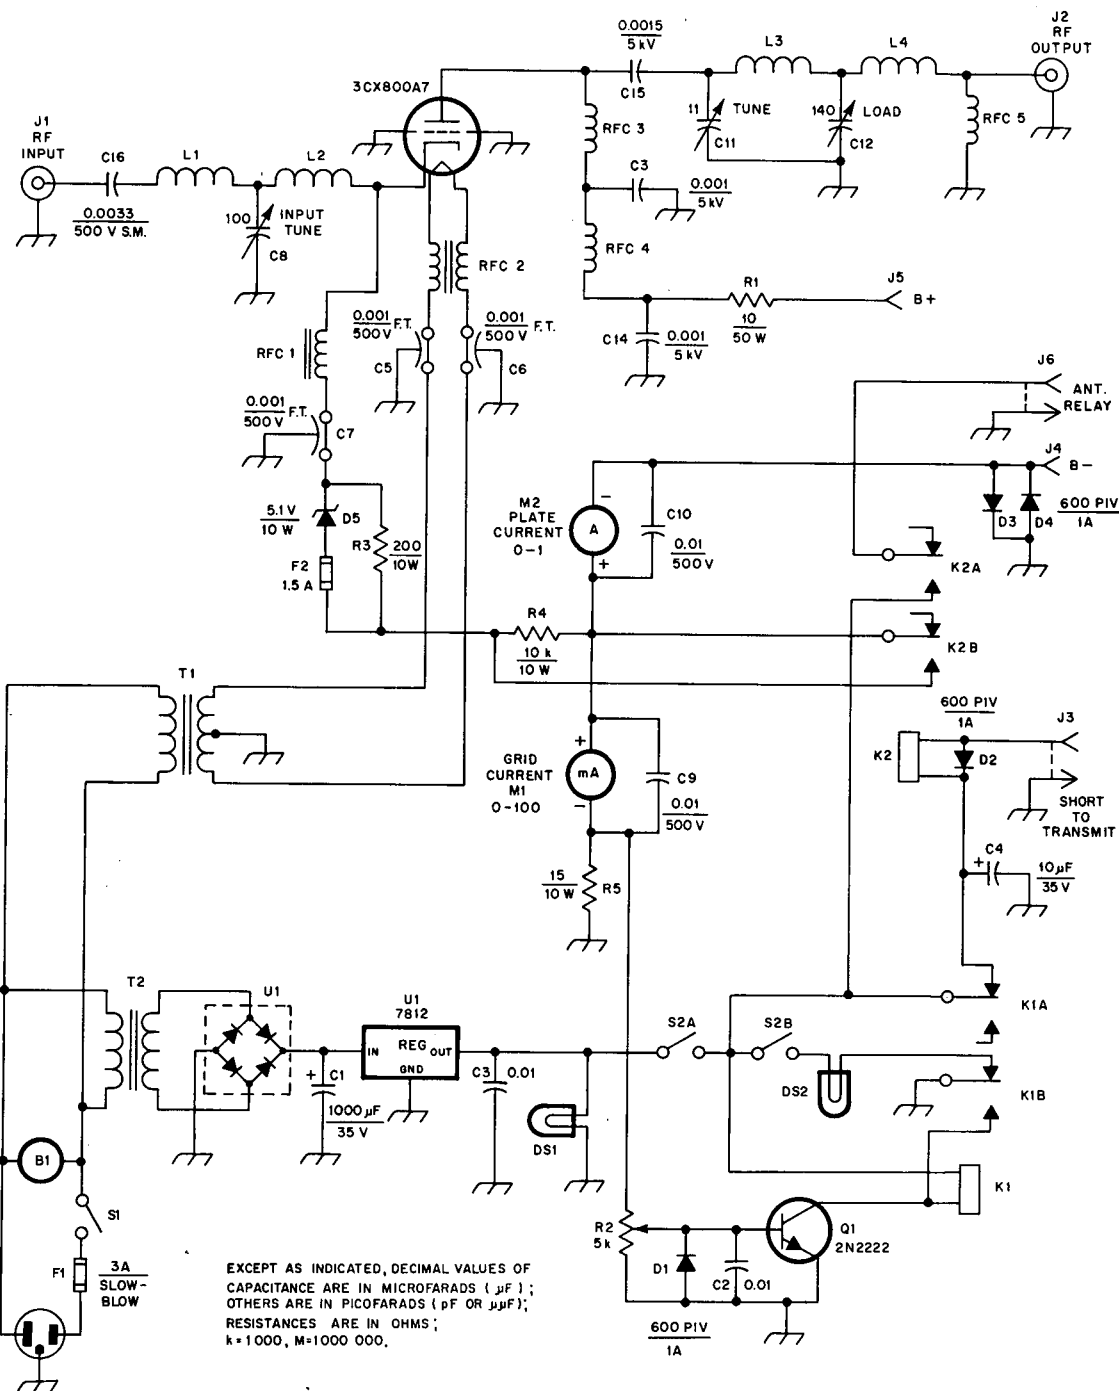

Fig 13.57—The output network mounts on a separate subassembly. C15 connects to the rest of the circuit with wide copper straps.

B1—Dayton 4C012A 54-CFM blower.  
C8—100-pF air variable (Millen 22100 or equiv.).  
C11—Modified air variable, 4 to 11 pF. See text.  
C12—8- to 140-pF air variable, receive spacing (Cardwell 149-6 or equiv.).  
C13, C14—1000-pF, 5-kV disk-ceramic capacitor.  
C15—1500-pF, 5-kV RF-type doorknob capacitor.  
C16—3300-pF, 500-V S. M. capacitor.  
D1-D4—600-PIV, 1-A silicon diode.  
D5—5.1-V, 10-W Zener diode (1N3996 or equiv.).  
DS1, DS2—12-V dc pilot light.  
J1—Chassis-mount female BNC connector.  
J2—Chassis-mount female Type-N

connector.  
J3, J6—Chassis-mount phono jack.  
J4, J5—Millen 37001 high-voltage connector.  
K1—DPDT miniature relay, PC-board mount, 12 V dc coil (RS 275-213).  
K2—DPDT relay, 12 V dc coil, 10 A contacts.  
L1, L2—10 turns #18 wire, 5/8-inch ID, 1 inch long.  
L3—5 turns 1/8-inch copper tubing, 1 1/8-inch ID, 2 1/2 inches long.

M1—0-100 mA dc meter.  
M2—0-1 A dc meter.  
Q1—2N2222 or equiv.  
RFC1—10- $\mu$ H RF choke. 40 turns #22

enameled wire on a 1/4-inch ferrite form or a Radio Shack no. 273-101.  
RFC2—14 turns #16 enameled wire on a 1/2-inch-OD ferrite rod. See text.  
RFC3—40 turns #22 enameled wire closewound on a 2-inch-long by 3/4-inch OD Teflon rod. See text.  
RFC4—Ohmite Z-144 RF choke.  
RFC5—Ohmite Z-50 RF choke.  
T1—Filament transformer. 120-V ac primary; 13.5 V, 1.5 A center-tapped secondary (Avatar AV-440 or equiv.).  
T2—Power transformer. 120-V ac primary; 12.6 V, 1.2 A secondary.  
U1—50-PIV, 4-A bridge rectifier.  
U2—12-V, 1.5-A three-terminal regulator (LM7812 or equiv.).

Considerable care must be given to the tank circuit construction to keep stray capacitance to a minimum. To this end, the plate tuning capacitor (C11) is rebuilt from a receiving type. All available commercial capacitors had too high a minimum capacitance.

The first step in construction is to fabricate the plate tuning capacitor. The capacitor is made from a stock Cardwell ER25AS split-stator capacitor having a maximum capacitance of 25 pF per section, with four stator and five rotor plates. The capacitor is  $1\frac{5}{8}$  inches long between the end bearing plates and is made up of individual stator and rotor plates held together with spacers, washers and nuts.

Carefully disassemble the capacitor. Be careful not to lose any of the small parts. Two new #4-40 by  $2\frac{1}{8}$ -inch-long tie rod bolts are needed. Reassemble the capacitor as a single section with four stator and three rotor plates with three spacers between plates. The completed capacitor will have a spacing adequate for 3.5-kV breakdown. The minimum capacitance is 4 pF and the maximum is 11 pF. Any capacitor of this type construction in the same general capacitance range should work. Alternatively, a small vacuum variable will work.

The tuning and loading capacitors, as well as L3 and C15, are mounted on an aluminum subassembly, as shown in Fig 13.57. C12, the plate loading capacitor, is a standard value and required no modification. L3 is made of  $\frac{1}{8}$ -inch copper tubing and is suspended between C11 and C12. The bottom of L3 should be about  $\frac{1}{2}$  inch above the bottom of the subassembly. Additional details of the plate compartment may be seen in Fig 13.58.

The subassembly is made from pieces of aluminum sheet that measures  $4\frac{3}{4}\times 5\frac{3}{4}$  inches. Fold up 2 inches on the longer side at a right angle to form an L bracket, as shown in Fig 13.57. The capacitor shafts are mounted 1 inch in from each end, in the center of the 2-inch lip.

RFC3, the plate choke, is wound on a 2-inch length of  $\frac{3}{4}$ -inch-OD Teflon rod. Drill each end to a depth of  $\frac{1}{2}$  inches and tap for #10-32 hardware. Screw a 1-inch length of #10-32 threaded rod (or a bolt with the head cut off) into each end. Starting at  $\frac{1}{2}$  inch from one end of the rod, wind 40 turns of #22 enameled wire. Leave extra wire at each end for making connections. The winding should be about 1 inch long and centered on the form. Secure both ends of the winding with epoxy cement. Slip a #10 solder lug over one of the pieces of threaded rod and solder one end of the winding to it. This will be the end that attaches to C15.

The plate compartment is pressurized, and a chimney made from Teflon sheet that fits around the tube anode forces the air up

through the tube to an exhaust hole cut in the top of the plate compartment. The hole is shielded with aluminum screen. See Fig 13.59 for details of chimney and exhaust hole screen construction.

Fig 13.60 shows the underside of the amplifier chassis. A partition down the center of the chassis shields the input circuitry. The tube socket, input network and filament choke mount on one side of the partition. The dc components and control circuitry mount on the other. Operating voltages reach the tube through feed-through capacitors in the partition.

To ensure stability, the grid grounding straps should go from pin 4 to pin 7, and from pin 4 to pin 11. Ground pin 4 to the chassis at a solder lug at one of the tube-socket mounting screws. Alternatively, EIMAC can supply a collet to ground the grid. The cathode straps should go between pins 1-8, 2-9 and 3-10. Solder these straps together where they cross at the center of the socket and make the cathode RF connection to this point.

Filament choke RFC2 is wound on a ferrite core. Cut two 36-inch lengths of #16 enameled wire and bifilar wind them on a  $\frac{1}{2}$ -inch wooden dowel. Dress the ends to make the winding 2 inches long. Cut a 3-inch length of ferrite rod and file the ends so there are no sharp edges. Carefully slide the bifilar winding off the dowel and onto the ferrite rod. After the winding is centered on the rod, give it a coat of epoxy to hold it in place.

The grid protection circuitry is built on a small piece of Radio Shack part no. 276-159 prototyping board. One half the board

is used. Most of the other components mount to the chassis or to terminal strips.

## INITIAL TUNE-UP AND ADJUSTMENT

Connect an SWR meter between a 6-m transmitter capable of supplying 20 W and the amplifier input. Connect a wattmeter and a good 50- $\Omega$  dummy load capable of handling at least 700 W to the output connector. Close S1 and allow the 3CX800A7 to warm up for at least 3 minutes before applying plate voltage. Caution: never apply filament voltage without the blower running. Never apply drive without plate voltage and a load connected to the tube, or the tube grid-dissipation rating may be exceeded.

Apply low plate voltage, about 1 kV, and a watt or two of drive. Adjust C8 for minimum input SWR. It might be necessary to spread or squeeze turns on L2 to get a 1.1:1 SWR.

Adjust C11 and C12 for maximum output. There is not much leeway with L3. It has to be the correct value to resonate with the output capacitance of the 3CX800A7 and the low capacitance of C11. Chances are that you may have to shut the amplifier off, disconnect the high voltage and spread the turns on L3 slightly to get the output circuit to resonate properly. The circuit should resonate with C11 set at  $\frac{1}{2}$  mesh.

When you get the output circuit to resonate at low power, bolt down all the covers and apply full plate voltage. Zero-signal plate current should be 65 to 70 mA. Apply a couple of watts drive and tune the amplifier

Fig 13.58—Top view of the 3CX800A7 6-m amplifier. The blower pressurizes the plate compartment and air exhausts through a chimney made from Teflon sheet. A Dow-Key 260B is used here as a TR relay. T1 and K2 are mounted on top of the chassis.

Fig 13.59—Chimney and exhaust hole screen construction details.

Fig 13.60—The underside of the chassis is divided in half by a partition to shield the input circuit.

Table 13.11

**Typical Operating Conditions for the 3CX800A7 6-m Amplifier**

Plate supply voltage	2200 V
Zero-signal plate current	65 mA
Single-tone plate current	500 mA
Single-tone grid current	40 mA
Drive power	20 W
Output power	700 W
Efficiency	62%

for maximum output. Slowly increase the drive, keeping the output tuned for maximum. With 10 W of drive from a typical multimode transceiver, output should be 400 to 500 W. With 20-W drive, output should be approximately 700 W. **Table 13.11** lists typical operating conditions. Check the input SWR at full power and readjust as necessary.

Most likely the grid overcurrent trip circuit will operate at some point during

Fig 13.61—Spectral output of the 3CX800A7 6-m amplifier. Power output is 700 W on 50 MHz. Each vertical division is 10 dB and each horizontal division is 10 MHz. All harmonics and spurious emissions are greater than 64 dB down. This amplifier complies with current FCC spectral purity requirements.

the initial tune-up, placing the amplifier in STANDBY. Decrease the sensitivity by adjusting R2, mounted on the grid-trip circuit board. A hole is cut in the chassis bottom plate for access to this control. With the values shown, the circuit should trip at 20 mA with R2 set to a minimum. Adjust R2 slightly until the circuit holds at 40 to 50 mA of grid current. The tube's maximum grid-current rating is 60 mA.

A spectral photograph of the amplifier output is shown in Fig 13.61. It meets current FCC spectral-purity requirements.

## A 144-MHz AMPLIFIER USING THE 3CX1200Z7

This 2-m, 1-kW amplifier uses the EIMAC 3CX1200Z7 triode. The original article by Russ Miller, N7ART, appeared in December 1994 *QST*. The tube requires a warmup of about 10 s after applying filament voltage—no more waiting for three agonizingly long minutes until an amplifier can go on-line!

The 3CX1200Z7 is different from the earlier 3CX1200A7 by virtue of its external grid ring, redesigned anode assembly and a 6.3-V ac filament. One advantage to the 3CX1200Z7 is the wide range of plate voltages that can be used, from 2000 to 5500 V. This amplifier looks much like the easily duplicated W6PO design. The RF deck is a compact unit, designed for table-top use (See Fig 13.62

and schematic in Fig 13.63.).

Table 13.12 gives some data on the 3CX1200Z7 and Table 13.13 lists CW operating performance for this amplifier.

### Input Circuit

Tuning is easy and docile. Grid bias is provided by an 8.2-V, 50-W Zener diode.

Cutoff bias is provided by a 10-k $\Omega$ , 25-W resistor. A relay on the control board shorts out the cutoff-bias resistor, to place the amplifier in the TRANSMIT mode.

The author didn't use a tube socket. Instead, he bolted the tube directly to the top plate of the subchassis, using the four holes (drilled to clear a #6 screw) in the grid

**Table 13.12**

### 3CX1200Z7 Specifications

#### Maximum Ratings

Plate voltage: 5500 V  
Plate current: 800 mA  
Plate dissipation: 1200 W  
Grid dissipation: 50 W

**Table 13.13**

### CW Operating Data

Plate voltage: 3200 V  
Plate current (operating): 750 mA  
Plate current (idling): 150 mA  
Grid current: 165 mA  
DC Power input: 2400 W  
RF Power output: 1200 W  
Plate dissipation: 1200 W  
Efficiency: 50%  
Drive power: 85 W  
Input reflected power: 1 W

Fig 13.62—This table-top 2-m power amplifier uses a quick-warm-up tube, a real plus when the band suddenly opens for DX and you want to join in.

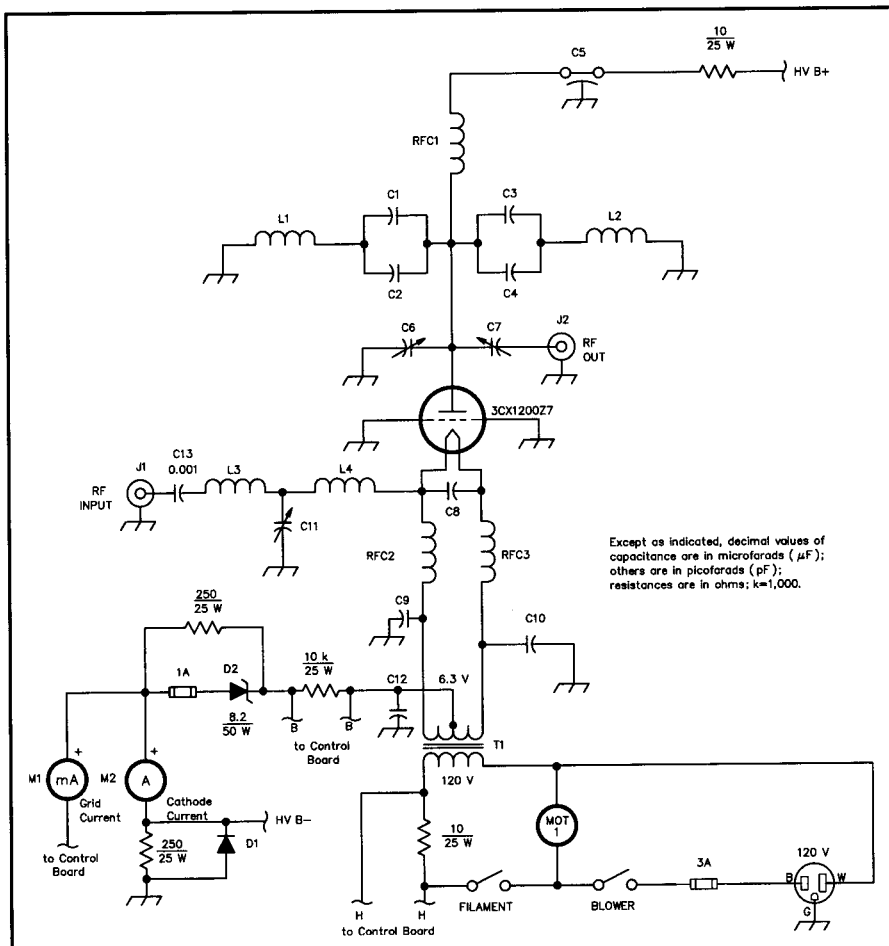

Fig 13.63—Schematic diagram of the 2-m amplifier RF deck. For supplier addresses, see the Address List in the References chapter.

C1-C4—100 pF, 5 kV, Centralab 850.

C5—1000 pF, 5 kV.

C6—Anode-tuning capacitor; see text and Fig 13.66 for details.

C7—Output-loading capacitor; see text and Fig 13.70 for details.

C8-C10, C13—1000-pF silver mica, 500 V.

C11—30-pF air variable.

C12—0.01  $\mu$ F, 1 kV.

D1—1000 PIV, 3-A diode, 1N5408 or equiv.

D2—8.2-V, 50-W Zener diode, ECG 5249A.

J1—Chassis-mount BNC connector.

J2—Type-N connector fitted to output coupling assembly (see Fig 13.70).

L1, L2—Plate lines; see text and Fig 13.68 for details.

L3—5 t #14 enameled wire, 1/2-inch diameter, close wound.

L4—3 t #14, 5/8-inch diameter, 1/4-inch spacing.

RFC1—7 t #14, 5/8-inch diameter, 1 3/8 inch long.

RFC2, RFC3—10 t #12, 5/8-inch diameter, 2 inches long.

T1—Filament transformer. Primary: 120 V; secondary: 6.3 V, 25 A, center tapped. Available from Avatar Magnetics; part number AV-539.

M1—Grid milliammeter, 200 mA dc full scale.

M2—Cathode ammeter, 2 A dc full scale.

MOT1—140 free-air cfm, 120-V ac blower, Dayton 4C442 or equivalent.

Sources for some of the "hard to get parts" include Fair Radio Sales and Surplus Sales of Nebraska.

Fig 13.64—This view of the cathode-circuit compartment shows the input tuned circuit and filament chokes.

Fig 13.65—(below) Schematic diagram of the amplifier-control circuits.

C3—0.47- $\mu$ F, 25-V tantalum capacitor.

D1-D5—1N4001 or equiv.

D6—1N4007 or equiv.

DS1—Yellow LED.

DS2—Green LED.

DS3—Red LED.

K1—Keying-inhibit relay, DPDT, 12-V dc coil, 1-A contact rating (Radio Shack 275-249 or equiv).

K2—Amplifier keying relay, SPDT, 12-V dc coil, 2-A contact rating (Radio Shack 275-248 or equiv).

K3—Filament delay relay, SPST, 12-V dc coil, 2-A contact rating (Radio Shack 275-248 or equiv).

K4—Grid-overcurrent relay, DPDT, 12-V dc coil, 1-A contact rating (Radio Shack 275-249 or equiv).

Q1, Q2, Q5—2N2222A or equiv.

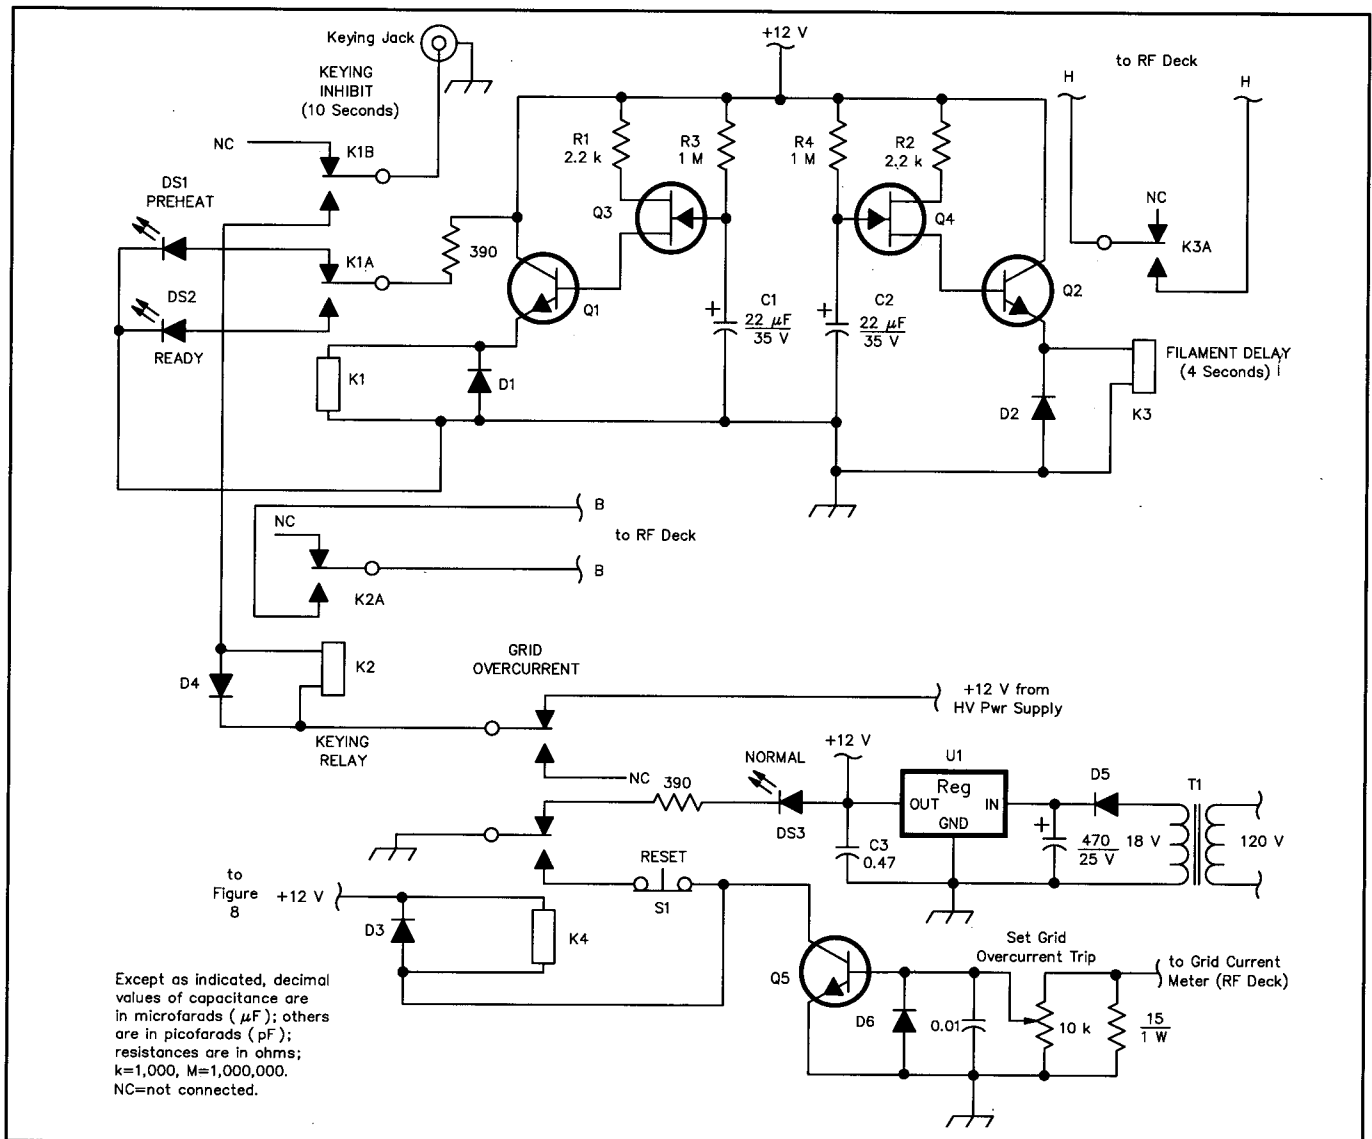

Q3—MPF102 or equiv.

Q4—2N3819 or equiv.

S1—Normally closed, momentary pushbutton switch (Radio Shack 275-1549 or equiv).

T1—Power transformer, 120-V primary, 18-V, 1-A secondary.

U1—+12 V regulator, 7812 or equiv.

**Fig 13.66—This top view of the plate compartment shows the plate-line arrangement, C1-C4 and the output coupling assembly.**

flange. Connections to the heater pins are via drilled and slotted brass rods. The input circuit is contained within a  $3\frac{1}{2} \times 6 \times 7\frac{1}{4}$ -inch (HWD) subchassis (**Fig 13.64**).

### Control Circuit

The control circuit (**Fig 13.65**) is a necessity. It provides grid overcurrent protection, keying control and filament surge control. To protect the tube filament from stressful surge current, a timer circuit places a resistor in series with the primary of the filament transformer. After four seconds, the timer shorts the resistor, allowing full filament voltage to be applied. C2 and R4 establish the time delay.

Another timer inhibits keying for a total of 10 s, to give the internal tube temperatures a chance to stabilize. C1 and R3 determine the time constant of this timer. After 10 s, the amplifier can be keyed by grounding the keying line. When the amplifier is not keyed, it draws no plate current. When keyed, idle current is approximately 150 mA, and the amplifier only requires RF drive to produce output. A safety factor is built in: the keying circuit requires +12 V from the high-voltage supply. This feature ensures that high voltage is present before the amplifier is driven.

The grid overcurrent circuit should be set to trip if grid current reaches 200 mA. When it trips, the relay latches and the NORMAL LED extinguishes. Restoration requires the operator to press the RESET switch.

### Plate Circuit

**Fig 13.66** shows an interior view of the plate compartment. A  $4 \times 2\frac{1}{4}$ -inch tuning capacitor plate and a  $2 \times 2$ -inch output coupling plate are centered on the anode collet. See **Fig 13.67**. Sufficient clearance in the collet hole for the 3CX1200Z7 anode must be left for the fingerstock. The hole diameter will be approximately  $3\frac{5}{8}$  inches. **Fig 13.68** is a drawing of the plate line, **Fig 13.69** is a drawing of the plate tuning capacitor assembly, and **Fig 13.70** shows the output coupling assembly.

### Cooling

The amplifier requires an air exhaust through the top cover, as the plate compartment is pressurized. Fashion a chimney from a  $3\frac{1}{2}$ -inch waste-water coupling (black PVC) and a piece of  $\frac{1}{32}$ -inch-thick Teflon sheet. The PVC should extend down from the underside of the amplifier cover plate by  $1\frac{1}{8}$  inches, with the Teflon sheet extending down  $\frac{3}{4}$  inch from the bottom of the PVC.

The base of the 3CX1200Z7 is cooled using bleed air from the plate compartment. This is directed at the tube base,

**Fig 13.67—Anode collet details.**

Fig 13.68—Plate line details.

through a  $7/8$ -inch tube set into the subchassis wall at a  $45^\circ$  angle. The recommended blower will supply more than enough air for any temperature zone. A smaller blower is not recommended, as it is doubtful that the base area will be cooled adequately. The 3CX1200Z7 filament draws 25 A at 6.3 V! It alone generates a great deal of heat around the tube base seals and pins, so good air flow is critical.

### Construction

The amplifier is built into a  $12 \times 12 \times 10$ -inch enclosure. A  $12 \times 10$ -inch partition is installed  $7\frac{1}{4}$  inches from the rear panel. The area between the partition and the front panel contains the filament transformer, control board, meters, switches,

Fig 13.70—Details of the output coupling assembly.

Zener diode and miscellaneous small parts. Wiring between the front-panel area and the rear panel is through a  $1/2$ -inch brass tube, located near the shorted end of the right-hand plate line.

High voltage is routed from an MHV jack on the rear panel, through a piece of solid-dielectric RG-59 (not foam dielectric!), just under the shorted end of the left-hand plate line. The cable then passes through the partition to a high-voltage standoff insulator made from nylon. This

insulator is fastened to the partition near the high-voltage feedthrough capacitor. A  $10\text{-}\Omega$ , 25-W resistor is connected between the insulator and the feedthrough capacitor.

The plate lines are connected to the dc-blocking capacitors on the plate collet with  $1\frac{3}{4} \times 2$ -inch phosphor-bronze strips. The bottom of the plate lines are attached to the sides of the subchassis, with the edge of the L-shaped mounting bracket flush with the bottom of the subchassis.

When preparing the subchassis top plate for the 3CX1200Z7, cut a  $2\frac{1}{16}$ -inch hole in the center of the plate. This hole size allows clearance between the tube envelope and the top plate, without putting stress on the envelope in the vicinity of the grid flange seal.

Exercise care in placing the movable tuning plate and the movable output coupling disc, to ensure they cannot touch their fixed counterparts on the plate collet.

### Operation

When the amplifier is first turned on, it cannot be keyed until:

- 10 s has elapsed
- High voltage is available, as confirmed by presence of +12 V to the keying circuit

Connect the amplifier to a dummy load through an accurate power meter capable of indicating 1500 W full scale. Key the amplifier and check the idling plate current. With 3200-V plate voltage, it should be in the vicinity of 150 mA. Now, apply a small amount of drive and adjust the input tuning for maximum grid current. Adjust the output tuning until you see an indication of RF output. Increase drive and adjust the output coupling and tuning for

Fig 13.69—Plate tuning capacitor details.

Fig 13.71—Schematic diagram of output harmonic filter.

C1, C2—27-pF Centralab 850 series ceramic transmitting capacitor.  
J1, J2—Female chassis-mount N connector (UG-58 or equiv).

L1, L3—2 t #14 wire, 0.3125 inch ID, 0.375 inch long.  
L2—3 t #14 wire, 0.3125 inch ID, 0.4375 inch long.

the desired output. Do not overcouple the output; once desired output is reached, do not increase loading. Insert the hold-down screw to secure the output coupling capacitor from moving. One setting is adequate for tuning across the 2-m band if the SWR on the transmission line is reasonably low.

When you shut down the amplifier, leave the blower running for at least three minutes after you turn off the filament voltage. The 3CX1200Z7 is an excellent

tube. The author tried it with excessive drive, plate-current saturation, excessive plate dissipation—all the abuse it's likely to encounter in amateur applications. There were no problems, but that doesn't mean you should repeat these torture tests!

### A Companion Power Supply

A good, solid-state high-voltage power supply is a necessity to ensure linearity in SSB operation. Specifications of the power supply are given in Table 13.14.

Table 13.14  
Power Supply Specifications

High voltage: 3200 V  
Continuous current: 1.2 A  
Intermittent current: 2 A  
Step/Start delay: 2 s

The schematic and parts list for the author's power supply are in the **Power Supplies and Projects** chapter.

### Conclusion

This amplifier is a reliable and cost-effective way to generate a big 2-m signal—almost as quickly as a solid-state amplifier. To ensure that the output of the amplifier meets current spectral purity requirements, a high-power output filter, as shown in Fig 13.71, should be used. The author reports that he can run full output while his wife watches TV in a nearby room.

## A 2-M BRICK AMP FOR HANDHELDS

Perhaps you've been looking for a fun weekend project and need a bit more output from your HT while operating mobile. This Brick Amp project may be exactly what you're looking for—construction is easy and all the parts are readily available. The following was contributed by ARRL Laboratory Engineer, Mike Gruber, WA1SVF.

The Brick Amp is easily driven at the low-output power setting of most handhelds. The same design is used for either a 25 or a 50 W version—only the amplifier module is changed. See Fig 13.72 for a view of what's inside a typical module, alongside the finished amplifier.

The low-power 25 W Brick Amp complies with the bioeffects guidelines set forth in the **Safety** chapter. The full 50 W version can be built when more output is required. (Note: The bioeffects guidelines recommend that field-strength measurements be made in mobile installations of greater than 25 W output. Be sure to consult the **Safety** chapter before building the 50 W version.)

### Circuit Details

The heart of this project is a Toshiba amplifier module. The S-AV7 is used for the 25 W output, while the mechanically identical S-AV17 is used in the 50 W version. Both modules are biased as class-C

amplifiers, keeping their efficiency up and making them ideally suited for FM or CW use. Since they are not linear, however, they are not useful for other modes, such as SSB or AM.

From a builder's standpoint, these modules keep the parts count down to a minimum and construction simple. All you need to add for circuitry is input drive attenuation, if required, transmit/receive switching, an output filter and the usual dc filter and decoupling components. Beginners and seasoned veterans alike will no doubt appreciate this Brick Amp's simplicity!

### DC Filtering and Decoupling

See the schematic diagram in Fig 13.73. C1 through C6 and chokes L1-L2 provide dc filtering and decoupling. D5 provides reverse-polarity protection, by blowing F1 should the +13.8 V line be wrongly connected.

### The Input and Output Circuitry

The Brick Amp's input circuitry consists of a resistive T-pad formed by R1, R2 and R3. The pad attenuates the HT's output to the input level required by the module. Select the proper pad values based upon the HT output and the amplifier module selected. Refer to Table 13.15 for pad resistor values for typical HT output levels.

Reduced drive power results in less than full rated output power, while excessive drive can result in exceeding the limits of the module. Proper T-pad selection is es-

Table 13.15  
T-Pad Values

#### 25 W Module, S-AV17

HT Power (W)	Attenuation (dB)	R1, R3 (Ω)	R2 (Ω)
0.5	1	2.9	430
0.8	2	5.6	220
1.0	4	12	100
1.5	6	16	68
2.0	7	18	56
2.5	8	22	47
3.0	9	24	39
4.0	10	27	36
5.0	11	56/56*	62/62*

#### 50 W Module, S-AV7

HT Power (W)	Attenuation (dB)	R1, R3 (Ω)	R2 (Ω)
0.5	4	12	100
0.8	6	16	68
1.0	7	20	56
1.5	9	24	39
2.0	10	27	36
2.5	11	27	30
3.0	12	30	27
4.0	13	33	24
5.0	14	62/62*	43/43*

**Note:** For power inputs up to and including 4.0 W, use 2 W resistors for R1 and R3, 1/2 W resistors for R2. All resistors are carbon composition or metal oxide.

\* Use parallel connected resistors: 2 W for R1 and R3; 1 W for R2.

(A)

**Fig 13.72—At A, photo of 2-m Brick Amp assembly and at B, a 25 W power module with cover removed.**

(B)

essential for full rated output power without exceeding design limits. Be sure to use only noninductive resistors, such as carbon or metal oxide, with the specified power ratings for the T pad.

**CAUTION:** Some HTs can generate a momentary high power output pulse when keyed in the low power mode, especially when first keyed. Such a spike could exceed the amplifier module specified input limits if a low-power T-pad is selected. Observe the HT output on an oscilloscope or check with its manufacturer to make sure it doesn't exhibit this characteristic.

The output circuitry is a low-pass filter consisting of C7, C8, C9, L3 and L4. **Fig 13.74** shows the filtered output to be better than -60 dBc, the FCC requirement for spectral purity for a transmitter at this frequency and power class.

### The TR Switching Circuit

While in the receive mode, signals from the antenna are applied to the receiver

through the normally closed relay contacts of K2-1 and K1-1. The low-pass filter used in transmit remains in the circuit for receive. This is a useful feature, since many HTs are prone to overload from strong out-of-band signals, such as from nearby UHF-TV transmitters. Further, harmonics generated by the TR switching circuit are suppressed to better than 60 dBc in the bypass mode. When the HT is keyed, RF is applied to voltage doubler D3 and D4. The junction of D3 and D4 is biased to approximately 0.5 V by R4 and R5 to facilitate diode turn-on at low RF levels. Once transistor Q1 is turned on, K2 is energized. The K2-2 contacts then energize K1 by applying +13.8 V to its coil. The K1-2 relay contacts provide power for an optional transmit light. This two-relay system provides two features not possible with a single relay:

1. Improved isolation between the input and output relay contacts. Coupling between these contacts is sufficiently

small to prevent the amplifier from oscillating. (Initial experiments in the Lab with a single two-pole relay resulted in an excellent 2-m oscillator.)

2. "Hot switching" the output relay is eliminated. Since K2 is activated first, RF cannot appear across the K1 output relay contacts until K2 is already closed. Contact bounce with output power applied is thus eliminated, resulting in improved switching reliability and enhanced contact life.

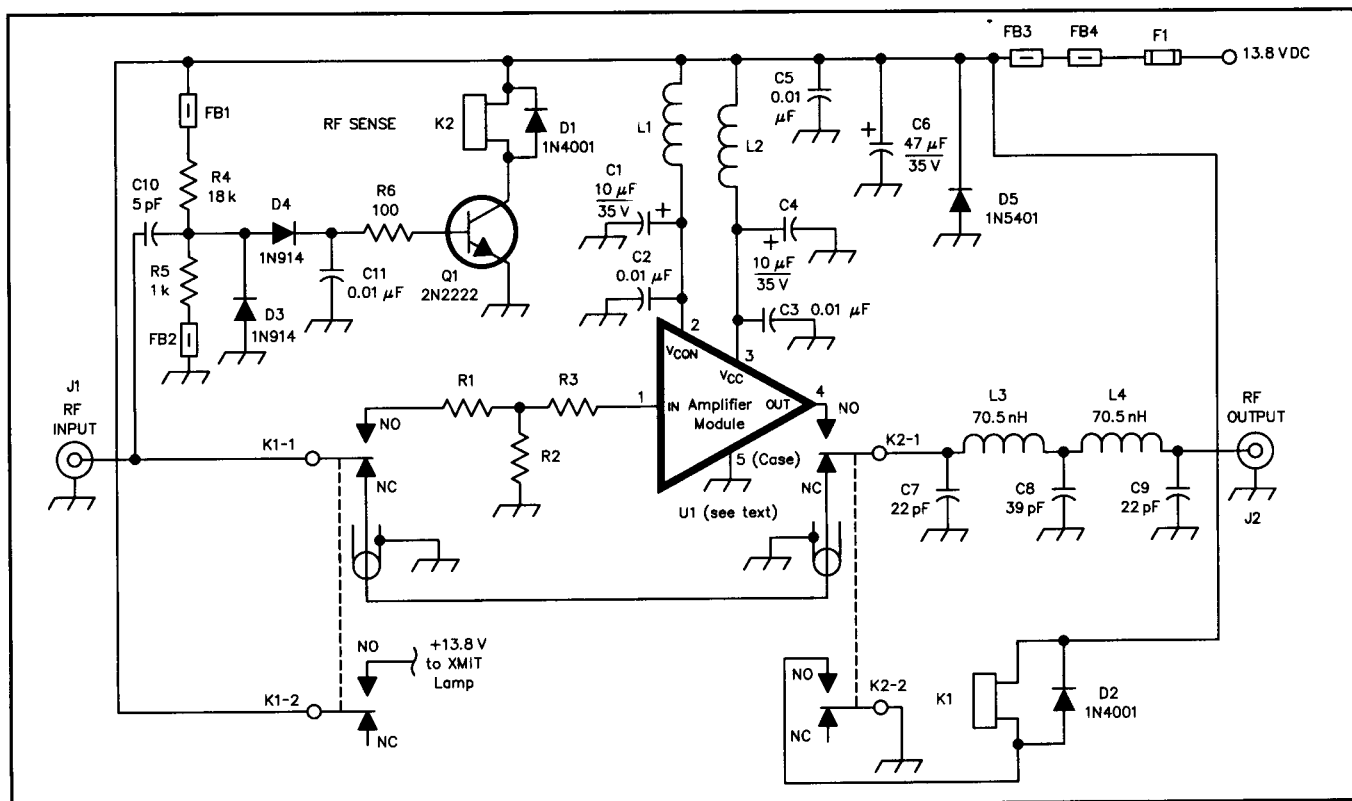

This sequence is reversed when switching from transmit to receive. Once the RF is removed, Q1 is cut off and relay K2 is deenergized. Diodes D1 and D2 protect against voltage spikes created by the relay coils as their magnetic fields collapse upon deactivation. K1 is returned to the receive mode by the opening of the K2-2 contacts.

### Construction Details

A surface-mount circuit board was selected for the Brick Amp, with traces on the top of the board and ground plane on the underside. Components connected to RF ground (such as the output filter capacitors C7, C8 and C9), have their ground leads soldered on both top and bottom sides to provide good RF ground continuity. Otherwise, component leads are soldered directly to top-side PC traces. The PC board is mounted above the heat sink surface, using metal #6 flat washers as spacers. The amplifier module pins and their associated PC board pads are in close vertical alignment, eliminating excessive bending of the pins at solder time.

The heat sink and case were selected on the basis of availability, ruggedness and heat dissipation ability. The heat sink may be overkill, especially for the 25 W version. It is, however, readily available and adequate for the task, even in a hot car on a summer day after a long-winded transmission (such as the author has been known to make on occasion). If you intend to mount the Brick Amp in a car trunk, the sharp edges of a heat sink could be hazardous to its other contents. Be sure to give your mounting options careful consideration before making your final decision.

The case is die-cast aluminum, strong enough to withstand the most severe abuse in a car trunk, or any other mounting spot you may select. If you are budget minded and have a big junk box, here is where cost saving substitutions may be made. The only critical aspects of the heat sink is that it present a flat surface upon which to mount the module, large enough to mount the PC board, and that it meet the heat dissipating requirements for the conditions in which you intend to use the Brick Amp.

**Fig 13.73—Schematic and parts list. Supplier contact information appears in the References chapter Address List.**

Case—Hammond cat. no. 1590D.  
Heat sink—5×7 inches, RF Parts.  
C1, C4—1.0  $\mu$ F, 35 V dipped tantalum (RS 272-1434).  
C2, C3, C5, C11—0.01  $\mu$ F, 500 V ceramic disc (RS 272-131).  
C6—47  $\mu$ F, 25 V electrolytic (RS 272-1027).  
C7, C9—22 pF, DM-15 dipped mica.

L1, L2—VK200-20/4B Ferroxcube ferrite choke, CCI.  
L3, L4—70.5 nH, 7 t #20 AWG, 0.125 inch ID, 0.33 inch long, 0.10 inch leads.

Q1—2N2222.  
R1, R2, R3—see Table 13.15.  
S1—20 A at 12 V.  
U1—Power module, Toshiba S-AV7 (25 W) or S-AV17 (50 W).  
DS1, DS2—Pilot and transmit indicator lamps, 13.8 V.  
J1, J2—connectors, BNC or UHF as desired.  
Coax—RG-8X, 2 ft.

**CAUTION:** Before considering a heat sink, make sure that the module lies perfectly flat against the sink's mounting surface. Attempts to mount a module on a surface that is not flat can cause permanent damage to the module!

Begin construction by mounting the module at the center of the heat sink. Using the module as a template, drill two holes with a #36 drill bit. Remove any burrs around the holes with an oversized drill, and thread them both with a #6 tap. Clean the holes and heat sink mounting surface with a rag. Lightly rub 400 to 600 grit emery cloth (or fine steel wool) across the module and heat sink surfaces. It is not necessary to remove the black finish from the aluminum of the heat sink shown in Fig 13.72. Clean both surfaces and screw holes with a suitable solvent, such as denatured alcohol or flux remover, to remove any dirt, grease or oil. Wipe the exposed

surfaces with a clean cloth and let dry.

Apply a very thin coat of thermal conducting grease to module and heat-sink mating surfaces. Place two #6 mounting screws through two flat washers and two #6 solder lugs (with internal lock teeth) pointing toward the PC board, through the mounting flanges on each side of the module. Alternately increase the torque on each screw until full torque is achieved and wipe off excess thermal compound with a rag. Be careful not to bend the module leads during this process.

Next, slide the board in place, line up the pins with the correct pads, center the board and mark the four mounting holes onto the heat sink. Drill holes with a #36 bit tap them for #6 screws. Deburr and clean with solvent as before. Next, solder jumper wires through the 6 holes so indicated. Bend as shown in the inset to the layout in Fig 13.75, and solder the wire on

the top and bottom of the PC board. These connections tie the underside ground plane foil on the board to ground. Install the components with ground connection through their holes now.

Mount the board to the heat sink using #6 screws and two washers as spacers. Make sure that the soldered wires do not touch the heat sink as torque is applied to the screws. More washers may be added as necessary to prevent the solder connections from touching the heat sink, but you must use an equal amount for each screw. Solder the module pins to the appropriate PC board pads, but be sure to leave sufficient free pin length to account for flexing from temperature changes and vibration.

Solder the ground lug at the input side of the module to ground on top of the PCB. Solder a short piece of braid from the underside of the PCB to the ground lug at the output side of the module.

**Fig 13.74—Plot of output spectrum for 25 W Brick Amp showing that it meets current FCC specifications for output purity, with second harmonic reduced by more than 60 dB.**

Carefully bend the pins on each of the relays outward. Pliers may be used to accomplish this, or you may wish to try gently pressing all four lead tips against a hard surface. It is not necessary that they be at right angles to the relay, but they must be sufficiently bent to permit surface mount soldering. Avoid any unnecessary reworking or bending of these pins. Before soldering the relays onto the board, make certain they are oriented correctly. Carefully line up each relay pin with its pad and solder it in place.

Continue soldering the components on the board as shown in Fig 13.75. L3 and L4 can both be wound on the shank of a  $\frac{1}{8}$  inch drill bit. Other construction data for these coils is given in the parts list. Finally, install the coax and +12 V dc jumpers.

Fuse the Brick Amp with either a ready-made cable having an in-line fuse pair, or a fuse holder in the case. Temporarily connect the dc power cable (with fuses installed) to the proper PC board pads and test the Brick Amp for operation and function.

Assuming the Brick Amp works correctly, install its case. Cut a square hole in

the case large enough to accommodate the PC board and module. Position the hole so that the heat sink will be centered on the case. Mark and drill and tap (#6) holes for four mounting screws.

Install one or both of the optional lights, if desired. Make holes for both input and output connectors, dc power cable and on/off switch. (NOTE: A BNC for the input, and a UHF connector for the output facilitates coax connection to the HT and prevents accidental input/output cable reversal.) Tailor the input/output connectors and cabinet layout to suit your requirements. Install the heat sink and other components in the cabinet. Be sure to install the ferrite beads before soldering the wires and cables!

# AC/RF Sources (Oscillators and Synthesizers)

## 14

**J**ust say in public that oscillators are one of the most important, fundamental building blocks in radio technology and you will immediately be interrupted by someone pointing out that *tuned-RF (TRF)* receivers can be built without any form of oscillator at all. This is certainly true, but it shows how some things can be taken for granted. What use is any receiver without signals to receive? All intentionally transmitted signals trace back to some sort of signal generator — an oscillator or frequency synthesizer. In contrast with the TRF receivers just mentioned, a modern, all-mode, feature-laden, MF/HF transceiver may contain in excess of a dozen RF oscillators and synthesizers, while a simple QRP CW transmitter may consist of nothing more than a single oscillator. (This chapter was written by David Stockton, GM4ZNX.)

In the 1980s, the main area of progress in the performance of radio equipment was the recognition of receiver intermodulation as a major limit to our ability to communicate, with the consequent development of receiver front ends with improved ability to handle large signals. So successful was this campaign that other areas of transceiver performance now require similar attention. One indication of this is any equipment review receiver dynamic range measurement qualified by a phrase like “limited by oscillator phase noise.” A plot of a receiver’s effective selectivity can provide another indication of work to be done: An IF filter’s high-attenuation region may appear to be wider than the filter’s published specifications would suggest — almost as if the filter characteristic has grown sidebands! In fact, in a

way, it has: This is the result of local-oscillator (LO) or synthesizer *phase noise* spoiling the receiver’s overall performance. Oscillator noise is the prime candidate for the next major assault on radio performance.

The sheer number of different oscillator circuits can be intimidating, but their great diversity is an illusion that evaporates once their underlying pattern is seen. Almost all RF oscillators share one fundamental principle of operation: an amplifier and a filter operate in a loop (**Fig 14.1**). There are plenty of filter types to choose from:

- LC
- Quartz crystal and other piezoelectric materials
- Transmission line (stripline, microstrip, troughline, open-wire, coax and so on)
- Microwave cavities, YIG spheres, dielectric resonators
- Surface-acoustic-wave (SAW) devices

Should any new forms of filter be invented, it’s a safe guess that they will also be applicable to oscillators. There is an equally large range of amplifiers to choose from:

- Vacuum tubes of all types
- Bipolar junction transistors
- Field effect transistors (JFET, MOSFET, GaAsFET, in all their varieties)
- Gunn diodes, tunnel diodes and other negative-resistance generators

It seems superfluous to state that anything that can amplify can be used in an oscillator, because of the well-known prop-

ensity of all prototype amplifiers to oscillate! The choice of amplifier is widened further by the option of using single- or multiple-stage amplifiers and discrete devices versus integrated circuits. Multiply all of these options with those of filter choice and the resulting set of combinations is very large, but a long way from complete. Then there are choices of how to couple the amplifier into the filter and the filter into the amplifier. And then there are choices to make in the filter section: Should it be tuned by variable capacitor, variable inductor or some form of sliding cavity or line?

Despite the number of combinations that are possible, a manageably small number of types will cover all but very special requirements. Look at an oscillator circuit and “read” it: What form of filter — *resonator* — does it use? What form of amplifier? How have the amplifier’s input and output been coupled into the filter? How is the filter tuned? These are simple, easily answered questions that put oscillator types into appropriate categories.

**Fig 14.1 — Reduced to essentials, an oscillator consists of a filter and an amplifier operating in a feedback loop.**

ries and make them understandable. The questions themselves may make more sense if we understand the mechanics of oscillation, in which *resonance* plays a major role.

## HOW OSCILLATORS WORK

### Maintained Resonance

The pendulum, a good example of a resonator, has been known for millennia and understood for centuries. It is closely analogous to an electronic resonator, as shown in **Fig 14.2**. The weighted end of the pendulum can store energy in two different forms: the kinetic energy of its motion and the potential energy of it being raised above its rest position. As it reaches its highest point at the extreme of a swing, its velocity is zero for an instant as it reverses direction. This means that it has, at

that instant, no kinetic energy, but because it is also raised above its rest position, it has some extra potential energy.

At the center of its swing, the pendulum is at its lowest point with respect to gravity and so has lost the extra potential energy. At the same time, however, it is moving at its highest speed and so has its greatest kinetic energy. Something interesting is happening: The pendulum's stored energy is continuously moving between potential and kinetic forms. Looking at the pendulum at intermediate positions shows that this movement of energy is smooth. Newton provided the keys to understanding this. It took his theory of gravity and laws of motion to explain the behavior of a simple weight swinging on the end of a length of string and calculus to perform a quantitative mathematical analysis. Experiments had shown the

period of a pendulum to be very stable and predictable. Apart from side effects of air drag and friction, the length of the period should not be affected by the mass of the weight, nor the amplitude of the swing.

A pendulum can be used for timing events, but its usefulness is spoiled by the action of drag or friction, which eventually stops it. This problem was overcome by the invention of the *escapement*, a part of a clock mechanism that senses the position of the pendulum and applies a small push in the right direction and at the right time to maintain the amplitude of its swing or oscillation. The result is a mechanical oscillator: The pendulum acts as the filter, the escapement acts as the amplifier and a weight system or wound-up spring powers the escapement.

Electrical oscillators are closely analogous to the pendulum, both in operation and in development. The voltage and current in the tuned circuit — often called *tank circuit* because of its energy-storage ability — both vary sinusoidally with time and are 90° out of phase. There are instants when the current is zero, so the energy stored in the inductor must be zero, but at the same time the voltage across the capacitor is at its peak, with all of the circuit's energy stored in the electric field between the capacitor's plates. There are also instants when the voltage is zero and the current is at a peak, with no energy in the capacitor. Then, all of the circuit's energy is stored in the inductor's magnetic field.

Just like the pendulum, the energy stored in the electrical system is swinging smoothly between two forms; electric field and magnetic field. Also like the pendulum, the tank circuit has losses. Its conductors have resistance, and the capacitor dielectric and inductor core are imperfect. Leakage of electric and magnetic fields also occurs, inducing currents in neighboring objects and just plain radiating energy off into space as radio waves. The amplitudes of the oscillating voltage and current decrease steadily as a result. Early intentional radio transmissions, such as those of Heinrich Hertz's experiments, involved abruptly dumping energy into a tuned circuit and letting it oscillate, or *ring*, as shown in **Fig 14.3**. This was done by applying a spark to the resonator. Hertz's resonator was a gapped ring, a good choice for radiating as much of the energy as possible. Although this looks very different from the LC tank of **Fig 14.2**, it has inductance *distributed* around its length and capacitance *distributed* across it and across its gap, as opposed to the *lumped* L and C values in

**Fig 14.2** — A resonator lies at the heart of every oscillatory mechanical and electrical system. A mechanical resonator (here, a pendulum) and an electrical resonator (here, a tuned circuit consisting of L and C in parallel) share the same mechanism: the regular movement of energy between two forms — potential and kinetic in the pendulum, electric and magnetic in the tuned circuit. Both of these resonators share another trait: Any oscillations induced in them eventually die out because of losses — in the pendulum, due to drag and friction; in the tuned circuit, due to the resistance, radiation and inductance. Note that the curves corresponding to the pendulum's displacement vs velocity and the tuned circuit's voltage vs current, differ by one quarter of a cycle, or 90°.

Fig 14.2. The gapped ring therefore works just the same as the LC tank in terms of oscillating voltages and currents. Like the pendulum and the LC tank, its period, and therefore the frequency at which it oscillates, is independent of the magnitude of its excitation.

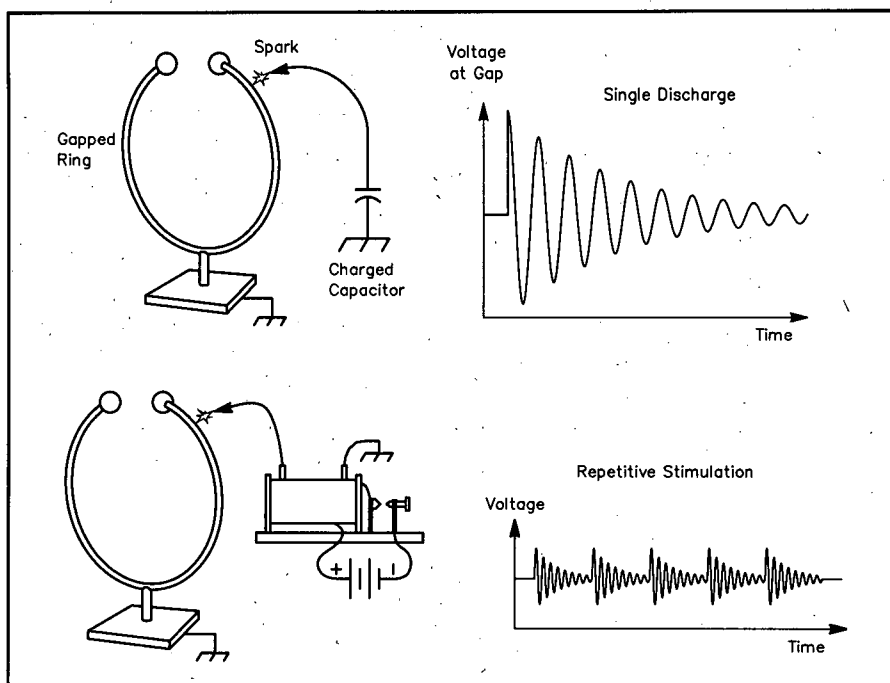

Making a longer-lasting signal with the Fig 14.3 arrangement merely involves repeating the sparks. The problem is that a truly continuous signal cannot be made this way. The sparks cannot be applied often enough or always timed precisely enough to guarantee that another spark reexcites the circuit at precisely the right instant. This arrangement amounts to a crude spark transmitter, variations of which served as the primary means of transmission for the first generation of radio amateurs. The use of damped waves is now entirely forbidden by international treaty because of their great impurity. Damped waves look a lot like car-ignition waveforms and sound like car-ignition interference when received.

What we need is a *continuous wave* (CW) oscillation — a smooth, sinusoidal signal of constant amplitude, without phase jumps, a “pure tone.” To get it, we must add to our resonator an equivalent of the clock’s escapement — a means of synchronizing the application of energy and a fast enough system to apply just enough energy every cycle to keep each cycle at the same amplitude.

## Amplification

A sample of the tank’s oscillation can be extracted, amplified and reinserted. The gain can be set to exactly compensate the tank losses and perfectly maintain the oscillation. The amplifier usually need only give low gain, so active devices can be used in oscillators not far below their unity (unity = 1) gain frequency. The amplifier’s output must be lightly coupled into the tank — the aim is just to replace lost energy, not forcibly drive the tank. Similarly, the amplifier’s input should not heavily load the tank. It is a good idea to think of *coupling* networks rather than *matching* networks in this application, because a matched impedance extracts the maximum available energy from a source, and this would certainly spoil an oscillator.

**Fig 14.4A** shows the block diagram of an oscillator. Certain conditions must be met for oscillation. The criteria that separate oscillator loops from stable loops are often attributed to Barkhausen by those aiming to produce an oscillator and to Nyquist by those aiming for amplifier stability, although they boil down to the same boundary. Fig 14.4B shows the loop

**Fig 14.3 — Stimulating a resonance, 1880s style. Shock-exciting a gapped ring with high voltage from a charged capacitor causes the ring to oscillate at its resonant frequency. The result is a damped wave, each successive alternation of which is weaker than its predecessor because of resonator losses. Repetitively stimulating the ring produces trains of damped waves, but oscillation is not continuous.**

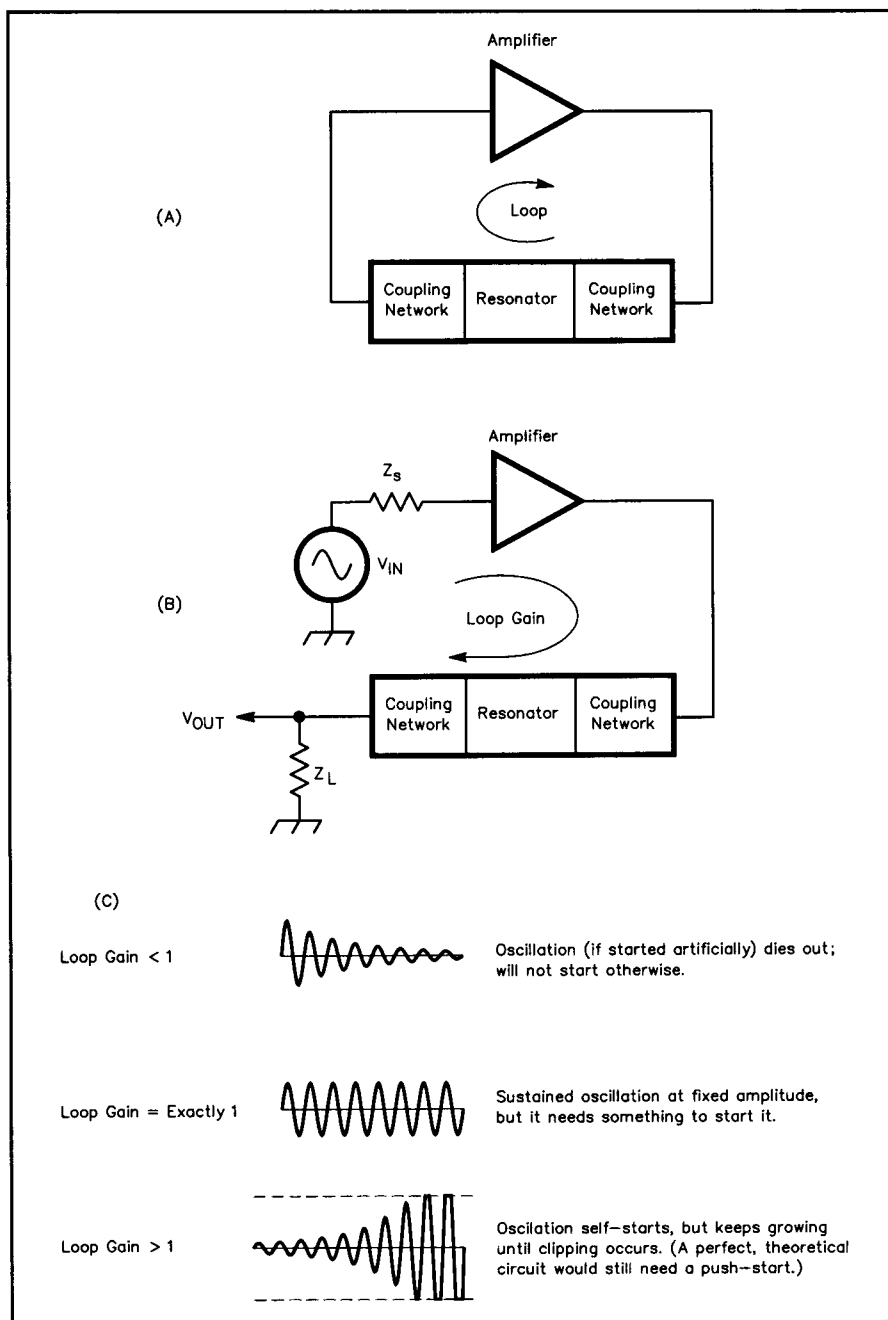

broken and a test signal inserted. (The loop can be broken anywhere; the amplifier input just happens to be the easiest place to do it.) The criterion for oscillation says that at a frequency at which the phase shift around the loop is exactly zero, the net gain around the loop must equal or exceed unity (that is, one). (Later, when we design phase-locked loops, we must revisit this concept in order to check that *those loops cannot oscillate.*) Fig 14.4C shows what happens to the amplitude of an oscillator if the loop gain is made a little higher or lower than one.

The loop gain has to be precisely one if we want a stable amplitude. Any inaccuracy will cause the amplitude to grow to clipping or shrink to zero, making the oscillator useless. Better accuracy will only slow, not stop this process. Perfect precision is clearly impossible, yet there are enough working oscillators in existence to prove that we are missing something important. In an amplifier, nonlinearity is a nuisance, leading to signal distortion and intermodulation, yet nonlinearity is what makes stable oscillation possible. All of the vacuum tubes and transistors used in oscillators tend to reduce their gain at higher signal levels. With such components, only a tiny change in gain can shift the loop’s operation between amplitude

growth and shrinkage. Oscillation stabilizes at that level at which the gain of the active device sets the loop gain at exactly one.

Another gain-stabilization technique involves biasing the device so that once some level is reached, the device starts to turn off over part of each cycle. At higher levels, it cuts off over more of each cycle. This effect reduces the effective gain quite strongly, stabilizing the amplitude. This badly distorts the signal (true in most common oscillator circuits) in the amplifying device, but provided the amplifier is lightly coupled to a high-Q resonant tank, the signal in the tank should not be badly distorted.

Many radio amateurs now have some form of circuit-analysis software, usually running on a PC. Attempts to analyze oscillators by this means often fail by predicting growing or shrinking amplitudes, and often no signal at all, in circuits that are known to work. Computer analysis of oscillator circuits can be done, but it requires a sophisticated program with accurate, nonlinear, RF-valid models of the devices used, to be able to predict operating amplitude. Often even these programs need some special tricks to get their modeled oscillators to start. Such software is likely to

**Fig 14.4 — The bare-bones oscillator block diagram of Fig 14.1 did not include two practical essentials: networks to couple power in and out of the resonator (A). Breaking the loop, inserting a test signal and measuring the loop's overall gain (B) allows us to determine whether the system can oscillate, sustain oscillation or clip (C).**

be priced higher than most private users can justify, and it still doesn't replace the need for the user to understand the circuit. With that understanding, some time, some parts and a little patience will do the job, unassisted.

Textbooks give plenty of coverage to the frequency-determining mechanisms of oscillators, but the amplitude-determining mechanism is rarely covered. It is often not even mentioned. There is a

good treatment in Clarke and Hess, *Communications Circuits: Analysis and Design*.

### Start-Up

Perfect components don't exist, but if we could build an oscillator from them, we would naturally expect perfect performance. We would nonetheless be disappointed. We could assemble from our perfect components an oscillator that exactly

met the criterion for oscillation, having slightly excessive gain that falls to the correct amount at the target operating level and so is capable of sustained, stable oscillation. But being capable of something is not the same as doing it, for there is another stable condition. If the amplifier in the loop shown in Fig 14.4 has no input signal, and is perfect, it will give no output! No signal returns to the amplifier's input via the resonator, and the result is a sustained and stable lack of oscillation. Something is needed to start the oscillator.

This fits the pendulum-clock analogy: A wound-up clock is stable with its pendulum at rest, yet after a push the system will sustain oscillation. The mechanism that drives the pendulum is similar to a Class C amplifier: It does not act unless it is driven by a signal that exceeds its threshold. An electrical oscillator based on a Class C amplifier can sometimes be kicked into action by the turn-on transient of its power supply. The risk is that this may not always happen, and also that should some external influence stop the oscillator, it will not restart until someone notices the problem and cycles the power. This can be very inconvenient!

A real-life oscillator whose amplifier does not lose gain at low signal levels can self-start due to noise. Fig 14.5 shows an oscillator block diagram with the amplifier's noise shown, for our convenience, as a second input that adds with the true input. The amplifier amplifies the noise. The resonator filters the output noise, and this signal returns to the amplifier input. The importance of having slightly excessive gain until the oscillator reaches operating amplitude is now obvious. If the loop gain is slightly above one, the recirculated noise must, within the resonator's bandwidth, be larger than its original level at the input. More noise is continually summed in as a noise-like signal continuously passes around the loop, undergoing amplification and filtering as it does. The level increases, causing the gain to reduce. Eventually, it stabilizes at whatever level is necessary to make the net loop gain equal to one.

So far, so good. The oscillator is running at its proper level, but something seems very wrong. It is not making a proper sine wave; it is recirculating and filtering a noise signal. It can also be thought of as a Q multiplier with a controlled (high) gain, filtering a noise input and amplifying it to a set level. Narrow-band filtered noise approaches a true sine wave as the filter is narrowed to zero width. What this means is that we cannot make a true sine-wave signal — all we can

do is make narrow-band filtered noise as an approximation to one. A high-quality, low-noise oscillator is merely one that does tighter filtering. Even a kick-started Class-C-amplifier oscillator has noise continuously entering its circulating signal, and so behaves similarly.

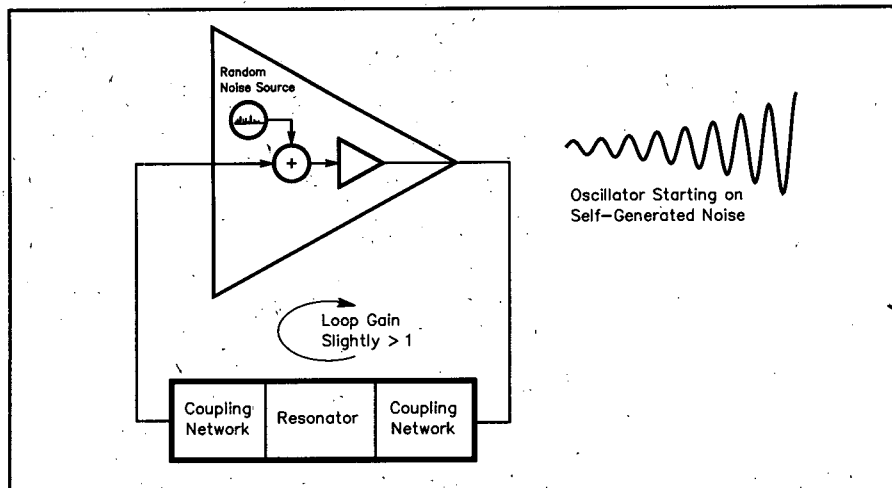

A small-signal gain greater than one is absolutely critical for reliable starting, but having too much gain can make the final operating level unstable. Some oscillators are designed around limiting amplifiers to make their operation predictable. AGC systems have also been used, with an RF detector and dc amplifier used to servo-control the amplifier gain. It is notoriously difficult to design reliable crystal oscillators that can be published or mass-produced without having occasional individuals refuse to start without some form of shock.

Mathematicians have been intrigued by “chaotic systems” where tiny changes in initial conditions can yield large changes in outcome. The most obvious example is meteorology, but much of the necessary math was developed in the study of oscillator start-up, because it is a case of chaotic activity in a simple system. The equations that describe oscillator start-up are similar to those used to generate many of the popular, chaotic fractal images.

## PHASE NOISE

Viewing an oscillator as a filtered-noise generator is relatively modern. The older approach was to think of an oscillator making a true sine wave with an added, unwanted noise signal. These are just different ways of visualizing the same thing: They are equally valid views, which are used interchangeably, depending which best makes some point clear. Thinking in terms of the signal-plus-noise version, the noise surrounds the carrier, looking like sidebands and so can also be considered to be equivalent to random-noise FM and AM on the ideal sine-wave signal. This gives us a third viewpoint. Strangely, these noise sidebands are called *phase noise*. If we consider the addition of a noise voltage to a sinusoidal voltage, we must take into account the phase relationship. A *phasor diagram* is the clearest way of illustrating this. Fig 14.6A represents a clean sine wave as a rotating vector whose length is equal to the peak amplitude and whose frequency is equal to the number of revolutions per second of its rotation. Moving things are difficult to depict on paper, so phasor diagrams are usually drawn to show the dominant signal as stationary, with other components drawn relative to this.

Noise contains components at many

**Fig 14.5 — An oscillator with noise. Real-world amplifiers, no matter how quiet, generate some internal noise; this allows real-world oscillators to self-start.**

frequencies, so its phase with respect to the dominant, theoretically pure signal — the “carrier” — is random. Its amplitude is also random. Noise can only be described in statistical terms because its voltage is constantly and randomly changing, yet it does have an average amplitude that can be expressed in RMS volts. Fig 14.6B shows noise added to the carrier phasor, with the noise represented as a fuzzy, uncertain region in which the sum phasor wanders randomly. The phase of the noise is uniformly random — no direction is more likely than any other — but the instantaneous magnitude of the noise obeys a probability distribution like that shown, higher values being progressively rarer. Fig 14.6C shows how the extremities of the noise region can be considered as extremes of phase and amplitude variation from the normal values of the carrier.

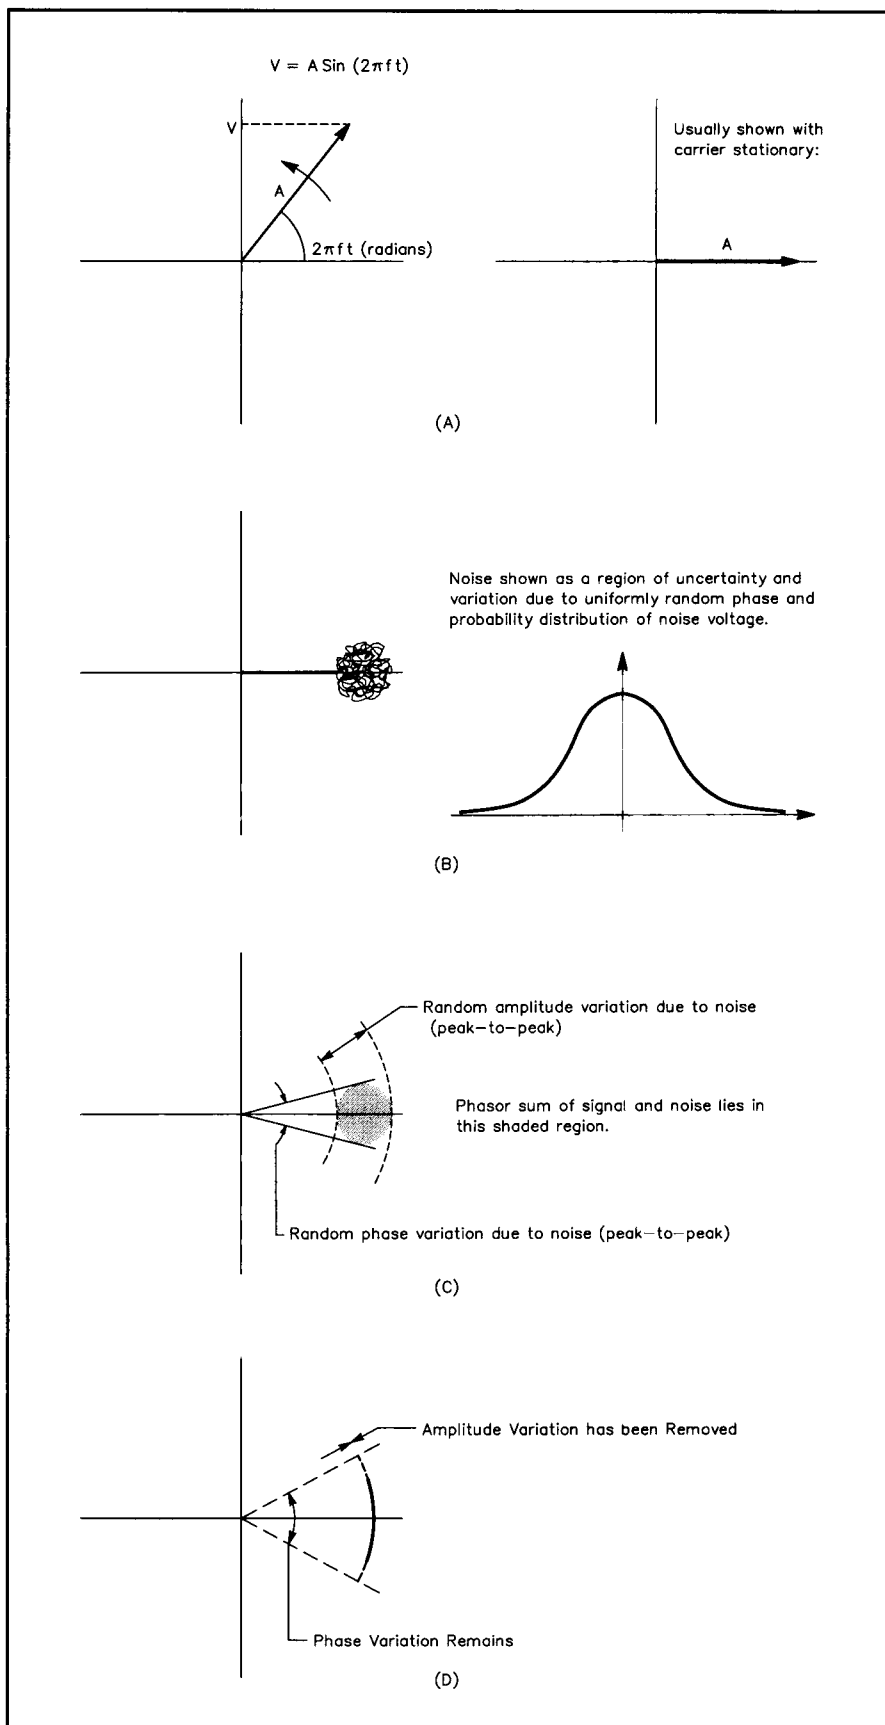

Phase modulation and frequency modulation are closely related. Phase is the integral of frequency, so phase modulation resembles frequency modulation in which deviation decreases with increasing modulating frequency. Thus, there is no need to talk of “frequency noise” because *phase noise* already covers it.

Fig 14.6C clearly shows AM noise as the random variation of the length of the sum phasor, yet “amplitude noise” is rarely discussed. The oscillator’s amplitude control mechanism acts to reduce the AM noise by a small amount, but the main reason is that the output is often fed into some form of limiter that strips off AM components just as the limiting IF amplifier in an FM receiver removes any AM on incoming signals. The limiter can be obvious, like a circuit to convert the signal to logic levels, or it can

be implicit in some other function. A diode ring mixer may be driven by a sine-wave LO of moderate power, yet this signal drives the diodes hard on and hard off, approximating square-wave switching. This is a form of limiter, and it removes the effect of any AM on the LO. Fig 14.6D shows the result of passing a signal with noise through a limiting amplifier. For these reasons, AM noise sidebands are rarely a problem in oscillators, and so are normally ignored. There is one subtle problem to beware of, however. If a sine wave drives some form of switching circuit or limiter, and the threshold is offset from the signal’s mean voltage, any level changes will affect the exact switching times and cause *phase jitter*. In this way, AM sidebands are translated into PM sidebands and pass through the limiter. This is usually called *AM-to-PM conversion* and is a classic problem of limiters.

## Effects of Phase Noise

You would be excused for thinking that phase noise is a recent discovery, but all oscillators have always produced it. Other changes have elevated an unnoticed characteristic up to the status of a serious impairment. Increased crowding and power levels on the ham bands, allied with greater expectations of receiver performance as a result of other improvements, have made phase noise more noticeable, but the biggest factor has been the replacement of VFOs in radios by frequency synthesizers. It is a major task to develop a synthesizer that tunes in steps fine enough for SSB and CW while competing with the phase-noise performance of a reasonable-quality LC VFO. Many synthesizers have fallen far short of that target. Phase noise is worse in higher-frequency oscillators

**Fig 14.6 — At A, a phasor diagram of a clean (ideal) oscillator. Noise creates a region of uncertainty in the vector's length and position (B). AM noise varies the vector's length; PM noise varies the vector's relative angular position (C) Limiting a signal that includes AM and PM noise strips off the AM and leaves the PM (D).**

and the trend towards general-coverage, upconverting structures has required that local oscillators operate at higher and higher frequencies. **Fig 14.7A** shows sketches of the relative phase-noise performance of some oscillators. The very high  $Q$  of the quartz crystal in a crystal oscillator gives it the potential for much lower phase noise than LC oscillators. A medium-quality synthesizer has close-in phase noise performance approaching that of a crystal oscillator, while further from the carrier frequency, it degrades to the performance of a modest-quality LC oscillator. There may be a small bump in the noise spectrum at the boundary of these two zones. A bad synthesizer can have extensive noise sidebands extending over many tens (hundreds in extreme cases) of kilohertz at high levels.

Phase noise on a transmitter's local oscillators passes through its stages, is amplified and fed to the antenna along with the intentional signal. The intentional signal is thereby surrounded by a band of noise. This radiated noise exists in the same proportion to the transmitter power as the phase noise was to the oscillator power if it passes through no narrow-band filtering capable of limiting its bandwidth. This radiated noise makes for a noisier band. In bad cases, nearby stations can be unable to receive over many tens of kilohertz. **Fig 14.7B** illustrates the difference between clean and dirty transmitters.

The effects of receiver-LO phase noise are more complicated, but at least it doesn't affect other stations' reception. The process is called *reciprocal mixing*.

### Reciprocal Mixing

This is an effect that occurs in all mixers, yet despite its name, reciprocal mixing is an LO, not a mixer, problem. Imagine that the outputs of two supposedly unmodulated signal generators are mixed together and the mixer output is fed into an FM receiver. The receiver produces sounds, indicating that the resultant signal is modulated nonetheless. Which signal generator is responsible? This is a trick question, of course. A moment spent thinking about how a change in the frequency of either input signal affects the output signal will show that FM or PM on either input reaches the output. The best answer to the trick question is therefore "either or both."

The modulation on the mixer output is the combined modulations of the inputs. This means that modulating a receiver's local oscillator is indistinguishable from using a clean LO and having the same modulation present on *all* incoming signals. (This is also true for AM provided

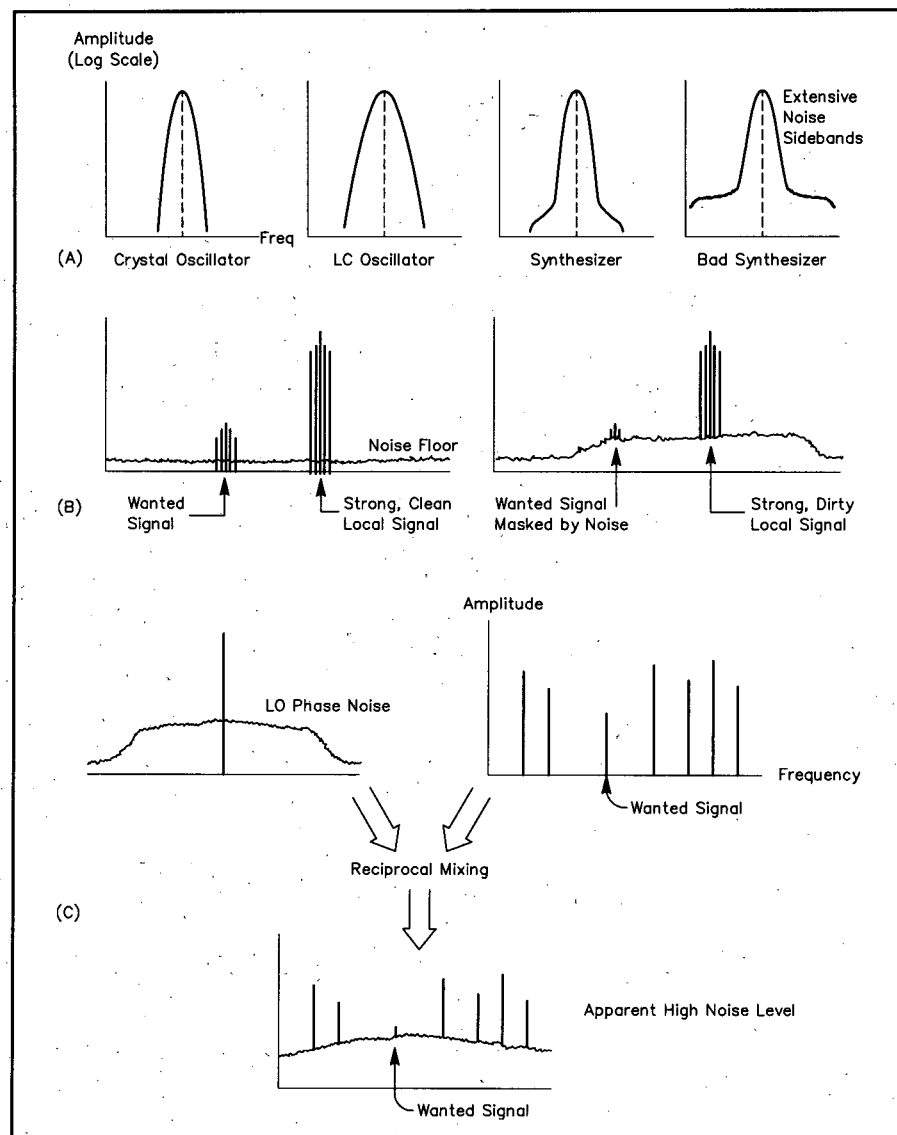

that a fully linear multiplier is used as the mixer, but mixers are commonly driven into switching, which strips any AM off the LO signal. This is the chief reason why the phase component of oscillator noise is more important than any AM component.)

The word *indistinguishable* is important in the preceding paragraph. It does not mean that the incoming signals are themselves modulated, but that the signals in the receiver IF and the noise in the IF, sound exactly as if they were. What really happens is that the noise components of the LO are extra LO signals that are offset from the carrier frequency. Each of them mixes other signals that are appropriately offset from the LO carrier into the receiver's IF. Noise is the sum of an infinite number of infinitesimal components spread over a range of frequencies, so the signals it mixes into the IF are spread into an infinite number of small replicas, all at different frequencies. This amounts to scrambling these other signals into noise. It is tedious to look at the effects of receiver LO phase noise this way. The concept of reciprocal mixing gives us an easier, alternative view that is much more digestible and produces identical results.

A poor oscillator can have significant noise sidebands extending out many tens of kilohertz on either side of its carrier. This is the same, as far as the signals in the receiver IF are concerned, as if the LO was clean and every signal entering the mixer had these noise sidebands. Not only will the wanted signal (and its noise sidebands) be received, but the noise sidebands added by the LO to signals near, but outside, the receiver's IF passband will overlap it. If the band is busy, each of many signals present will add its set of noise sidebands — and the effect is cumulative. This produces the appearance of a high background-noise level on the band. Many hams tend to accept this, blaming “conditions.”

Hams now widely understand reception problems due to intermodulation, and almost everyone knows to apply RF attenuation until the signal gets no clearer. Intermodulation is a nonlinear effect, and the levels of the intermod products fall by greater amounts than the reduction in the intermodulating signals. The net result is less signal, but with the intermodulation products dropped still further. This improvement reaches a limit when more attenuation pushes the desired signal too close to the receiver's noise floor.

Reciprocal mixing is a linear process, and the mixer applies the same amount of noise “deviation” to incoming signals as that present on the LO. Therefore the ratio of noise-sideband power to signal power

**Fig 14.7 — The effects of phase noise.** At A, the relative phase-noise spectra of several different signal-generation approaches. At B, how transmitted phase noise degrades the weak-signal performance even of nearby receivers with phase-quiet oscillators, raising the effective noise floor. What is perhaps most insidious about phase noise in Amateur Radio communication is that its presence in a receiver LO can allow strong, clean transmitted signals to degrade the receiver's noise floor just as if the transmitted signals were dirty. This effect, reciprocal mixing, is shown at C.

is the same for each signal, and the same as that on the LO. Switching in RF attenuation reduces the power of signals entering the mixer, but the reciprocal mixing process still adds the noise sidebands at the same *relative* power to each. Therefore, no reception improvement results. Other than building a quieter oscillator, the only way of improving things is to use narrow preselection to band-limit the receiver's input response and reduce the number of incoming signals subject to reciprocal mixing. This reduces the number of times the phase noise sidebands get added into the IF signal. Commercial *tracking*

*preselectors* — selective front-end circuits that tune in step with a radio's band changes and tuning, are expensive, but one that is manually tuned would make a modest-sized home-brew project and could also help reduce intermodulation effects. When using a good receiver with a linear front end and a clean LO, amateurs accustomed to receivers with poor phase-noise performance report the impression is of a seemingly emptier band with gaps between signals — and then they begin to find readable signals in some of the gaps.

Fig 14.7C shows how a noisy oscillator

affects transmission and reception. The effects on reception are worst in Europe, on 40 m, at night. Visitors from North America, and especially Asia, are usually shocked by the levels of background noise. In ITU Region 1, the Amateur Radio 40-m allocation is 7.0 to 7.1 MHz; above this, ultra-high-power broadcasters operate. The front-end filters in commercial ham gear are usually fixed band-pass designs that cover the wider 40-m allocations in the other regions. This allows huge signals to reach the mixer and mix large levels of LO phase noise into the IF. Operating colocated radios, on the same band, in a multioperator contest, requires linear front ends, preselection and state-of-the-art phase-noise performance. Outside of amateur circles, only warship operation is more demanding, with kilowatt transmitters and receivers sharing antennas on the same mast.

### A Phase Noise Demonstration

Healthy curiosity demands some form of demonstration so the scale of a problem can be judged "by ear" before measurements are attempted. We need to be able to measure the noise of an oscillator alone (to aid in the development of quieter ones) and we also need to be able to measure the phase noise of the oscillators in a receiver (a transmitter can be treated as an oscillator). Conveniently, a receiver contains most of the functions needed to demonstrate its own phase noise.

**Fig 14.8 — Tuning in a strong, clean crystal-oscillator signal can allow you to hear your receiver's relative phase-noise level. Listening with a narrow CW filter switched in allows you to get better results closer to the carrier.**

No mixer has perfect port-to-port isolation, and some of its local-oscillator signal leaks through into the IF. If we tune a general-coverage receiver, with its antenna disconnected, to exactly 0 Hz, the local oscillator is exactly at the IF center frequency, and the receiver acts as if it is tuned to a very strong unmodulated carrier. A typical mixer might give only 40 dB of LO isolation and have an LO drive power of at least 10 mW. If we tune away from 0 Hz, the LO carrier tunes away from the IF center and out of the passband. The apparent signal level falls. Although this moves the LO carrier out of the IF passband, some of its noise sidebands will not be, and the receiver will respond to this energy as an incoming noise signal. To the receiver operator, this sounds like a rising noise floor as the receiver is tuned toward 0 Hz. To get good noise floor at very low frequencies, some professional/military receivers, like the Racal RA1772, use very carefully balanced mixers to get as much port-to-port isolation as possible, and they also may switch a crystal notch filter into the first mixer's LO feed.

This demonstration cannot be done if the receiver tunes amateur bands only. As it is, most general-coverage radios inhibit tuning in the LF or VLF region. It could be suggested by a cynic that how low manufacturers allow you to tune is an indication of how far they think their phase-noise sidebands could extend!

The majority of amateur transceivers with general-coverage receivers are programmed not to tune below 30 to 100 kHz, so means other than the "0 Hz" approach are needed to detect LO noise in these radios. Because reciprocal mixing adds the LO's sidebands to clean incoming signals, in the same proportion to the incoming carrier as they exist with respect to the LO carrier, all we need do is to apply a strong, clean signal wherever we want within the receiver's tuning range. This signal's generator must have lower phase noise than the radio being evaluated. A general-purpose signal generator is unlikely to be good enough; a crystal oscillator is needed.

It's appropriate to set the level into the receiver to about that of a strong broadcast carrier, say S9 + 40 dB. Set the receiver's mode to SSB or CW and tune around the test signal, looking for an increasing noise floor (higher hiss level) as you tune closer towards the signal, as shown in **Fig 14.8**. Switching in a narrow CW filter allows you to hear noise closer to the carrier than is possible with an SSB filter. This is also the technique used to measure a receiver's effective selectivity, and some equipment reviewers kindly publish their plots in this

format. *QST* reviews, done by the ARRL Lab, often include the results of specific phase-noise measurements.

### Measuring Receiver Phase Noise

There are several different ways of measuring phase noise, offering different trade-offs between convenience, cost and effort. Some methods suit oscillators in isolation, others suit them in situ (in their radios).

If you're unfamiliar with noise measurements, the units involved may seem strange. One reason for this is that a noise signal's power is spread over a frequency range, like an infinite number of infinitesimal sinusoidal components. This can be thought of as similar to painting a house. The area that a gallon of paint can cover depends on how thinly it's spread. If someone asks how much paint was used on some part of a wall, the answer would have to be in terms of paint volume per square foot. The wall can be considered to be an infinite number of points, each with an infinitesimal amount of paint applied to it. The question of what volume of paint has been applied at some specific point is unanswerable. With noise, we must work in terms of *power density*, of watts per hertz. We therefore express phase-noise level as a ratio of the carrier power to the noise's power density. Because of the large ratios involved, expression in decibels is convenient. It has been a convention to use *dBc* to mean "decibels with respect to the carrier."

For phase noise, we need to work in terms of a standard bandwidth, and 1 Hz is the obvious candidate. Even if the noise is measured in a different bandwidth, its equivalent power in 1 Hz can be easily calculated. A phase-noise level of 120 dBc in a 1-Hz bandwidth (often written as *120 dBc/Hz*) translates into each hertz of the noise having a power of  $10^{-12}$  of the carrier power. In a bandwidth of 3 kHz, this would be 3000 times larger.

The most convenient way to measure phase noise is to buy and use a commercial phase noise test system. Such a system usually contains a state-of-the-art, low-noise frequency synthesizer and a low-frequency spectrum analyzer, as well as some special hardware. Often, a second, DSP-based spectrum analyzer is included to speed up and extend measurements very close to the carrier by using the Fast Fourier Transform (FFT). The whole system is then controlled by a computer with proprietary software. With a good system like this costing about \$100,000, this is not a practical method for amateurs, although a few fortunate individuals have access to them at work. These systems are

also overkill for our needs, because we are not particularly interested in determining phase-noise levels very close to and very far from the carrier.

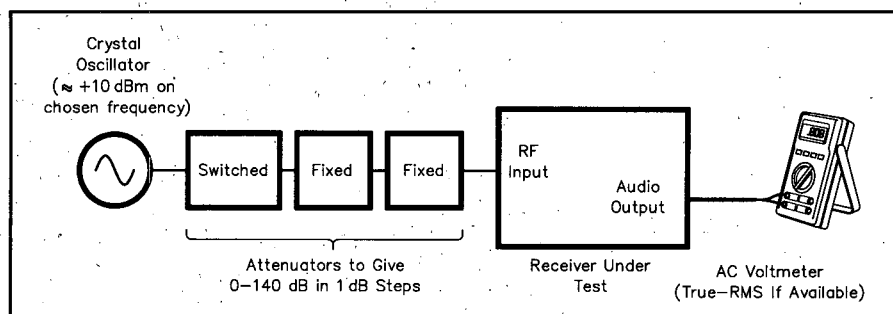

It's possible to make respectable receiver-oscillator phase-noise measurements with less than \$100 of parts and a multimeter. Although it's time-consuming, the technique is much more in keeping with the amateur spirit than using a \$100k system! An ordinary multimeter will produce acceptable results, a meter capable of indicating "true RMS" ac voltages is preferable because it can give correct readings on sine waves and noise.

**Fig 14.9** shows the setup. Measurements can only be made around the frequency of the crystal oscillator, so if more than one band is to be tested, crystals must be changed, or else a set of appropriate oscillators is needed. The oscillator should produce about +10 dBm (10 mW) and be very well shielded. (To this end, it's advisable to build the oscillator into a die-cast box and power it from internal batteries. A noticeable shielding improvement results even from avoiding the use of an external power switch; a reed-relay element inside the box can be positioned to connect the battery when a small permanent magnet is placed against a marked place outside the box.)

Likewise, great care must be taken with attenuator shielding. A total attenuation of around 140 dB is needed, and with so much attenuation in line, signal leakage can easily exceed the test signal that reaches the receiver. It's not necessary to be able to switch-select all 140 dB of the attenuation, nor is this desirable, as switches can leak. (The **Test Procedures** chapter of this *Handbook* contains a step attenuator that's satisfactory.) All of the attenuators' enclosure seams must be soldered. A pair of boxes with 30 dB of fixed attenuation each are needed to complete the set. With 140 dB of attenuation, coax cable leakage is also a problem. The only countermeasure against this is to minimize all cable lengths and to interconnect test-system modules with BNC plug-to-plug adapters (UG-491As) where possible.

Ideally, the receiver could simply be tuned across the signal from the oscillator and the response measured using its signal-strength (S) meter. Unfortunately, receiver S meters are notoriously imprecise, so an equivalent method is needed that does not rely on the receiver's AGC system.

The trick is not to measure the response to a fixed level signal, but to measure the changes in applied signal power needed to give a fixed response. Here is a step-by-

**Fig 14.9 — Setup for measuring receiver-oscillator phase noise.**

step procedure based on that described by John Grebenkemper, KI6WX, in March and April 1988 *QST*:

1. Connect the equipment as shown in Fig 14.9, but with the crystal oscillator off. Set the step attenuator to maximum attenuation. Set the receiver for SSB or CW reception with its narrowest available IF filter selected. Switch out any internal preamplifiers or RF attenuators. Select AGC off, maximum AF and RF gain. It may be necessary to reduce the AF gain to ensure the audio amplifier is at least 10 dB below its clipping point. The ac voltmeter or an oscilloscope on the AF output can be used to monitor this.

2. To measure noise, it is important to know the bandwidth being measured. A true-RMS ac voltmeter measures the power in the noise reaching it. To calculate the noise density, we need to divide by the receiver's noise bandwidth. The receiver's -6-dB IF bandwidth can be used as an approximation, but purists will want to plot the top 20 dB of the receiver's bandwidth on linear scales and integrate the area under it to find the width of a rectangle of equal area and equal height. This accounts properly for the noise in the skirt regions of the overall selectivity. (The very rectangular shape of common receiver filters tends to minimize the error of just taking the approximation.)

Switch on the test oscillator and set the attenuators to give an AF output above the noise floor and below the clipping level with the receiver peaked on the signal. Tune the receiver off to each side to find the frequencies at which the AF voltage is half that at the peak. The difference between these is the receiver's -6-dB bandwidth. High accuracy is not needed: 25% error in the receiver bandwidth will only cause a 1-dB error in the final result. The receiver's published selectivity specifications will be close enough. The benefit of integration is greater if the receiver has a very rounded, low-ringing or low-order filter.

3. Retune the receiver to the peak.

Switch the oscillator off and note the noise-floor voltage. Turn the oscillator back on and adjust the attenuator to give an AF output voltage 1.41 times (3 dB) larger than the noise floor voltage. This means that the noise power and the test signal power at the AF output are equal — a value that's often called the *MDS* (minimum discernible signal) of a receiver. Choosing a test-oscillator level at which to do this test involves compromise. Higher levels give more accurate results where the phase noise is high, but limit the lowest level of phase noise that can be measured because better receiver oscillators require a greater input signal to produce enough noise to get the chosen AF-output level. At some point, either we've taken all the attenuation out and our measurement range is limited by the test oscillator's available power, or we overload the receiver's front end, spoiling the results.

Record the receiver frequency at the peak, ( $f_0$ ), the attenuator setting ( $A_0$ ) and the audio output voltage ( $V_0$ ). These are the carrier measurements against which all the noise measurements will be compared.

4. Now you must choose the offset frequencies — the spacings from the carrier — at which you wish to make measurements. The receiver's skirt selectivity will limit how close to the carrier noise measurements can be made. (Any measurements made too close in are valid measurements of the receiver selectivity, but because the signal measured under these conditions is sinusoidal and not noise like, the corrections for noise density and noise bandwidth are not appropriate.) It is difficult to decide where the filter skirt ends and the noise begins, and what corrections to apply in the region of doubt and uncertainty. A good practical approach is to listen to the audio and tune away from the carrier until you can't distinguish a tone in the noise. The ear is superb at spotting sine tones buried in noise, so this criterion, although subjective, errs on the conservative side.

**Table 14.1****SSB Phase Noise of ICOM IC-745 Receiver Section**

Oscillator output power = -3 dBm (0.5 mW)

Receiver bandwidth ( $\Delta f$ ) = 1.8 kHz

600	0	0.97			-154
800	0	0.96			-154
1000	0	0.96			-154

\*Asterisks indicate measurements possibly affected by receiver overload (see text).

Tune the receiver to a frequency offset from  $f_0$  by your first chosen offset and adjust the attenuators to get an audio output voltage as close as possible to  $V_0$ . Record the total attenuation,  $A_1$  and the audio output voltage,  $V_1$ . The SSB phase noise (qualified as *SSB* because we're measuring the phase noise on only one side of the carrier, whereas some other methods cannot segregate between upper and lower noise sidebands and measure their sum, giving *DSB* phase noise) is now easy to calculate:

$$L(f) = A_1 - A_0 - 10 \log(BW_{\text{noise}}) \quad (1)$$

where

 $L(f)$  = SSB phase noise in dBc/Hz $BW_{\text{noise}}$  = receiver noise bandwidth, Hz.

5. It's important to check for overload. Decrease the attenuation by 3 dB, and record the new audio output voltage,  $V_2$ . If all is well, the output voltage should increase by 22% (1.8 dB); if the receiver is operating nonlinearly, the increase will be less. (An 18% increase is still acceptable for the overall accuracy we want.) Record  $V_2/V_1$  as a check: a ratio of 1.22:1 is ideal, and anything less than 1.18:1 indicates a bad measurement.

If too many measurements are bad, you may be overdriving the receiver's AF

**Transmitter Phase-Noise Measurement in the ARRL Lab**

Here is a brief description of the technique used in the ARRL Lab to measure transmitter phase noise. The system essentially consists of a direct-conversion receiver with very good phase-noise characteristics. As shown in Fig B, we use an attenuator after the transmitter, a Mini-Circuits ZAY-1 mixer, a Hewlett-Packard 8640B signal generator, a band-pass filter, an audio-frequency low-noise amplifier and a spectrum analyzer (HP 8563E) to make the measurements.

The transmitter signal is mixed with the output of the signal generator, and signals produced in the mixing process that are not required for the measurement process are filtered out. The spectrum analyzer then displays the transmitted phase-noise spectrum. The 100 mW output of the HP 8640B is barely enough to drive the mixer—the setup would work better with 200 mW of drive. To test the phase noise of an HP 8640B, we use a second '8640B as a reference source. It is quite important to be sure that the phase noise of the reference source is lower than that of the signal under test, because we are really measuring the combined phase-noise output of the signal generator and the transmitter. It would be quite embarrassing to publish phase-noise plots of the reference generator instead of the transmitter under test! The HP 8640B has much cleaner spectral output than most transmitters.

A sample phase-noise plot for an amateur transceiver is shown in Fig A. It was produced with the test

setup shown in Fig B. Measurements from multiple passes are taken and averaged. A 3-Hz video bandwidth also helps average and smooth the plots. These plots do not necessarily reflect the phase-noise characteristics of all units of a particular model.

The log reference level (the top horizontal line on the

**Fig A —Sample phase noise plot for an amateur transceiver.**

amplifier, so try reducing the AF gain and starting again back at Step 3. If this doesn't help, reducing the RF gain and starting again at Step 3 should help if the compression is occurring late in the IF stages.

6. Repeat Steps 4 and 5 at all the other offsets you wish to measure. If measurements are made at increments of about half the receiver's bandwidth, any discrete (non-noise) spurs will be found. A noticeable tone in the audio can indicate the presence of one of these. If it is well clear of the noise, the measurement is valid, but the noise bandwidth correction should be ignored, giving a result in dBc.

Table 14.1 shows the results for an ICOM IC-745 as measured by KI6WX,

and Fig 14.10 shows this data in graphic form. His oscillator power was only -3 dBm, which limited measurements to offsets less than 200 kHz. More power might have allowed noise measurements to lower levels, although receiver overload places a limit on this. This is not important, because the real area of interest has been thoroughly covered. When attempting phase-noise measurements at large offsets, remember that any front-end selectivity, before the first mixer, will limit the maximum offset at which LO phase-noise measurement is possible.

### Measuring Oscillator and Transmitter Phase Noise

Measuring the composite phase noise of

Fig 14.10 — The SSB phase noise of an ICOM IC-745 transceiver (serial number 01528) as measured by KI6WX.

scale in the plot) represents -60 dBc/Hz. It is common in industry to use a 0-dBc log reference, but such a reference level would not allow measurement of phase-noise levels below -80 dBc/Hz. The actual measurement bandwidth used on the spectrum analyzer is 100 Hz, but the reference is scaled for a 1-Hz bandwidth. This allows phase-noise levels to be read directly from the display in dBc/Hz. Because each vertical division represents 10 dB, the plot shows the noise level between -60 dBc/Hz (the top horizontal line) and -140 dBc/Hz (the bottom horizontal line). The horizontal scale is 2 kHz per division. The offsets shown in the plots are 2 through 20 kHz.

### What Do the Phase-Noise Plots Mean?

Although they are useful for comparing different radios, plots can also be used to calculate the amount of interference you may receive from a nearby transmitter with known phase-noise characteristics. An approximation is given by

$$A_{QRM} = NL + 10 \times \log(BW)$$

where

$A_{QRM}$  = Interfering signal level, dBc

NL = noise level on the receive frequency, dBc

BW = receiver IF bandwidth, in Hz

For instance, if the noise level is -90 dBc/Hz and you are using a 2.5-kHz SSB filter, the approximate interfering signal will be -56 dBc. In other words, if the transmitted signal is 20 dB over S9, and each S unit is 6 dB, the interfering signal will be as strong as an S3 signal.

The measurements made in the ARRL Lab apply only to transmitted signals. It is reasonable to assume that the phase-noise characteristics of most transceivers are similar on transmit and receiver because the same oscillators are generally used in local-oscillator (LO) chain.

In some cases, the receiver may have better phase-noise characteristics than the transmitter. Why the possible difference? The most obvious reason is that circuits often perform less than optimally in strong RF fields, as anyone who has experienced RFI problems can tell you. A less obvious reason results from the way that many high-dynamic-range receivers work. To get good dynamic range, a sharp crystal filter is often

placed immediately after the first mixer in the receive line. This filter removes all but a small slice of spectrum for further signal processing. If the desired filtered signal is a product of mixing an incoming signal with a noisy oscillator, signals far away from the desired one can end up in this slice. Once this slice of spectrum is obtained, however, unwanted signals cannot be reintroduced, no matter how noisy the oscillators used in further signal processing. As a result, some oscillators in receivers don't affect phase noise.

The difference between this situation and that in transmitters is that crystal filters are seldom used for reduction of phase noise in transmitting because of the high cost involved. Equipment designers have enough trouble getting smooth, click-free break-in operation in transceivers without having to worry about switching crystal filters in and out of circuits at 40-wpm keying speeds!—Zack Lau, KH6CP/1, ARRL Laboratory Engineer

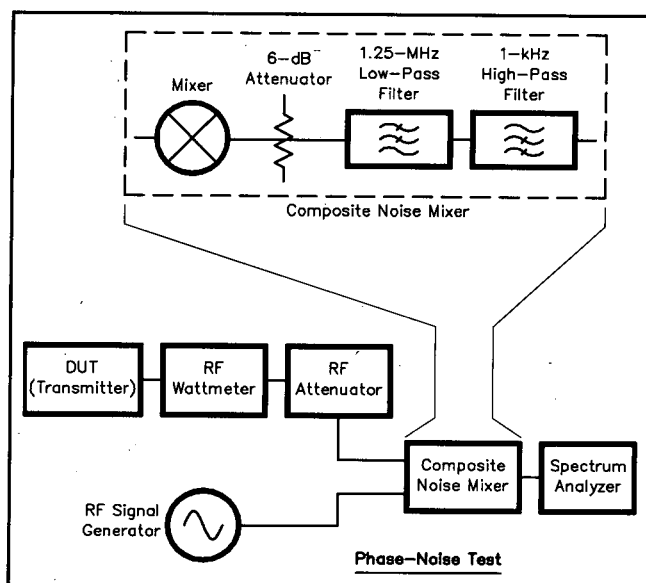

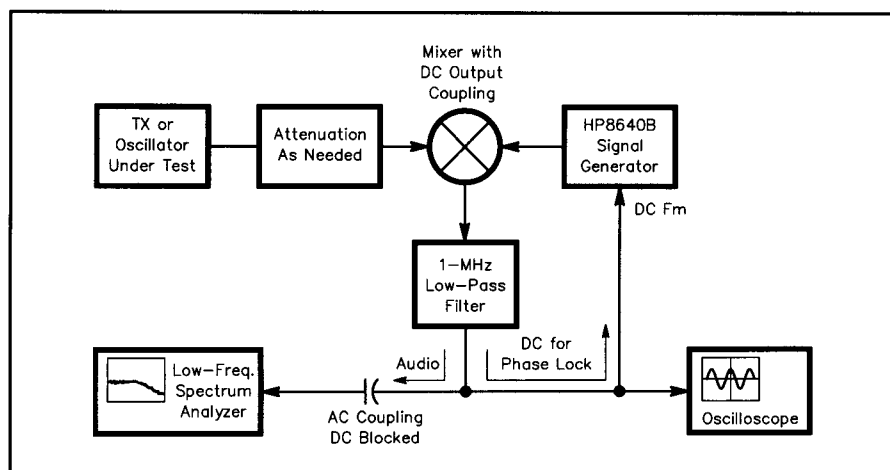

Fig B — ARRL transmitter phase-noise measurement setup.

**Fig 14.11 — Arrangement for measuring phase noise by directly converting the signal under test to audio. The spectrum analyzer views the signal's noise sidebands as audio; the signal's carrier, converted to dc, provides a feedback signal to phase-lock the Hewlett-Packard HP8640B signal generator to the signal under test.**

a receiver's LO requires a clean test oscillator. Measuring the phase noise of an incoming signal, whether from a single oscillator or an entire transmitter, requires the use of a clean receiver, with lower phase noise than the source under test. The sidebar, "Transmitter Phase-Noise Measurement in the ARRL Lab," details the method used to measure composite noise (phase noise and amplitude noise, the practical effects of which are indistinguishable on the air) for QST Product Reviews. Although targeted at measuring high power signals from entire transmitters, this approach can be used to measure lower-level signals simply by changing the amount of input attenuation used.

At first, this method — using a low-frequency spectrum analyzer and a low-phase-noise signal generator — looks unnecessarily elaborate. A growing number of radio amateurs have acquired good-quality spectrum analyzers for their shacks since older model Tektronix and Hewlett-Packard instruments have started to appear on the surplus market at affordable prices. The obvious question is, "Why not just use one of these to view the signal and read phase-noise levels directly off the screen?" Reciprocal mixing is the problem. Very few spectrum analyzers have clean enough local oscillators not to completely swamp the noise being measured. Phase-noise measurements involve the measurement of low-level components very close to a large carrier, and that carrier will mix the noise sidebands of the analyzer's LO into its IF. Some way of notching out the carrier is needed, so that the analyzer need only handle the noise sidebands. A crystal filter could be designed to do the job, but this would be expensive, and

one would be needed for every different oscillator frequency to be tested. The alternative is to build a direct-conversion receiver using a clean LO like the Hewlett-Packard HP8640B signal generator and spectrum-analyze its "audio" output with an audio analyzer. This scheme mixes the carrier to dc; the LF analyzer is then ac-coupled, and this removes the carrier. The analyzer can be made very sensitive without overload or reciprocal mixing being a problem. The remaining problem is then keeping the LO — the HP8640B in this example — at exactly the carrier frequency. 8640s are based on a shortened-UHF-cavity oscillator and can drift a little. The oscillator under test will also drift. The task is therefore to make the 8640B track the oscillator under test. For once we get something for free: The HP8640B's FM input is dc coupled, and we can use this as an electronic fine-tuning input. As a further bonus, the 8640B's FM deviation control acts as a sensitivity control for this input. We also get a phase detector for free, as the mixer output's dc component depends on the phase relationship between the 8640B and the signal under test (remember to use the dc coupled port of a diode ring mixer as the output). Taken together, the system includes everything needed to create a crude phase-locked loop that will automatically track the input signal over a small frequency range. Fig 14.11 shows the arrangement.

The oscilloscope is not essential for operation, but it is needed to adjust the system. With the loop unlocked (8640B FM input disconnected), tune the 8640 off the signal frequency to give a beat at the mixer output. Adjust the mixer drive levels to get an undistorted sine wave on the scope. This

ensures that the mixer is not being overdriven. While the loop is off-tuned, adjust the beat to a frequency within the range of the LF spectrum analyzer and use it to measure its level, " $A_c$ ," in dBm. This represents the carrier level and is used as the reference for the noise measurements. Connect the FM input of the signal generator, and switch on the generator's dc FM facility. Try a deviation range of 10 kHz to start with. When you tune the signal generator toward the input frequency, the scope will show the falling beat frequency until the loop jumps into lock. Then it will display a noisy dc level. Fine tune to get a mean level of 0 V. (This is a very-low-bandwidth, very-low-gain loop. Stability is not a problem, careful loop design is not needed. We actually want as slow a loop as possible; otherwise, the loop would track and cancel the slow components of the incoming signal's phase noise, preventing their measurement.)

When you first take phase-noise plots, it's a good idea to duplicate them at the generator's next lower FM-deviation range and check for any differences in the noise level in the areas of interest. Reduce the FM deviation range until you find no further improvement. Insufficient FM deviation range makes the loop's lock range narrow, reducing the amount of drift it can compensate. (It's sometimes necessary to keep gently trimming the generator's fine tune control.)

Set up the LF analyzer to show the noise. A sensitive range and 100-Hz resolution bandwidth are appropriate. Measure the noise level, " $A_n$ ," in dBm. We must now calculate the noise density that this represents. Spectrum-analyzer filters are normally Gaussian-shaped and bandwidth-specified at their -3-dB points. To avoid using integration to find their true-noise power bandwidth, we can reasonably assume a value of  $1.2 \times BW$ . A spectrum analyzer logarithmically compresses its IF signal ahead of the detectors and averaging filter. This affects the statistical distribution of noise voltage and causes the analyzer to read low by 2.5 dB. To produce the same scale as the ARRL Lab photographs, the analyzer reference level must be set to -60 dBc/Hz, which can be calculated as:

$$A_{ref} = A_c - 10 \log (1.2 \times BW) + 62.5 \text{ dBm} \quad (2)$$

where

$A_{ref}$  = analyzer reference level, dBm  
 $A_c$  = carrier amplitude, dBm.

This produces a scale of -60 dBc/Hz at the top of the screen, falling to -140 dBc/Hz at the bottom. The frequency scale is 0 to 20 kHz with a resolution bandwidth (BW in

the above equation) of 100 Hz. This method combines the power of *both* sidebands and so measures DSB phase noise. To calculate the equivalent SSB phase noise, subtract 3 dB for noncoherent noise (the general "hash" of phase noise) and subtract 6 dB for coherent, discrete components (that is, single-frequency spurs). This can be done by setting the reference level 3 to 6 dB higher.

### Low-Cost Phase Noise Testing

All that expensive equipment may seem far beyond the means of the average Amateur Radio experimenter. With careful shopping and a little more effort, alternative equipment can be put together for pocket money. (All of the things needed — parts for a VXO, a surplus spectrum analyzer and so on — have been seen on sale cheap enough to total less than \$100.) The HP8640B is good and versatile, but for use at one oscillator frequency, you can build a VXO for a few dollars. It will only cover one oscillator frequency, but a VXO can provide even better phase-noise performance than the 8640B.

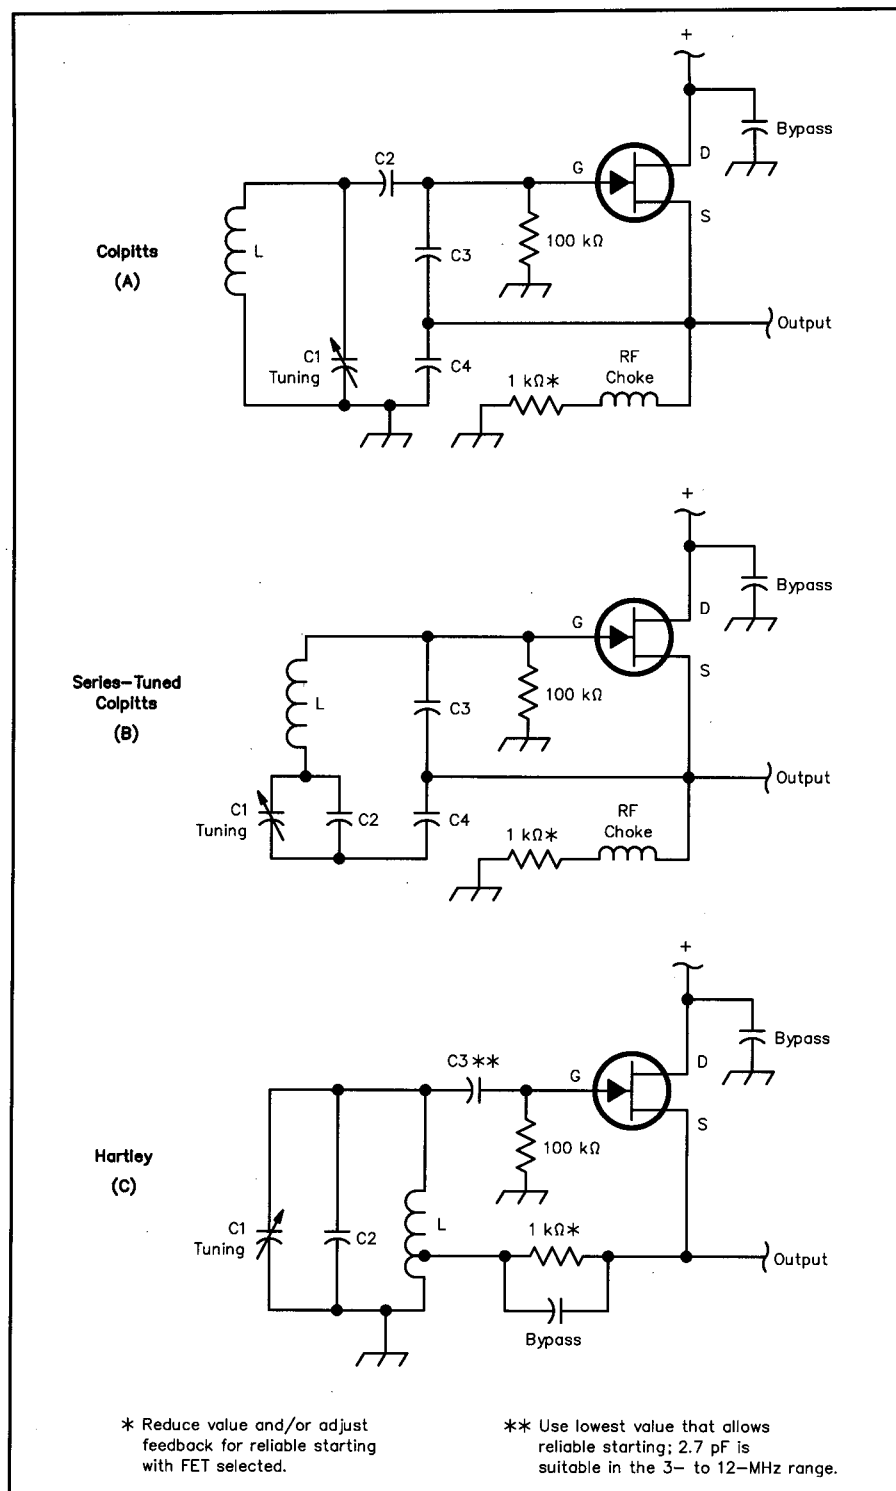

You can also get away without an audio spectrum analyzer. A spectrum-analyzer forerunner, the *wave analyzer*, may suffice. A wave analyzer neither scans nor plots signals. It has simple, hand-cranked tuning calibrated with a mechanical scale or frequency counter and displays received-signal level on a meter. The telephone companies used some variants of these called *selective level measuring sets (SLMSs)* to measure channel powers and pilot tones on their systems, and some of these instruments covered the frequency range of interest. Surplus dealers see little demand for them; they get treated as "boat anchors" and sold cheaply for stripping. One of these instruments will do just fine, but you'll have to plot your noise graph manually, point-by-point.

The mixer need not be an expensive, packaged unit. A Mini-Circuits Labs SRA-2H (see Address List in the **References** chapter) or any other medium-level diode-ring unit will do just as well.

## OSCILLATOR CIRCUITS AND CONSTRUCTION

### LC Oscillator Circuits

The LC oscillators used in radio equipment are usually arranged as *variable frequency oscillators (VFOs)*. Tuning is achieved by either varying part of the capacitance of the resonator or, less commonly, by using a movable magnetic core to vary the inductance. Since the early days of radio, there has been a huge quest for the ideal, low-drift VFO. Amateurs and professionals have spent immense effort on this

**Fig 14.12 — The Colpitts (A), series-tuned Colpitts (B) and Hartley oscillator circuits. Rules of thumb: C3 and C4 at A and B should be equal and valued such that their  $X_C = 45 \Omega$  at the operating frequency; for C2 at A,  $X_C = 100 \Omega$ . For best stability, use C0G or NP0 units for all capacitors associated with the FETs' gates and sources. Depending on the FET chosen, the 1-k $\Omega$  source-bias-resistor value shown may require adjustment for reliable starting.**

pursuit. A brief search of the literature reveals a large number of designs, many accompanied by claims of high stability. The quest for stability has been solved by the

development of low-cost frequency synthesizers, which can give crystal-controlled stability. Synthesizers have other problems though, and the VFO still has much to offer

**Fig 14.12** shows three popular oscillator circuits stripped of any unessential frills so they can be more easily compared. The original Colpitts circuit (Fig 14.12A) is now often referred to as the *parallel-tuned Colpitts* because its series-tuned derivative (Fig 14.12B) has become com-

$$f = \frac{1}{2\pi\sqrt{LC}} \quad (3)$$

$f$  = frequency in hertz  
 $L$  = inductance in henries  
 $C$  = capacitance in farads.

The series-tuned Colpitts circuit works in much the same way. The difference is that the variable capacitor, C1, is positioned so that it is well-protected from being swamped by the large values of C3 and C4. In fact, *small* values of C3, C4 would act to limit the tuning range. Fixed capacitance, C2, is often added across C1 to allow the tuning range to be reduced to that required, without interfering with C3 and C4, which set the amplifier coupling. The series-tuned Colpitts has a reputation for better stability than the parallel-tuned original. Note how C3 and C4 swamp the capacitances of the amplifier in both versions.

The Hartley is similar to the parallel-tuned Colpitts, but the amplifier source is tapped up on the tank inductance instead of the tank capacitance. A typical tap placement is 10 to 20% of the total turns up from the "cold" end of the inductor. (It's usual to refer to the lowest-signal-voltage end of an inductor as *cold* and the other, with the highest signal voltage as *hot*.) C2 limits the tuning range as required; C3 is reduced to the minimum value that allows reliable starting. This is necessary because the Hartley's lack of the

Colpitts's capacitive divider would otherwise couple the FET's capacitances to the tank more strongly than in the Colpitts, potentially affecting the circuit's frequency stability.

In all three circuits, the 1-k $\Omega$  source resistor aids frequency stability by keeping the source higher above ground than the gate. Some commercial circuits accomplish this by connecting the gate to a high-value voltage divider (for example, 1 M $\Omega$  from the positive rail to gate, 1 M $\Omega$  from gate to ground). The gate-to-ground clamping diode (1N914 or similar) long used by radio amateurs as a means of avoiding gate-source conduction has been shown by Ulrich Rohde, KA2WEU, to degrade oscillator phase-noise performance, and its use is virtually unknown in professional circles.

Fig 14.13 shows some more VFOs to illustrate the use of different devices. The triode Hartley shown includes *permeability tuning*, which has no sliding contact like that to a capacitor's rotor and can be made reasonably linear by artfully spacing the coil turns. The slow-motion drive can be done with a screw thread. The disadvantage is that special care is needed to avoid backlash and eccentric rotation of the core. If a nonrotating core is used, the slides have to be carefully designed to prevent motion in unwanted directions. The Collins Radio Company made extensive use of tube-based permeability tuners, and a semiconductor version can still be found in a number of Ten-Tec radios.

Vacuum tubes cannot run as cool as competitive semiconductor circuits, so care is needed to keep the tank circuit away from the tube heat. In many amateur and commercial vacuum-tube oscillators, oscillation drives the tube into grid current at the positive peaks, causing rectification and producing a negative grid bias. The oscillator thus runs in Class C, in which the conduction angle reduces as the signal amplitude increases until the amplitude stabilizes. As in the FET circuits of Fig 14.12, better stability and phase-noise performance can be achieved in a vacuum-tube oscillator by moving it out of true Class C — that is, by including a bypassed cathode-bias resistor (the resistance appropriate for Class A operation is a good starting value). A small number of people still build vacuum-tube radios partly to be different, partly for fun, but the semiconductor long ago achieved dominance in VFOs.

The voltage regulator (VR) tube shown in Fig 14.13 has a potential drawback: It is a gas-discharge device with a high striking voltage at which it starts to conduct

and a lower extinguishing voltage, at which it stops conducting. Between these extremes lies a region in which decreasing voltage translates to increasing current, which implies negative resistance. When the regulator strikes, it discharges any capacitance connected across it to the extinguishing voltage. The capacitance then charges through the source resistor until the tube strikes again, and the process repeats. This *relaxation oscillation* demonstrates how negative resistance can cause oscillation. The oscillator translates the resultant sawtooth modulation of its power supply into frequency and amplitude variation. Because of VR tubes' ability to support relaxation oscillation, a traditional rule of thumb is to keep the capacitance directly connected across a VR tube to 0.1  $\mu$ F or less. A value much lower than this can provide sufficient bypassing in Fig 14.13A because the dropping resistor acts as a decoupler, increasing the bypass's effectiveness.

There is a related effect called *squegging*, which can be loosely defined as oscillation on more than one frequency at a time, but which may also manifest itself as RF oscillation interrupted at an AF rate, as in a superregenerative detector. One form of squegging occurs when an oscillator is fed from a power supply with a high source impedance. The power supply charges up the decoupling capacitor until oscillation starts. The oscillator draws current and pulls down the capacitor voltage, starving itself of power until oscillation stops. The oscillator stops drawing current, and the decoupling capacitor then recharges until oscillation restarts. The process, the low-frequency cycling of which is a form of relaxation oscillation, repeats indefinitely. The oscillator output can clearly be seen to be pulse modulated if an oscilloscope is used to view it at a suitable time-base setting. This fault is a well-known consequence of poor design in battery-powered radios. As dry cells become exhausted, their internal resistance rises quickly and circuits they power can begin to misbehave. In audio stages, such misbehavior may manifest itself in the *putt-putt* sound of the slow relaxation oscillation called *motorboating*.

Compared to the frequently used JFET, bipolar transistors, Fig 14.13B, are relatively uncommon in oscillators because their low input and output impedances are more difficult to couple into a high-Q tank without excessively loading it. Bipolar devices do tend to give better sample-to-sample amplitude uniformity for a given oscillator circuit, however, as JFETs of a given type tend to vary more in their characteristics.

The dual-gate MOSFET, Fig 14.13C, is very rarely seen in VFO circuits. It imposes the cost of the components needed to bias and suppress VHF parasitic oscillation at the second gate, and its inability to generate its own AGC through gate-source conduction forces the addition of a blocking capacitor, resistor and diode at the first gate for amplitude control.

## VFO Components and Construction

### Tuning Capacitors and Reduction Drives

As most commercially made radios now use frequency synthesizers, it has become increasingly difficult to find certain key components needed to construct a good VFO. The slow-motion drives, dials, gearboxes, associated with names like Millen, National, Eddystone and Jackson are no longer available. Similarly, the most suitable silver-plated variable capacitors with ball races at both ends, although still made, are not generally marketed and are expensive. Three approaches remain: scavenge suitable parts from old equipment; use tuning diodes instead of variable capacitors — an approach that, if uncorrected through phase locking, generally degrades stability and phase-noise performance; or use two tuning capacitors, one with a capacitance range  $1/5$  to  $1/10$  that of the other, in a bandset/bandsread approach.

Assembling a variable capacitor to a chassis and its reduction drive to a front panel can result in *backlash* — an annoying tuning effect in which rotating the capacitor shaft deforms the chassis and/or panel rather than tuning the capacitor. One way of minimizing this is to use the reduction drive to support the capacitor, and use the capacitor to support oscillator circuit board.

### Fixed Capacitors

Traditionally, silver-mica-fixed capacitors have been used extensively in oscillators, but their temperature coefficient is not as low as can be achieved by other types, and some silver micas have been known to behave erratically. Polystyrene film has become a proven alternative. One warning is worth noting: Polystyrene capacitors exhibit a permanent change in value should they ever be exposed to temperatures much over 70°C; they do not return to their old value on cooling. Particularly suitable for oscillator construction are the low-temperature-coefficient ceramic capacitors, often described as *NPO* or *C0G* types. These names are actually temperature-coefficient codes. Some ceramic capacitors are available with deliberate, controlled temperature coefficients so

that they can be used to compensate for other causes of frequency drift with temperature. For example, the code N750 denotes a part with a temperature coefficient of  $-750$  parts per million per degree Celsius. These parts are now somewhat difficult to obtain, so other methods are needed.

In a Colpitts circuit, the two large-value capacitors that form the voltage divider for the active device still need careful selection. It would be tempting to use any available capacitor of the right value, because the effect of these components on the tank frequency is reduced by the proportions of the capacitance values in the circuit. This reduction is not as great as the difference between the temperature stability of an NP0 ceramic part and some of the low-cost, decoupling-quality X7R-dielectric ceramic capacitors. It's worth using low-temperature coefficient parts even in the seemingly less-critical parts of a VFO circuit — even as decouplers. Chasing the cause of temperature drift is more challenging than fun. Buy critical components like high-stability capacitors from trustworthy sources.

### Inductors

Ceramic coil forms can give excellent results, as can self-supporting air-wound coils (Miniductor). If you use a magnetic core, make it powdered iron, never ferrite, and support it stably. Stable VFOs have been made using toroidal cores, but again, ferrite must be avoided. Micrometals mix number 6 has a low temperature coefficient and works well in conjunction with NP0 ceramic capacitors. Coil forms in other materials have to be assessed on an individual basis.

A material's temperature stability will not be apparent until you try it in an oscillator, but you can apply a quick test to identify those nonmetallic materials that are lossy enough to spoil a coil's  $Q$ . Put a sample of the coil-form material into a microwave oven along with a glass of water and cook it about 10 s on low power. *Do not include any metal fittings or ferromagnetic cores.* Good materials will be completely unaffected; poor ones will heat and may even melt, smoke, or burst into flame. (This operation is a fire hazard if you try more than a tiny sample of an unknown material. Observe your experiment continuously and do not leave it unattended.)

Wes Hayward, W7ZOI, suggests annealing toroidal VFO coils after winding. Roy Lewallen, W7EL reports achieving success with this method by boiling his coils in water and letting them cool in air.

### Voltage Regulators

VFO circuits are often run from locally

regulated power supplies, usually from resistor/Zener diode combinations. Zener diodes have some idiosyncrasies which could spoil the oscillator. They are noisy, so decoupling is needed down to audio frequencies to filter this out. Zener diodes are often run at much less than their specified optimum bias current. Although this saves power, it results in a lower output voltage than intended, and the diode's impedance is much greater, increasing its sensitivity to variations in input voltage, output current and temperature. Some common Zener types may be designed to run at as much as 20 mA; check the data sheet for your diode family to find the optimum current.

True Zener diodes are low-voltage devices; above a couple of volts, so-called Zener diodes are actually avalanche types. The temperature coefficient of these diodes depends on their breakdown voltage and crosses through zero for diodes rated at about 5 V. If you intend to use nothing fancier than a common-variety Zener, designing the oscillator to run from 5 V and using a 5.1-V Zener, will give you a free advantage in voltage-versus-temperature stability. There are some diodes available with especially low temperature coefficients, usually referred to as *reference* or *temperature-compensated diodes*. These usually consist of a series pair of diodes designed to cancel each other's temperature drift. Running at 7.5 mA, the 1N829A gives  $6.2\text{ V} \pm 5\%$  and a temperature coefficient of just  $\pm 5$  parts per million (ppm) maximum per degree Celsius. A change in bias current of 10% will shift the voltage less than 7.5 mV, but this increases rapidly for greater current variation. The 1N821A is a lower-grade version, at  $\pm 100$  ppm/°C. The LM399 is a complex IC that behaves like a superb Zener at 6.95 V,  $\pm 0.3$  ppm/°C. There are also precision, low-power, three-terminal regulators designed to be used as voltage references, some of which can provide enough current to run a VFO. There are comprehensive tables of all these devices between pages 334 and 337 of Horowitz and Hill, *The Art of Electronics*, 2nd ed.

### Oscillator Devices

The 2N3819 FET, a classic from the 1960s, has proven to work well in VFOs, but, like the MPF102 also long-popular with ham builders, it's manufactured to wide tolerances. Considering an oscillator's importance in receiver stability, you should not hesitate to spend a bit more on a better device. The 2N5484, 2N5485 and 2N5486 are worth considering; together, their transconductance ranges span

that of the MPF102, but each is a better-controlled subset of that range. The 2N5245 is a more recent device with better-than-average noise performance that runs at low currents like the 2N3819. The 2N4416/A, also available as the plastic-cased PN4416, is a low-noise device, designed for VHF/UHF amplifier use, that has been featured in a number of good oscillators up to the VHF region. Its low internal capacitance contributes to low frequency drift. The J310 (plastic; the metal-cased U310 is similar) is another popular JFET in oscillators.

The 2N5179 (plastic, PN5179 or MPS5179) is a bipolar transistor capable of good performance in oscillators up to the top of the VHF region. Care is needed because its absolute-maximum collector-emitter voltage is only 12 V, and its collector current must not exceed 50 mA. Although these characteristics may seem to convey fragility, the 2N5179 is sufficient for circuits powered by stabilized 6-V power supplies.

VHF-UHF devices are not really necessary in LC VFOs because such circuits are rarely used above 10 MHz. Absolute frequency stability is progressively harder to achieve with increasing frequency, so free-running oscillators are rarely used to generate VHF-UHF signals for radio communication. Instead, VHF-UHF radios usually use voltage-tuned, phase-locked oscillators in some form of synthesizer. Bipolar devices like the BFR90 and MRF901, with  $f_T$ s in the 5-GHz region and mounted in stripline packages, are needed at UHF.

Integrated circuits have not been mentioned until now because few specific RF-oscillator ICs exist. Some consumer ICs — the NE602, for example — include the active device(s) necessary for RF oscillators, but often this is no more than a single transistor fabricated on the chip. This works just as a single discrete device would, although using such on-chip devices may result in poor isolation from the rest of the circuits on the chip. There is one specialized LC-oscillator IC: the Motorola MC1648. This device has been made since the early 1970s and is a surviving member of a long-obsolete family of emitter-coupled-logic (ECL) devices. Despite the MC1648's antiquity, it has no real competition and is still widely used in current military and commercial equipment. Market demand should force its continued production for some more years to come. Its circuitry is complex for an oscillator, with a multitransistor oscillator cell controlled by a detector and amplifier in an on-chip ALC system. The MC1648's first problem is that the ECL families use only

about a 1-V swing between logic levels. Because the oscillator is made using the same ECL-optimized semiconductor manufacturing processes and circuit design techniques, this same limitation applies to the signal in the oscillator tuned circuit. It is possible to improve this situation by using a tapped or transformer-coupled tank circuit to give improved Q, but this risks the occurrence of the device's second problem.

Periodically, semiconductor manufacturers modernize their plants and scrap old assembly lines used to make old products. Any surviving devices then must undergo some redesign to allow their production by the new processes. One common result of this is that devices are shrunk, when possible, to fit more onto a wafer. All this increases the  $f_T$  of the transistors in the device, and such evolution has rendered today's MC1648s capable of operation at much higher frequencies than the specified 200-MHz limit. This allows higher-frequency use, but great care is needed in the layout of circuits using it to prevent spurious oscillation. A number of old designs using this part have needed reengineering because the newer parts generate spurious oscillations that the old ones didn't, using PC-board traces as parasitic tuned circuits.

The moral is that a UHF-capable device requires UHF-cognizant design and layout even if the device will be used at far lower frequencies. Fig 14.14 shows the MC1648 in a simple circuit and with a tapped resonator. These more complex circuits have a greater risk of presenting a stray resonance within the device's operating range, risking oscillation at an unwanted frequency. This device is *not* a prime choice for an HF VFO because the physical size of the variable capacitor and the inevitable lead lengths, combined with the need to tap couple to get sufficient Q for good noise performance, makes spurious oscillation difficult to avoid. The MC1648 is really intended for tuning-diode control in phase-locked loops operating at VHF. This difficulty is inherent in wideband devices, especially oscillator circuits connected to their tank by a single "hot" terminal, where there is simply no isolation between the amplifier's input and output paths. Any resonance in the associated circuitry can control the frequency of oscillation.

The popular NE602 mixer IC has a built-in oscillator and can be found in many published circuits. This device has separate input and output pins to the tank and has proved to be quite tame. It's still a relatively new part and may not have been "improved" yet (so far, it has pro-

gressed from the NE602 to the NE602A, the A version affording somewhat higher dynamic range than the original NE602). It might be a good idea for anyone laying out a board using one to take a little extra care to keep PCB traces short in the oscillator section to build in some safety margin so that the board can be used reliably in the future. Experienced (read: "bitten") professional designers know that their designs are going to be built for possibly more than 10 years and have learned to make allowances for the progressive improvement of semiconductor manufacture.

### Three High-Performance HF VFOs

#### The G3PDM Vackar VFO

The Vackar VFO shown in Fig 14.15 was developed over 20 years ago by Peter Martin, G3PDM, for the Mark II version of his high-dynamic range receiver. This can be found in the Radio Society of Great Britain's *Radio Communication Handbook*, with some further comments on the oscillator in RSGB's *Amateur Radio Techniques*. This is a prime example of an oscillator that has been successfully optimized for maximum frequency stability. Not only does it work extremely well, but it still represents the highest stability that can be achieved. Its developer commented

on a number of points, which also apply to the construction of different VFO circuits.

- Use a genuine Vackar circuit, with  $C1/(C4+C6)$  and  $C3/C2 = 6$ .
- Use a strong box, die-cast or milled from solid metal.
- Use a high-quality variable capacitor (double ball bearings, silver plated).
- Adjust feedback control C2, an air-dielectric trimmer, so that circuit just oscillates.
- Thoroughly clean all variable capacitors in an ultrasonic bath.
- Use an Oxley "Tempatrimmer," a fixed capacitor whose temperature coefficient is variable over a wide range, for adjustable temperature compensation. (The "Thermatrimmer" is a lower cost, smaller range alternative.)
- C1, C3 and C6 are silver-mica types glued to a solid support to reduce sensitivity to mechanical shock.
- The gate resistor is a 4.7-k $\Omega$ , 2-W carbon-composition type to minimize self-heating.
- The buffer amplifier is essential.
- Circuits using an added gate-ground diode seem to suffer increased drift.
- Its power supply should be well-regulated. Make liberal use of decoupling capacitors to prevent unintentional feedback via supply rails.

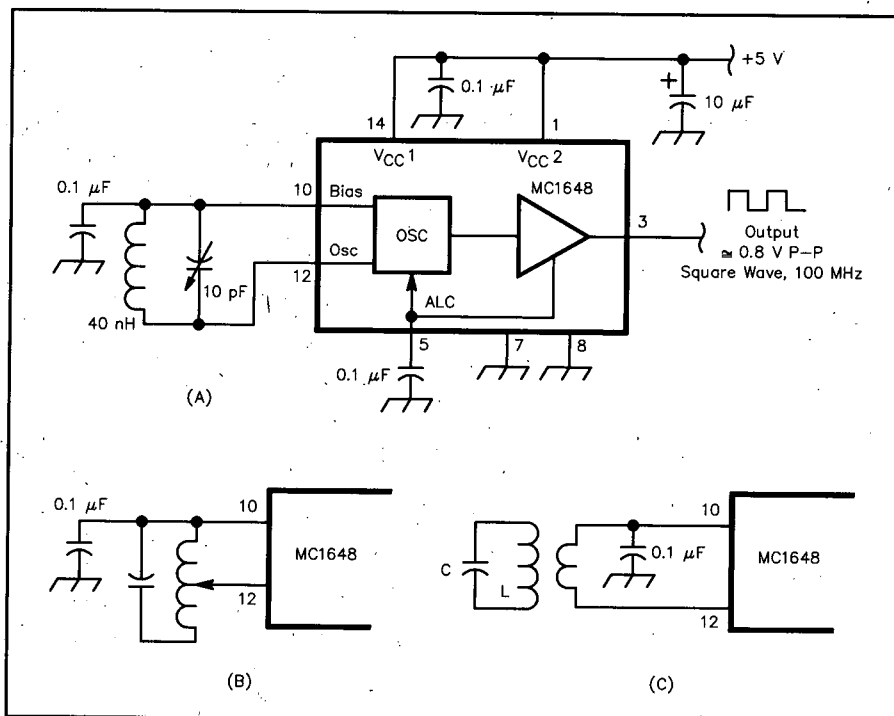

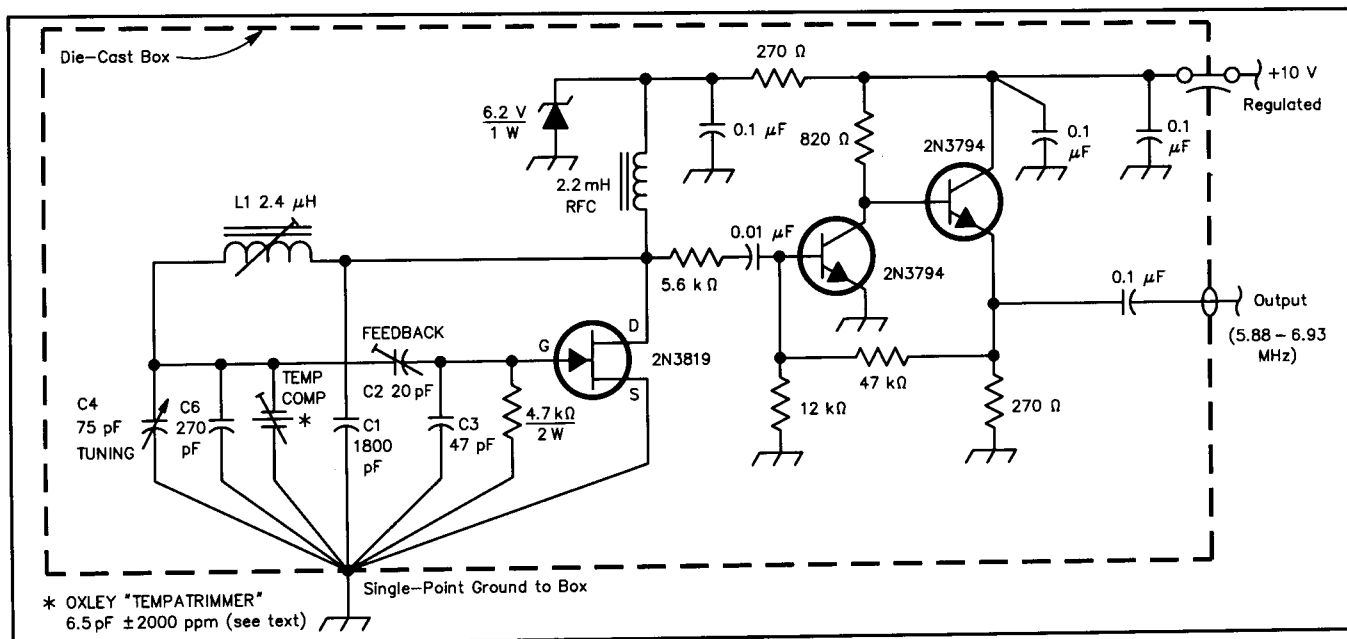

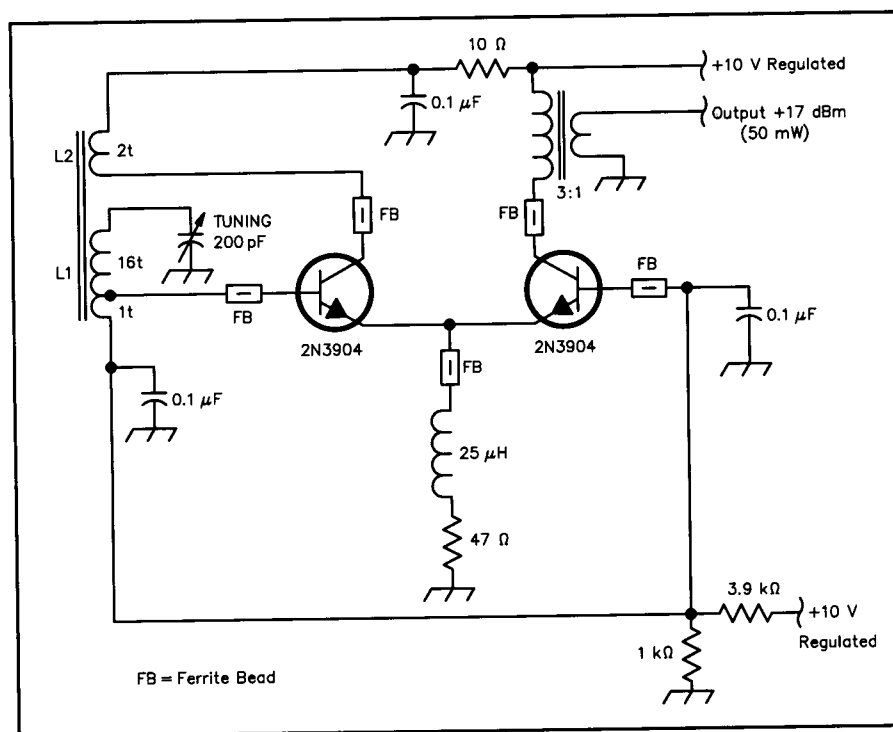

Fig 14.14 — One of the few ICs ever designed solely for oscillator service, the ECL Motorola MC1648 (A) requires careful design to avoid VHF parasitics when operating at HF. Keeping its tank Q high is another challenge; B and C show means of coupling the IC's low-impedance oscillator terminals to the tank with a link or by tapping up on the tank coil.

**Fig 14.15** — G3PDM's Vackar VFO has proved popular and successful for two decades. The MPF102 can be used as a substitute for the 2N3819. Generally, VFOs can be adapted to work at other frequencies (within the limits of the active device). To do so, compute an adjustment factor:  $f_{old} / f_{new}$ . Multiply the value of each frequency-determining or feedback L or C by the factor. As frequency increases, it may help to increase feedback even more than indicated by the factor.

**Fig 14.16** — This low-noise oscillator design by K7HFD operates at an unusually high power level to achieve a high C/N (carrier-to-noise) ratio. Need other frequencies? See Fig 14.15 (caption) for a frequency-scaling technique.

2 Hz in 30 minutes. It must be stressed that such performance does not indicate a wonderful circuit so much as care in construction, skillful choice of components, artful mechanical layout and diligence in adjustment. The 2-W gate resistor may seem strange, but 20 years ago many components were not as good as they are today. A modern, low-inductance component of low temperature coefficient and more modest power rating should be fine.

The buffer amplifier is an important part of a good oscillator system as it serves to prevent the oscillator seeing any impedance changes in the circuit being driven, which could otherwise affect the frequency.

The Oxley Tempatrimmer used by G3PDM was a rare and expensive component, used commercially only in very high-quality equipment, and it may no longer be made. An alternative temperature compensator can be constructed from currently available components, as will be described shortly. G3PDM also referred to his "standard mallet test," where a thump with a wooden hammer produced an average shift of 6 Hz, as an illustration of the benefits of solid mechanical design.

#### The K7HFD Low-Noise Oscillator

The other high performance oscillator example, shown in Fig 14.16, was designed for low-noise performance by Linley Gumm, K7HFD, and appears on page 126 of ARRL's *Solid State Design for the Radio Amateur*. Despite its publication in the home-brewer's bible, this circuit seems to

- Single-point grounding for the tank and FET is important. This usually means using one mounting screw of the tuning capacitor.
- The inductor used a ceramic form with a powdered-iron core mounted on a spring-steel screw.

- Short leads and thick solid wire (#16 to #18 gauge) are essential for mechanical stability.

Operating in the 6-MHz region, this oscillator drifted 500 Hz during the first minute as it warmed up and then drifted at

have been overlooked by many builders. It uses no unusual components and looks simple, yet it is a subtle and sophisticated circuit. It represents the antithesis of G3PDM's VFO: In the pursuit of low noise sidebands, a number of design choices have been made that will degrade the stability of frequency over temperature.

The effects of oscillator noise have already been covered, and Fig 14.6 shows the effect of limiting on the signal from a noisy oscillator. Because AM noise sidebands can get translated into PM noise sidebands by imperfect limiting, there is an advantage to stripping off the AM as early as possible, in the oscillator itself. An ALC system in the oscillator will counteract and cancel only the AM components within its bandwidth, but an oscillator based on a limiter will do this over a broad bandwidth. K7HFD's oscillator uses a differential pair of bipolar transistors as a limiting amplifier. The dc bias voltage at the bases and the resistor in the common emitter path to ground establishes a controlled dc bias current. The ac voltage between the bases switches this current between the two collectors. This applies a rectangular pulse of current into link winding L2, which drives the tank. The output impedance of the collector is high in both the current on and current off states. Allied with the small number of turns of the link winding, this presents a very high impedance to the tank circuit, which minimizes the damping of the tank Q. The input impedance of the limiter is also quite high and is applied across only a one-turn tap of L1, which similarly minimizes the effect on the tank Q. The input transistor base is driven into conduction only on one peak of the tank waveform, so the circuit is working in Class C. The output transformer has the inverse of the current pulse applied to it, so the output is not a low distortion sine wave, although the output harmonics will not be as extensive as simple theory would suggest because the circuit's high output impedance allows stray capacitances to attenuate high-frequency components. The low-frequency transistors used also act to reduce the harmonic power.

With an output of +17 dBm, this is a power oscillator, running with a large dc input power, so appreciable heating results that can cause temperature-induced drift. The circuit's high-power operation is a deliberate ploy to create a high signal-to-noise ratio by having as high a signal power as possible. This also reduces the problem of the oscillator's broadband noise output. The limitation on the signal level in the tank is the transistors' base-emitter-junction breakdown voltage. The circuit runs with a few volts peak-to-peak across the one-turn tap, so the full tank is running at over 50 V P-P. The single easiest way to damage a bipolar

transistor is to reverse bias the base-emitter junction until it avalanches. Most devices are only rated to withstand 5 V applied this way, the current needed to do damage is small, very little power is needed. If the avalanche current is limited to less than that needed to perform immediate destruction of the transistor, it is likely that there will be some degradation of the device, a reduction in its bandwidth and gain along with an increase in its noise. These changes are irreversible and cumulative. Small, fast signal diodes have breakdown voltages of over 30 V and less capacitance than the transistor bases, so one possible experiment would be to try the effect of adding a diode in series with the base of each transistor and running the circuit at even higher levels.

The amplitude must be controlled by the drive current limit. The voltage on L2 must never allow the collector of the transistor driving it to go into saturation, if this happens, the transistor presents a very low impedance to L2 and badly loads the tank, wrecking the Q and the noise performance. The circuit can be checked to verify the margin from saturation by probing the hot end of L2 and the emitter with an oscilloscope. Another, less obvious, test is to vary the power-supply voltage and monitor the output power. While the circuit is under current control, there is very little change in output power, but if the supply is low enough to allow saturation, the output power will change significantly.

The use of the 2N3904 is interesting, as it is not normally associated with RF oscillators. It is a cheap, plain, general-purpose type more often used at dc or audio frequencies. There is evidence that suggests some transistors, which have good noise performance at RF, have worse noise performance at low frequencies, and that the low-frequency noise they create can modulate an oscillator, creating noise sidebands. Experiments with low-noise audio transistors may be worthwhile, but many such devices have very low  $f_T$  and high junction capacitances. In the description of this circuit in *Solid State Design for the Radio Amateur*, the results of a phase-noise test made using a spectrum analyzer with a crystal filter as a preselector are given. Ten kilohertz out from the carrier, in a 3-kHz measurement bandwidth, the noise was over 120 dB below the carrier level. This translates into better than  $-120 - 10 \log(3000)$ , which equals  $-154.8$  dBc/Hz, SSB. At this offset,  $-140$  dBc is usually considered to be excellent. This is state-of-the-art performance by today's standards — in a 1977 publication.

#### A JFET Hartley VFO

Fig 14.17 shows an 11.1-MHz version of a VFO and buffer closely patterned

after that used in 7-MHz transceiver designs published by Roger Hayward, KA7EXM, and Wes Hayward, W7ZOI (The Ugly Weekender) and Roy Lewallen, W7EL (the Optimized QRP Transceiver). In it, a 2N5486 JFET Hartley oscillator drives the two-2N3904 buffer attributed to Lewallen. This version diverges from the originals in that its JFET uses source bias (the bypassed 910- $\Omega$  resistor) instead of a gate-clamping diode and is powered from a low-current 7-V regulator IC instead of a Zener diode and dropping resistor. The 5-dB pad sets the buffer's output to a level appropriate for "Level 7" (+7-dBm-LO) diode ring mixers.

The circuit shown was originally built with a gate clamping diode, no source bias and a 3-dB output pad. Rebiasing the oscillator as shown increased its output by 2 dB without degrading its frequency stability (200 to 300-Hz drift at power up, stability within  $\pm 20$  Hz thereafter at a constant room temperature).

#### Temperature Compensation

The general principle for creating a high-stability VFO is to use components with minimal temperature coefficients in circuits that are as insensitive as possible to changes in components' secondary characteristics. Even after careful minimization of the causes of temperature sensitivity, further improvement can still be desirable. The traditional method was to split one of the capacitors in the tank so that it could be apportioned between low-temperature-coefficient parts and parts with deliberate temperature dependency. Only a limited number of different, controlled temperature coefficients are available, so the proportioning between low coefficient and controlled coefficient parts was varied to "dilute" the temperature sensitivity of a part more sensitive than needed. This was a tedious process, involving much trial and error, an undertaking made more complicated by the difficulty of arranging means of heating and cooling the unit being compensated. (Hayward described such a means in December 1993 *QST*.) As commercial and military equipment have been based on frequency synthesizers for some time, supplies of capacitors with controlled temperature sensitivity are drying up. An alternative approach is needed.

A temperature-compensated crystal oscillator (TCXO) is an improved-stability version of a crystal oscillator, that is used widely in industry. Instead of using controlled-temperature coefficient-capacitors, most TCXOs use a network of thermistors and normal resistors to control the bias of a tuning

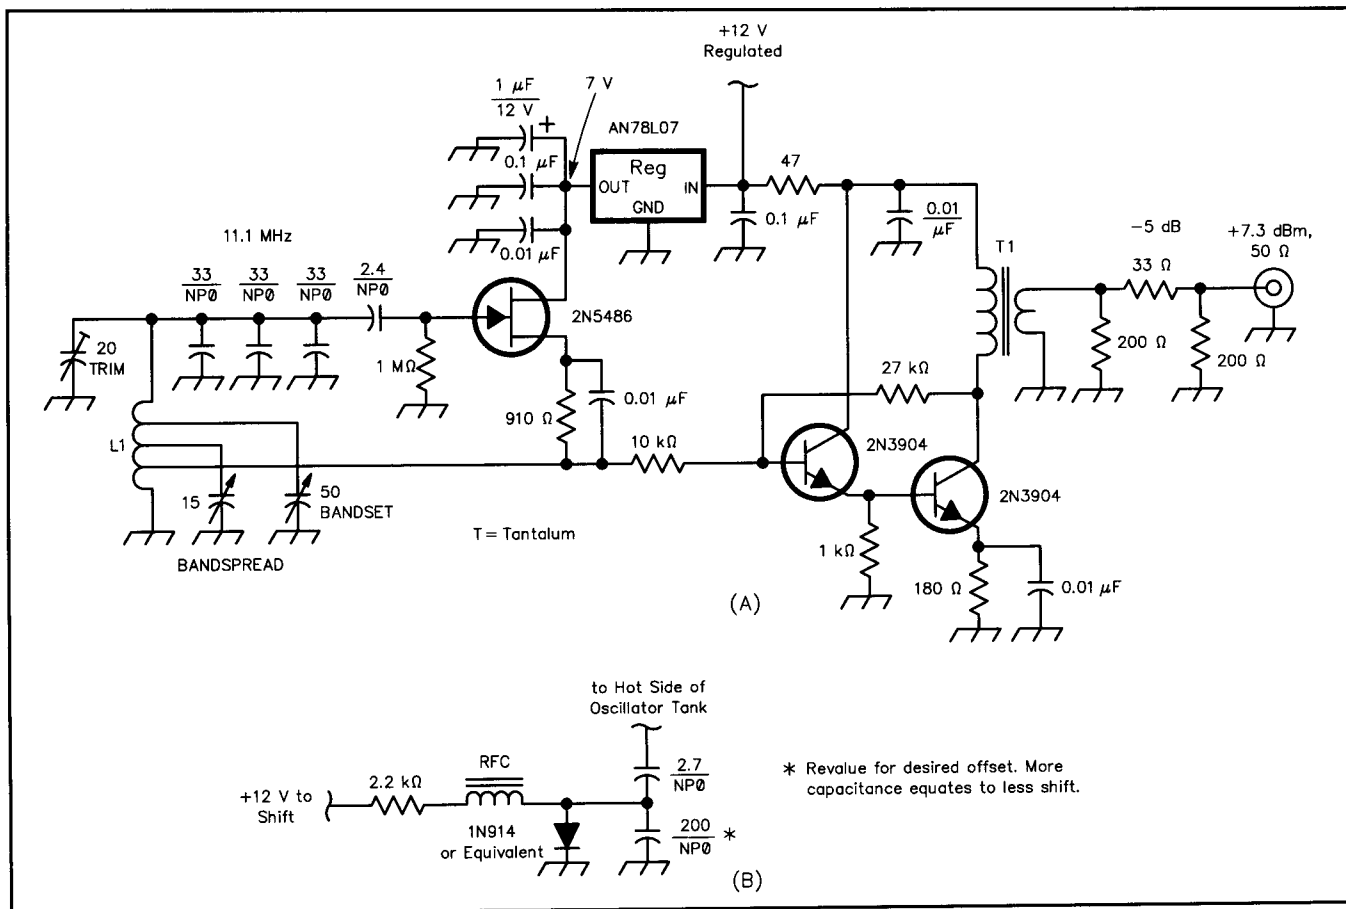

Fig 14.17 — Incorporating ideas from KA2WEU, KA7EXM, W7ZOI and W7EL, the oscillator at A achieves excellent stability and output at 11.1 MHz without the use of a gate-clamping diode, as well as end-running the shrinking availability of reduction drives through the use of bandset and bandspread capacitors. L1 consists of 10 turns of B & W #3041 Miniductor (#22 tinned wire,  $\frac{5}{8}$  inch in diameter, 24 turns per inch). The source tap is  $2\frac{1}{2}$  turns above ground; the tuning-capacitor taps are positioned as necessary for bandset and bandspread ranges required. T1's primary consists of 15 turns of #28 enameled wire on an FT-37-72 ferrite core; its secondary, 3 turns over the primary. B shows a system for adding fixed TR offset that can be applied to any LC oscillator. The RF choke consists of 20 turns of #26 enameled wire on an FT-37-43 core. Need other frequencies? See Fig 14.15 (caption) for a frequency-scaling technique.

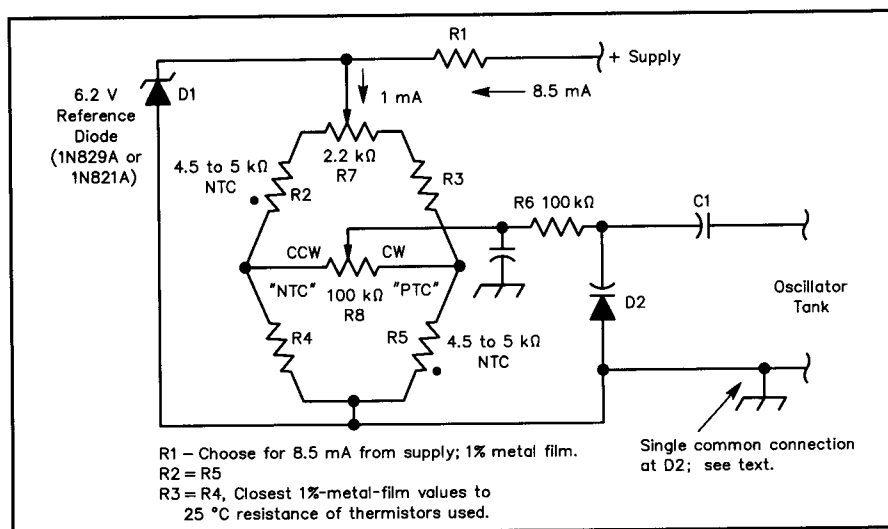

Fig 14.18 — Oscillator temperature compensation has become more difficult because of the scarcity of negative-temperature-coefficient diodes. This circuit, by GM4ZNX, uses a bridge containing two identical thermistors to steer a tuning diode for drift correction. The 6.2-V Zener diode used (a 1N821A or 1N829A) is a temperature-compensated part; just any 6.2-V Zener will not do.

diode. Manufacturers measure the temperature vs frequency characteristic of sample oscillators, and use a computer program to calculate the optimum normal resistor values for production. This can reliably achieve at least a tenfold improvement in stability. We are not interested in mass manufacture, but the idea of a thermistor tuning a varactor is likely to be available for a long time.

Browsing through component suppliers' catalogs shows ready availability of 4.5- to 5-kΩ-bead thermistors intended for temperature-compensation purposes, at less than a dollar each. Fig 14.18 shows a circuit based on these. Commonly available thermistors have negative temperature coefficients, so as temperature rises, the voltage at the counterclockwise (ccw) end of R8 increases, while that at the clockwise (cw) end drops. Somewhere near the center,

there is no change. Increasing the voltage on the tuning diode decreases its capacitance, so settings toward R8's ccw end simulate a negative-temperature-coefficient capacitor; toward its clockwise end, a positive-temperature-coefficient part. Choose R1 to pass 8.5 mA from whatever supply voltage is available to the 6.2-V reference diode, D1. The 1N821A/1N829A-family diode used has a very low temperature coefficient and needs 7.5 mA bias for best performance; the bridge takes 1 mA. R7 and R8 should be good-quality multiturn trimmers. D2 and C1 are best determined via trial and error; practical components aren't known well enough to rely on analytical models. Choose the least capacitance that provides enough compensation range. This reduces the noise added to the oscillator. (It is possible, though tedious, to solve for the differential varactor voltage with respect to R2 and R5, via differential calculus and circuit theory. The equations in Hayward's 1993 article can then be modified to accommodate the additional capacitors formed by D2 and C1.) Use a single ground point near D2 to reduce the influence of ground currents from other circuits. Use good-quality metal-film components for the circuit's fixed resistors.

The circuit requires two adjustments, one at each of two different temperatures, and achieving them requires a stable frequency counter that can be kept far enough from the radio so that the radio, not the counter, is subjected to the temperature extremes. (Using a receiver to listen to the oscillator under test can speed the adjustments.) After connecting the counter to the oscillator to be corrected, run the radio containing the oscillator and compensator in a room-temperature, draft-free environment until the oscillator's frequency reaches its stable operating temperature rise over ambient. Lock its tuning, if possible. Adjust R7 to balance the bridge. This causes a drop of 0 V across R8, a condition you can reach by winding R8 back and forth across its range while slowly adjusting R7. When the bridge is balanced and 0 V appears across R8, adjusting R8 causes no frequency shift. When you've found this R7 setting, leave it there, set R8 is to the exact center of its range and record the oscillator frequency.

Run the radio in a hot environment and allow its frequency to stabilize. Adjust R8 to restore the frequency to the recorded value. The sensitivity of the oscillator to temperature should now be significantly reduced between the temperatures at which you performed the adjustments.

You will also have somewhat improved the oscillator's stability outside this range.

For best results with any temperature-compensation scheme, it's important to group all the oscillator and compensator components in the same box, avoiding differences in airflow over components. A good oscillator should not dissipate much power, so it's feasible, even advisable, to mount all of the oscillator components in an unventilated box. In the real world, temperatures change, and if the components being compensated and the components doing the compensating have different thermal time constants, a change in temperature can cause a temporary change in frequency until the slower components have caught up. One cure for this is to build the oscillator in a thick-walled metal box that's slow to heat or cool, and so dominates and reduces the possible rate of change of temperature of the circuits inside. This is sometimes called a *cold oven*.

### Shielding and Isolation

Oscillators contain inductors running at moderate power levels and so can radiate strong enough signals to cause interference with other parts of a radio, or with other radios. Oscillators are also sensitive to radiated signals. Effective shielding is therefore important. A VFO used to drive a power amplifier and antenna (to form a simple CW transmitter) can prove surprisingly difficult to shield well enough. Any leakage of the power amplifier's high-level signal back into the oscillator can affect its frequency, resulting in a poor transmitted note. If the radio gear is in the station antenna's near field, sufficient shielding may be even more difficult. The following rules of thumb continue to serve ham builders well:

- Use a complete metal box, with as few holes as possible drilled in it, with good contact around surface(s) where its lid(s) fit(s) on.
- Use feedthrough capacitors on power and control lines that pass in and out of the VFO enclosure, and on the transmitter or transceiver enclosure as well.
- Use *buffer amplifier* circuitry that amplifies the signal by the desired amount and provide sufficient attenuation of signal energy flowing in the reverse direction. This is known as *reverse isolation* and is a frequently overlooked loophole in shielding. Figs 14.15 and 14.17 include buffer circuitry of proven performance. As another (and higher-cost) option, consider using a high-speed buffer-amplifier IC (such as the LM6321N by National Semiconductor, a part that combines the high input impedance of an op amp with the ability to drive 50-Ω loads directly up into the VHF range).

- Use a mixing-based frequency-generation scheme instead of one that operates straight through or by means of multiplication. Such a system's oscillator stages can operate on frequencies with no direct frequency relationship to its output frequency.
- Use the time-tested technique of running your VFO at a *subharmonic* of the output signal desired — say, 3.5 MHz in a 7-MHz transmitter — and *multiply* its output frequency in a suitably nonlinear stage for further amplification at the desired frequency.

### Quartz Crystals in Oscillators

Because crystals afford Q values and frequency stabilities that are orders of magnitude better than those achievable with LC circuits, fixed-frequency oscillators are usually on quartz-crystal resonators. Master references for frequency counters and synthesizers are always based on crystal oscillators.

So glowing is the executive summary of the crystal's reputation for stability that newcomers to radio experimentation naturally believe that the presence of a crystal in an oscillator will force oscillation at the frequency stamped on the can. This impression is usually revised after the first few experiences to the contrary! There is no sure-fire crystal oscillator circuit (although some are better than others); reading and experience soon provide a learner with plenty of anecdotes to the effect that:

- Some circuits have a reputation of being temperamental, even to the point of not always starting.
- Crystals sometimes mysteriously oscillate on unexpected frequencies.

Even crystal manufacturers have these problems, so don't be discouraged from building crystal oscillators. The occasional uncooperative oscillator is a nuisance, not a disaster, and it just needs a little individual attention. Knowing how a crystal behaves is the key to a cure.

### Quartz and the Piezoelectric Effect

Quartz is a crystalline material with a regular atomic structure that can be distorted by the simple application of force. Remove the force, and the distorted structure springs back to its original form with very little energy loss. This property allows acoustic waves — sound — to propagate rapidly through quartz with very little attenuation, because the velocity of an acoustic wave depends on the elasticity and density (mass/volume) of the medium through which the wave travels.

If you heat a material, it expands. Heating may cause other characteristics of a material

to change — such as elasticity, which affects the speed of sound in the material. In quartz, however, expansion and change in the speed of sound are very small and tend to cancel, which means that the transit time for sound to pass through a piece of quartz is very stable.

The third property of this wonder material is that it is *piezoelectric*. Apply an electric field to a piece of quartz and the crystal lattice distorts just as if a force had been applied. The electric field applies a force to electrical charges locked in the lattice structure. These charges are captive and cannot move around in the lattice as they can in a semiconductor, for quartz is an insulator. A capacitor's dielectric stores energy by creating physical distortion on an atomic or molecular scale. In a piezoelectric crystal's lattice, the distortion affects the entire structure. In some piezoelectric materials, this effect is sufficiently pronounced that special shapes can be made that bend *visibly* when a field is applied.

Consider a rod made of quartz. Any sound wave propagating along it eventually hits an end, where there is a large and abrupt change in acoustic impedance. Just as when an RF wave hits the end of an unterminated transmission line, a strong reflection occurs. The rod's other end similarly reflects the wave. At some frequency, the phase shift of a round trip will be such that waves from successive round trips exactly coincide in phase and reinforce each other, dramatically increasing

the wave's amplitude. This is resonance.

The passage of waves in opposite directions forms a standing wave with antinodes at the rod ends. Here we encounter a seeming ambiguity: not just one, but a *family* of different frequencies, causes standing waves — a family fitting the pattern of  $\frac{1}{2}$ ,  $\frac{1}{2}$ ,  $\frac{3}{2}$ ,  $\frac{5}{2}$  and so on, wavelengths into the length of the rod. And this is the case: A quartz rod *can* resonate at any and all of these frequencies.

The lowest of these frequencies, where the crystal is  $\frac{1}{2}$  wavelength long, is called the *fundamental* mode. The others are named the third, fifth, seventh and so on, *overtones*. There is a small phase-shift error during reflection at the ends, which causes the frequencies of the overtone modes to differ slightly from odd integer multiples of the fundamental. Thus, a crystal's third overtone is very close to, but not exactly, three times, its fundamental frequency. Many people are confused by overtones and harmonics. Harmonics are additional signals at *exact* integer multiples of the fundamental frequency. Overtones are not signals at all; they are additional resonances that can be exploited if a circuit is configured to excite them.

The crystals we use most often resonate in the 1- to 30-MHz region and are of the *AT cut, thickness shear* type, although these last two characteristics are rarely mentioned. A 15-MHz-fundamental crystal of this type is about 0.15 mm thick. Because of the widespread use of reprocessed war-surplus, pressure-mounted *FT-243* crystals, you may think of crystals as small rectangles on the order of a half inch in size. The crystals we commonly use today are discs, etched and/or doped to their final dimensions, with metal electrodes deposited directly on the quartz. A crystal's diameter does not directly affect its frequency; diameters of 8 to 15 mm are typical.

*AT cut* is one of a number of possible standard designations for the orientation at which a crystal disc is sawn from the original quartz crystal. The crystal lattice atomic structure is asymmetric, and the orientation of this with respect to the faces of the disc influences the crystal's performance. *Thickness shear* is one of a number of possible orientations of the crystal's mechanical vibration with respect to the disc. In this case, the crystal vibrates perpendicularly to its thickness. This is not easy to visualize, and diagrams don't help much, but **Fig 14.19A** is an attempt at illustrating this. Place a moist bathroom sponge between the palms of your hands, move one hand up and down, and you'll see thickness shear in action.

There is a limit to how thin a disc can be made, given requirements of accuracy and price. Traditionally, fundamental-mode

crystals have been made up to 20 MHz, although 30 MHz is now common at a moderately raised price. Using techniques pioneered in the semiconductor industry, crystals have been made with a central region etched down to a thin membrane, surrounded by a thick ring for robustness. This approach can push fundamental resonances to over 100 MHz, but these are more lab curiosities than parts for everyday use. The easy solution for higher frequencies is to use a nice, manufacturably thick crystal on an overtone mode. All crystals have all modes, so if you order a 28.060-MHz, third-overtone unit for a little QRP transmitter, you'll get a crystal with a fundamental resonance somewhere near 9.353333 MHz, but its manufacturer will have adjusted the thickness to plant the third overtone exactly on the ordered frequency. An accomplished manufacturer can do tricks with the flatness of the disc faces to make the wanted overtone mode a little more active and the other modes a little less active. (As some builders discover, however, this does not *guarantee* that the wanted mode is the most active!)

Quartz's piezoelectric property provides a simple way of driving the crystal electrically. Early crystals were placed between a pair of electrodes in a case. This gave amateurs the opportunity to buy surplus crystals, open them and grind them a little to reduce their thickness, thus moving them to higher frequencies. The frequency could be reduced very slightly by loading the face with extra mass, such as by blackening it with a soft pencil. Modern crystals have metal electrodes deposited directly onto their surfaces (**Fig 14.19B**), and such tricks no longer work.

The piezoelectric effect works both ways. Deformation of the crystal produces voltage across its electrodes, so the mechanical energy in the resonating crystal can also be extracted electrically by the same electrodes. Seen electrically, at the electrodes, the mechanical resonances look like electrical resonances. Their *Q* is very high. A *Q* of 10,000 would characterize a *poor* crystal nowadays; 100,000 is often reached by high-quality parts. For comparison, a *Q* of over 200 for an LC tank is considered good.

### Accuracy

A crystal's frequency accuracy is as outstanding as its *Q*. Several factors determine a crystal's frequency accuracy.

First, the manufacturer makes parts with certain tolerances:  $\pm 200$  ppm for a low-quality crystal for use as in a microprocessor clock oscillator,  $\pm 10$  ppm for a good-quality part for professional radio use. Anything much better than this starts to get expensive! A crystal's resonant frequency is influenced by the impedance presented to its terminals,

**Fig 14.19 — Thickness-shear vibration at a crystal's fundamental and third overtone (A); B shows how the modern crystals commonly used by radio amateurs consist of etched quartz discs with electrodes deposited directly on the crystal surface.**

and manufacturers assume that once a crystal is brought within several parts per million of the nominal frequency, its user will perform fine adjustments electrically.

Second, a crystal ages after manufacture. Aging could give increasing or decreasing frequency; whichever, a given crystal usually keeps aging in the same direction. Aging is rapid at first and then slows down. Aging is influenced by the care in polishing the surface of the crystal (time and money) and by its holder style. The cheapest holder is a soldered-together, two-part metal can with glass bead insulation for the connection pins. Soldering debris lands on the crystal and affects its frequency. Alternatively, a two-part metal can be made with flanges that are pressed together until they fuse, a process called *cold-welding*. This is much cleaner and improves aging rates roughly fivefold compared to soldered cans. An all-glass case can be made in two parts and fused together by heating in a vacuum. The vacuum raises the  $Q$ , and the cleanliness results in aging that's roughly ten times slower than that achievable with a soldered can. The best crystal holders borrow from vacuum-tube assembly processes and have a *getter*, a highly reactive chemical substance that traps remaining gas molecules, but such crystals are used only for special purposes.

Third, temperature influences a crystal. A reasonable, professional quality part might be specified to shift not more than  $\pm 10$  ppm over 0 to 70°C. An AT-cut crystal has an S-shaped frequency-versus-temperature characteristic, which can be varied by slightly changing the crystal cut's orientation. Fig 14.20 shows the general shape and the effect of changing the cut angle by only a few seconds of arc. Notice how all the curves converge at 25°C. This is because this temperature is normally chosen as the reference for specifying a crystal. The temperature stability specification sets how accurate the manufacturer must make the cut. Better stability may be needed for a crystal used as a receiver frequency standard, frequency counter clock and so on. A crystal's temperature characteristic shows a little hysteresis. In other words, there's a bit of offset to the curve depending whether temperature is increasing or decreasing. This is usually of no consequence except in the highest-precision circuits.

It is the temperature of the quartz which is important, and as the usual holders for crystals all give effective thermal insulation, only a couple of milliwatts dissipation by the crystal itself can be tolerated before self-heating becomes troublesome. Because such heating occurs in the quartz itself and does not come from the surrounding environment, it defeats the effects of temperature

compensators and ovens.

The techniques shown earlier for VFO for temperature compensation can also be applied to crystal oscillators. An after-compensation drift of 1 ppm is routine and 0.5 ppm is good. The result is a *temperature-compensated crystal oscillator (TCXO)*. Recently, oscillators have appeared with built-in digital thermometers, microprocessors and ROM look-up tables customized on a unit-by-unit basis to control a tuning diode via a digital-to-analog converter (DAC) for temperature compensation. These *digitally temperature-compensated oscillators (DTCXOs)* can reach 0.1 ppm over the temperature range. With automated production and adjustment, they promise to become the cheapest way to achieve this level of stability.

Oscillators have long been placed in temperature-controlled *ovens*, which are typically held at 80°C. Stability of several parts per billion can be achieved over temperature, but this is a limited benefit as aging can easily dominate the accuracy. These are usually called *oven-controlled crystal oscillators (OCXOs)*.

Fourth, the crystal is influenced by the impedance presented to it by the circuit in which it is used. This means that care is needed to make the rest of an oscillator circuit stable, in terms of impedance and phase shift.

Gravity can slightly affect crystal resonance. Turning an oscillator upside down usually produces a small frequency shift, usually much less than 1 ppm; turning the oscillator back over reverses this. This effect is quantified for the highest-quality reference oscillators.

### The Equivalent Circuit of a Crystal

Because a crystal is a passive, two-terminal device, its electrical appearance is that of an impedance that varies with frequency. Fig 14.21A shows a very simplified sketch of the magnitude (phase is ignored) of the impedance of a quartz

Fig 14.20 — Slight changes in a crystal cut's orientation shift its frequency-versus-temperature curve.

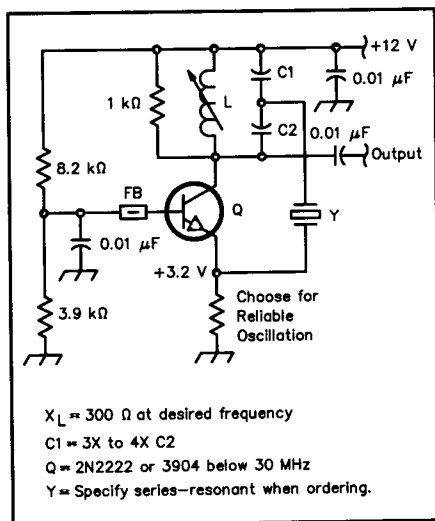

Fig 14.21 — Exploring a crystal's impedance (A) and equivalent circuit (B) through simplified diagrams. C and D extend the investigation to include overtones; E, to spurious responses not easily predictable by theory or controllable through manufacture. A crystal may oscillate on any of its resonances under the right conditions.

**Table 14.2**

**Typical Equivalent Circuit Values for a Variety of Crystals**

Crystal Type	Series L	Series C (pF)	Series R ( $\Omega$ )	Shunt C (pF)
1-MHz fundamental	3.5 H	0.007	340	3
10-MHz fundamental	9.8 mH	0.026	7	6.3
30-MHz third overtone	14.9 mH	0.0018	27	6.2
100-MHz fifth overtone	4.28 mH	0.0006	45	7

**Fig 14.22 — A basic series-mode crystal oscillator. A 2N5179 can be used in this circuit if a lower supply voltage is used; see text.**

crystal. The general trend of dropping impedance with increasing frequency implies capacitance across the crystal. The sharp fall to a low value resembles a series-tuned tank, and the sharp peak resembles a parallel-tuned tank. These are referred to as series and parallel resonances. Fig 14.21B shows a simple circuit that will produce this impedance characteristic. The impedance looks purely resistive at the exact centers of both resonances, and the region between them has impedance increasing with frequency, which looks inductive.

C1 (sometimes called *motional capacitance*,  $C_m$ , to distinguish it from the lumped capacitance it approximates) and L1 (*motional inductance*,  $L_m$ ) create the series resonance, and as C0 and R1 are both fairly small, the impedance at the bottom of the dip is very close to R1. At parallel resonance, L1 is resonating with C1 and C0 in series, hence the higher frequency. The impedance of the parallel tank is immense, the terminals are connected to a capacitive tap, that causes them to see only a small fraction of this, which is still a very large impedance. The

overtones should not be neglected, so Figs 14.21C and 14.21D show them included. Each overtone has series and parallel resonances and so appears as a series tank in the equivalent circuit. C0 again provides the shifted parallel resonance.

This is still simplified, because real-life crystals have a number of spurious, unwanted modes which add yet more resonances, as shown in Fig 14.21E. These are not well controlled and may vary a lot even between crystals made to the same specification. Crystal manufacturers work hard to suppress these spurs and have evolved a number of recipes for shaping crystals to minimize them. Just where they switch from one design to another varies from manufacturer to manufacturer.

Always remember that the equivalent circuit is just a representation of crystal behavior and does not represent circuit components actually present. Its only use is as an aid in designing and analyzing circuits using crystals. Table 14.2 lists typical equivalent-circuit values for a variety of crystals. It is impossible to build a circuit with 0.026 to 0.0006-pF capacitors; such values would simply be swamped by strays. Similarly, the inductor must have a Q orders of magnitude better than is practically achievable, and impossibly low stray C in its winding.

The values given in Table 14.2 are nothing more than rough guides. A crystal's frequency is tightly specified, but this still allows inductance to be traded for capacitance. A good manufacturer could hold these characteristics within a  $\pm 25\%$  band or could vary them over a 5:1 range by special design. Similarly marked parts from different sources vary widely in motional inductance and capacitance.

Quartz is not the only material that behaves in this way, but it is the best. Resonators can be made out of lithium tantalate and a group of similar materials that have lower Q, allowing them to be pulled over a larger frequency range in VCXOs. Much more common, however, are ceramic resonators based on the technology of the well-known ceramic IF filters. These have much lower Q than quartz

and much poorer frequency precision. They serve mainly as clock resonators for cheap microprocessor systems in which every last cent must be saved. A ceramic resonator could be used as the basis of a wide range, cheap VXO, but its frequency stability would not be as good as a good LC VFO.

### Crystal Oscillator Circuits

Crystal oscillator circuits are usually categorized as series- or parallel-mode types, depending on whether the crystal's low- or high-impedance resonance comes into play at the operating frequency. The series mode is now the most common; parallel-mode operation was more often used with vacuum tubes. Fig 14.22 shows a basic series-mode oscillator. Some people would say that it is an overtone circuit, used to run a crystal on one of its overtones, but this is not necessarily true. The tank (L-C1-C2) tunes the collector of the common-base amplifier. C1 is larger than C2, so the tank is tapped in a way that transforms to a lower impedance, decreasing signal voltage, but increasing current. The current is fed back into the emitter via the crystal. The common-base stage provides a current gain of less than unity, so the transformer in the form of the tapped tank is essential to give loop gain. There are *two* tuned circuits, the obvious collector tank and the series-mode one "in" the crystal. The tank kills the amplifier's gain away from its tuned frequency, and the crystal will only pass current at the series resonant frequencies of its many modes. The tank resonance is much broader than any of the crystal's modes, so it can be thought of as the crystal setting the frequency, but the tank selecting which of the crystal's modes is active. The tank could be tuned to the crystal's fundamental, or one of its overtones.

Fundamental oscillators can be built without a tank quite successfully, but there is always the occasional one that starts up on an overtone or spurious mode. Some simple oscillators have been known to change modes while running (an effect triggered by changes in temperature or loading) or to not always start in the same mode! A series-mode oscillator should present a low impedance to the crystal at the operating frequency. In Fig 14.22, the tapped collector tank presents a transformed fraction of the 1-k $\Omega$  collector load resistor to one end of the crystal, and the emitter presents a low impedance to the other. To build a practical oscillator from this circuit, choose an inductor with a reactance

of about  $300\ \Omega$  at the wanted frequency and calculate  $C1$  in series with  $C2$  to resonate with it. Choose  $C1$  to be 3 to 4 times larger than  $C2$ . The amplifier's quiescent ("idling") current sets the gain and hence the operating level. This is not easily calculable, but can be found by experiment. Too little quiescent current and the oscillator will not start reliably; too much and the transistor can drive itself into saturation. If an oscilloscope is available, it can be used to check the collector waveform; otherwise, some form of RF voltmeter can be used to allow the collector voltage to be set to 2 to 3 V RMS.  $3.3\ \text{k}\Omega$  would be a suitable starting point for the emitter bias resistor. The transistor type is not critical; 2N2222A or 2N3904 would be fine up to 30 MHz; a 2N5179 would allow operation as an overtone oscillator to over 100 MHz (because of the low collector voltage rating of the 2N5179, a supply voltage lower than 12 V is required). The ferrite bead on the base gives some protection against parasitic oscillation at UHF.
